NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.
not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill Education’s prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

THE WORK IS PROVIDED “AS IS.” McGRAW-HILL EDUCATION AND ITS LICENSORS MAKE NO GUARANTEES OR WARRANTIES AS TO THE ACCURACY, ADEQUACY OR COMPLETENESS OF OR RESULTS TO BE OBTAINED FROM USING THE WORK, INCLUDING ANY INFORMATION THAT CAN BE ACCESSED THROUGH THE WORK VIA HYPERLINK OR OTHERWISE, AND EXPRESSLY DISCLAIM ANY WARRANTY, EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. McGraw-Hill Education and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Appendix I Principles of Prescription Order Writing and Patient Compliance

Index
Preface to the Second Edition

This Manual derives from the 12th edition of Goodman & Gilman’s The Pharmacological Basis of Therapeutics. The parent text covers not just principles and mechanisms of action but also details of clinical use and recent basic research that supports therapeutic applications and points the way toward new therapies; as a consequence of this thoroughness, the book is large and not in the fashion of the shorter texts preferred by students of this era. To make core material from G&G more accessible, we have abridged the 12th edition of the parent text, trying to present the essentials of mechanism and clinical use while omitting research data, references, and the pharmacokinetic data of Appendix II, all of which can be found at the G&G website on AccessMedicine.com and AccessPharmacy.com, along with regular therapeutic updates and mechanistic animations. We have also generally omitted the structures of therapeutics agents, which are readily available on the book’s website and on PubChem (pubchem.ncbi.nlm.nih.gov/). This Manual of Pharmacology and Therapeutics is organized identically to the parent text, using many of the same figures and tables; a number of figures have been improved or added anew for this edition.

Some realizations gained from editing the 12th edition and this volume stand out:

• The invention of new classes of drugs has slowed to a trickle.
• Therapeutics has barely begun to capitalize on the information from the Human Genome Project.
• The development of resistance to antimicrobial agents, mainly through their overuse and misuse in agriculture and medicine, threatens to return us to the pre-antibiotic era.
We have the ingenuity to correct these shortcomings if we can muster the will and the research support to do so.

We thank the contributors and editors of the 12th edition of G&G, Saloni Narang of Thomson Digital, Christie Naglieri and James Shanahan of McGraw-Hill, and a long line of contributors and editors who have worked on Goodman & Gilman over 12 editions. It is a tribute to Louis Goodman and Alfred Gilman that their book is alive and vigorous 72 years after the publication of the first edition.

Section I
General Principles
The first edition of *Goodman & Gilman* helped to organize the field of pharmacology, giving it intellectual validity and an academic identity. That edition began: “The subject of pharmacology is a broad one and embraces the knowledge of the source, physical and chemical properties, compounding, physiological actions, absorption, fate, and excretion, and therapeutic uses of drugs. A *drug* may be broadly defined as any chemical agent that affects living protoplasm, and few substances would escape inclusion by this definition.” This *General Principles* section provides the underpinnings for these definitions by exploring the processes of drug invention, followed by the basic properties of the interactions between the drug and biological systems: *pharmacodynamics*, *pharmacokinetics* (including drug transport and metabolism), and *pharmacogenomics*. Subsequent sections deal with the use of drugs as therapeutic agents in human subjects.

Use of the term *invention* to describe the process by which a new drug is identified and brought to medical practice, rather than the more conventional term *discovery*, is intentional. The term *invention* emphasizes the process by which drugs are sculpted and brought into being based on experimentation and optimization of many independent properties; there is little serendipity.

**FROM EARLY EXPERIENCES WITH PLANTS TO MODERN CHEMISTRY**

The human fascination—and sometimes infatuation—with chemicals that alter biological function is ancient and results from long experience with and dependence on plants. Many plants produce harmful compounds for defense that animals have learned to avoid and humans to exploit.
Examples are described in earlier editions of this text: the appreciation of coffee (caffeine) by the prior of an Arabian convent who noted the behavior of goats that gamboled and frisked through the night after eating the berries of the coffee plant; the use of mushrooms and the deadly nightshade plant by professional poisoners; of belladonna (“beautiful lady”) to dilate pupils; of the Chinese herb ma huang (containing ephedrine) as a circulatory stimulant; of curare by South American Indians to paralyze and kill animals hunted for food; and of poppy juice (opium) containing morphine (from the Greek Morpheus, the god of dreams) for pain relief and control of dysentery. Morphine, of course, has well-known addicting properties, mimicked in some ways by other problematic (“recreational”) natural products—nicotine, cocaine, and ethanol.

Although terrestrial and marine organisms remain valuable sources of compounds with pharmacological activities, drug invention became more allied with synthetic organic chemistry as that discipline flourished over the past 150 years, beginning in the dye industry. Dyes are colored compounds with selective affinity for biological tissues. Study of these interactions stimulated Paul Ehrlich to postulate the existence of chemical receptors in tissues that interacted with and “fixed” the dyes. Similarly, Ehrlich thought that unique receptors on microorganisms or parasites might react specifically with certain dyes and that such selectivity could spare normal tissue. Ehrlich’s work culminated in the invention of arsphenamine in 1907, which was patented as “salvarsan,” suggestive of the hope that the chemical would be the salvation of humankind. This and other organic arsenicals were invaluable for the chemotherapy of syphilis until the discovery of penicillin. Through the work of Gerhard Domagk, another dye, prontosil (the first clinically useful sulfonamide), was shown to be dramatically effective in treating streptococcal infections, launching the era of antimicrobial chemotherapy. The collaboration of pharmacology with chemistry on the one hand, and with clinical medicine on the other, has been a major contributor to the effective treatment of disease, especially since the middle of the 20th century.

**SOURCES OF DRUGS**

**SMALL MOLECULES ARE THE TRADITION**

With the exception of a few naturally occurring hormones (e.g.,
insulin), most drugs were small organic molecules (typically <500 Da) until recombinant DNA technology permitted synthesis of proteins by various organisms (bacteria, yeast) and mammalian cells. The usual approach to invention of a small-molecule drug is to screen a collection of chemicals (“library”) for compounds with the desired features. An alternative is to synthesize and focus on close chemical relatives of a substance known to participate in a biological reaction of interest (e.g., congeners of a specific enzyme substrate chosen to be possible inhibitors of the enzymatic reaction), a particularly important strategy in the discovery of anticancer drugs.

Drug discovery in the past often resulted from serendipitous observations of the effects of plant extracts or individual chemicals on animals or humans; today’s approach relies on high-throughput screening of libraries containing hundreds of thousands or even millions of compounds for their capacity to interact with a specific molecular target or elicit a specific biological response. Ideally, the target molecules are of human origin, obtained by transcription and translation of the cloned human gene. The potential drugs that are identified in the screen (“hits”) are thus known to react with the human protein and not just with its relative (ortholog) obtained from mouse or another species.

Among the variables considered in screening are the “drugability” of the target and the stringency of the screen in terms of the concentrations of compounds that are tested. “Drugability” refers to the ease with which the function of a target can be altered in the desired fashion by a small organic molecule. If the protein target has a well-defined binding site for a small molecule (e.g., a catalytic or allosteric site), chances are excellent that hits will be obtained. If the goal is to employ a small molecule to mimic or disrupt the interaction between 2 proteins, the challenge is much greater.

**FROM HITS TO LEADS**

Initial hits in a screen are rarely marketable drugs, often having modest affinity for the target, and lacking the desired specificity and pharmacological properties. Medicinal chemists synthesize derivatives of the hits, thereby defining the structure–activity relationship and
optimizing parameters such as affinity for the target, agonist/antagonist activity, permeability across cell membranes, absorption and distribution in the body, metabolism, and unwanted effects.

This approach was driven largely by instinct and trial and error in the past; modern drug development frequently takes advantage of determination of a high-resolution structure of the putative drug bound to its target. X-ray crystallography offers the most detailed structural information if the target protein can be crystallized with the lead drug bound to it. Using techniques of molecular modeling and computational chemistry, the structure provides the chemist with information about substitutions likely to improve the “fit” of the drug with the target and thus enhance the affinity of the drug for its target. Nuclear magnetic resonance (NMR) studies of the drug-receptor complex also can provide useful information, with the advantage that the complex need not be crystallized.

The holy grail of this approach to drug invention is to achieve success entirely through computation. Imagine a database containing detailed chemical information about millions of chemicals and a second database containing detailed structural information about all human proteins. The computational approach is to “roll” all the chemicals over the protein of interest to find those with high-affinity interactions. The dream gets bolder if we acquire the ability to roll the chemicals that bind to the target of interest over all other human proteins to discard compounds that have unwanted interactions. Finally, we also will want to predict the structural and functional consequences of a drug binding to its target (a huge challenge), as well as all relevant pharmacokinetic properties of the molecules of interest. Indeed, computational approaches have suggested new uses for old drugs and offered explanations for recent failures of drugs in the later stages of clinical development (e.g., torcetrapib; see below).

**LARGE MOLECULES ARE INCREASINGLY IMPORTANT**

Protein therapeutics were uncommon before the advent of recombinant DNA technology. Insulin was introduced into clinical medicine for the treatment of diabetes following the experiments of Banting and Best in 1921. Insulins purified from porcine or bovine
pancreas are active in humans, although antibodies to the foreign proteins are occasionally problematic. Growth hormone, used to treat pituitary dwarfism, exhibits more stringent species specificity: only the human hormone could be used after purification from pituitary glands harvested during autopsy, and such use had its dangers. Some patients who received the human hormone developed Creutzfeldt-Jakob disease (the human equivalent of mad cow disease), a fatal degenerative neurological disease caused by prion proteins that contaminated the drug preparation. Thanks to gene cloning and the production of large quantities of proteins by expressing the cloned gene in bacteria or eukaryotic cells, protein therapeutics now use highly purified preparations of human (or humanized) proteins. Rare proteins can be produced in quantity, and immunological reactions are minimized. Proteins can be designed, customized, and optimized using genetic engineering techniques. Other types of macromolecules may also be used therapeutically. For example, antisense oligonucleotides are used to block gene transcription or translation, as are small interfering RNAs (siRNAs).

Proteins used therapeutically include hormones, growth factors (e.g., erythropoietin, granulocyte-colony stimulating factor), cytokines, and a number of monoclonal antibodies used in the treatment of cancer and autoimmune diseases. Murine monoclonal antibodies can be “humanized” (by substituting human for mouse amino acid sequences). Alternatively, mice have been engineered by replacement of critical mouse genes with their human equivalents, such that they make completely human antibodies. Protein therapeutics are administered parenterally, and their receptors or targets must be accessible extracellularly.

TARGETS OF DRUG ACTION

Early drugs came from observation of the effects of plants after their ingestion by animals, with no knowledge of the drug’s mechanism and site of action. Although this approach is still useful (e.g., in screening for the capacity of natural products to kill microorganisms or
malignant cells), modern drug invention usually takes the opposite approach—starting with a statement (or hypothesis) that a certain protein or pathway plays a critical role in the pathogenesis of a certain disease, and that altering the protein’s activity would therefore be effective against that disease. Crucial questions arise:

- Can one find a drug that will have the desired effect against its target?
- Does modulation of the target protein affect the course of disease?
- Does this project make sense economically?

The effort expended to find the desired drug will be determined by the degree of confidence in the answers to the latter 2 questions.

**IS THE TARGET DRUGABLE?**

The drugability of a target with a low-molecular-weight organic molecule relies on the presence of a binding site for the drug that exhibits considerable affinity and selectivity.

If the target is an enzyme or a receptor for a small ligand, one is encouraged. If the target is related to another protein that is known to have, for example, a binding site for a regulatory ligand, one is hopeful. However, if the known ligands are large peptides or proteins with an extensive set of contacts with their receptor, the challenge is much greater. If the goal is to disrupt interactions between 2 proteins, it may be necessary to find a “hot spot” that is crucial for the protein-protein interaction, and such a region may not be detected. Accessibility of the drug to its target also is critical. Extracellular targets are intrinsically easier to approach and, in general, only extracellular targets are accessible to macromolecular drugs.

**HAS THE TARGET BEEN VALIDATED?**

This question is obviously a critical one. A negative answer, frequently obtained only retrospectively, is a common cause of failure in drug invention.
Biological systems frequently contain redundant elements, or can alter expression of drug-regulated elements to compensate for the effect of the drug. In general, the more important the function, the greater the complexity of the system. For example, many mechanisms control feeding and appetite, and drugs to control obesity have been notoriously difficult to find. The discovery of the hormone leptin, which suppresses appetite, was based on mutations in mice that cause loss of either leptin or its receptor; either kind of mutation results in enormous obesity in both mice and people. Leptin thus appeared to be a marvelous opportunity to treat obesity. However, obese individuals have high circulating concentrations of leptin and appear quite insensitive to its action.

Modern techniques of molecular biology offer powerful tools for validation of potential drug targets, to the extent that the biology of model systems resembles human biology. Genes can be inserted, disrupted, and altered in mice. One can thereby create models of disease in animals or mimic the effects of long-term disruption or activation of a given biological process. If, for example, disruption of the gene encoding a specific enzyme or receptor has a beneficial effect in a valid murine model of a human disease, one may believe that the potential drug target has been validated. Mutations in humans also can provide extraordinarily valuable information. For example, loss-of-function mutations in the PCSK9 gene (encoding proprotein convertase subtilisin/kexin type 9) greatly lower concentrations of LDL cholesterol in plasma and reduce the risk of myocardial infarction. Based on these findings, many drug companies are actively seeking inhibitors of PCSK9 function.

**IS THIS DRUG INVENTION EFFORT ECONOMICALLY VIABLE?**

Drug invention and development is expensive (see below), and economic realities influence the direction of pharmaceutical research.

For example, investor-owned companies generally cannot afford to develop products for rare diseases or for diseases that are common only in economically underdeveloped parts of the world. Funds to invent drugs targeting rare diseases or diseases primarily affecting developing countries (especially parasitic diseases) usually come from taxpayers or very wealthy philanthropists.
ADDITIONAL PRECLINICAL RESEARCH

Following the path just described can yield a potential drug molecule that interacts with a validated target and alters its function in the desired fashion. Now one must consider all aspects of the molecule in question—its affinity and selectivity for interaction with the target, its pharmacokinetic properties (absorption, distribution, metabolism, excretion: ADME), issues of its large-scale synthesis or purification, its pharmaceutical properties (stability, solubility, questions of formulation), and its safety. One hopes to correct, to the extent possible, any obvious deficiencies by modification of the molecule itself or by changes in the way the molecule is presented for use.

Before being administered to people, potential drugs are tested for general toxicity by monitoring the activity of various systems in 2 species of animals for extended periods of time. Compounds also are evaluated for carcinogenicity, genotoxicity, and reproductive toxicity. Animals are used for much of this testing. Usually 1 rodent (usually mouse) and 1 nonrodent (often rabbit) species are used. In vitro and ex vivo assays are used when possible, both to spare animals and to minimize cost. If an unwanted effect is observed, an obvious question is whether it is mechanism-based (i.e., caused by interaction of the drug with its intended target) or caused by an off-target effect of the drug, which might be minimized by further optimization of the molecule.

Before the drug candidate can be administered to human subjects in a clinical trial, the sponsor must file an IND (Investigational New Drug) application, a request to the U.S. Food and Drug Administration (FDA; see the next section) for permission to administer the drug to human test subjects. The IND describes the rationale and preliminary evidence for efficacy in experimental systems, as well as pharmacology, toxicology, chemistry, manufacturing, and so forth. It also describes the plan for investigating the drug in human subjects. The FDA has 30 days to review the application, by which time the agency may disapprove the application, ask for more data, or allow initial clinical testing to proceed.

CLINICAL TRIALS
ROLE OF THE FDA

The FDA is a regulatory agency within the U.S. Department of Health and Human Services.

The FDA is responsible for protecting the public health by assuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation’s food supply, cosmetics, and products that emit radiation. The FDA is also responsible for advancing the public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable; and helping the public get the accurate, science-based information they need to use medicines and foods to improve their health. One of the FDA’s responsibilities is to protect the public from harmful medications. The 1962 Kefauver-Harris Amendments to the Food, Drug, and Cosmetic Act established the requirement for proof of efficacy as well of documentation of relative safety in terms of the risk-to-benefit ratio for the disease entity to be treated (the more serious the disease, the greater the acceptable risk).

The FDA faces an enormous challenge, especially in view of the widely held belief that its mission cannot possibly be accomplished with the available resources. Moreover, harm from drugs that cause unanticipated adverse effects is not the only risk of an imperfect system; harm also occurs when the approval process delays the marketing of a new drug with important beneficial effects.

THE CONDUCT OF CLINICAL TRIALS

Clinical trials of drugs are designed to acquire information about the pharmacokinetic and pharmacodynamic properties of a candidate drug in humans. Efficacy must be proven and an adequate margin of safety established for a drug to be approved for sale in the U.S.

The U.S. National Institutes of Health notes 7 ethical requirements that must be met before a clinical trial can begin: social value, scientific validity, fair and objective selection of subjects, informed consent, favorable ratio of risks to benefits, approval and oversight by an independent review board (IRB), and respect for human subjects.

FDA-regulated clinical trials typically are conducted in 4 phases. The first 3 are
designed to establish safety and efficacy, while phase IV postmarketing trials
delineate additional information regarding new indications, risks, and optimal
doses and schedules. Table 1–1 and Figure 1–1 summarize the important features
of each phase of clinical trials; note the attrition at each successive stage over a
relatively long and costly process. When initial phase III trials are complete, the
sponsor (usually a pharmaceutical company) applies to the FDA for approval to
market the drug; this application is called either a New Drug Application (NDA)
or a Biologics License Application (BLA). These applications contain
comprehensive information, including individual case-report forms from the
hundreds or thousands of individuals who have received the drug during its
phase III testing. Applications are reviewed by teams of specialists, and the FDA
may call on the help of panels of external experts in complex cases.

Figure 1–1 The phases, time lines, and attrition that characterize the invention of new drugs. See also Table 1–1.

Under the provisions of the Prescription Drug User Fee Act (PDUFA; enacted initially in 1992 and renewed in 2007), pharmaceutical companies now provide a significant portion of the FDA budget via user fees, a legislative effort to expedite the drug approval review process. PDUFA also broadened the FDA’s drug safety program and increased resources for review of television drug advertising. A 1-year review time is considered standard, and 6 months is the target if the drug candidate is granted priority status because of its importance in filling an unmet need. Unfortunately, these targets are not always met.

Before a drug is approved for marketing, the company and the FDA must agree on the content of the “label” (package insert)—the official prescribing information. This label describes the approved indications for use of the drug and clinical pharmacological information including dosage, adverse reactions, and special warnings and precautions (sometimes posted in a “black box”). Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. Importantly, the physician is not bound by the package insert; a physician in the U.S. may legally prescribe a drug for any purpose that she or he deems reasonable. However, third-party payers (insurance companies, Medicare, and so on) generally will not reimburse a patient for the cost of a drug used for an “off-label” indication unless the new
use is supported by one of several compendia such as the U.S. Pharmacopeia. Furthermore, a physician may be vulnerable to litigation if untoward effects result from an unapproved use of a drug.

**DETERMINING “SAFE” AND “EFFECTIVE”**

Demonstrating efficacy to the FDA requires performing “adequate and well-controlled investigations,” generally interpreted to mean 2 replicate clinical trials that are usually, but not always, randomized, double-blind, and placebo-controlled.

Is a placebo the proper control? The World Medical Association’s *Declaration of Helsinki* (2000) discourages use of placebo controls when an alternative treatment is available for comparison. What must be measured in the trials? In a straightforward trial, a readily quantifiable parameter (a secondary or surrogate end point), thought to be predictive of relevant clinical outcomes, is measured in matched drug- and placebo-treated groups. Examples of surrogate end points include LDL cholesterol as a predictor of myocardial infarction, bone mineral density as a predictor of fractures, or hemoglobin A₁c as a predictor of the complications of diabetes mellitus. More stringent trials would require demonstration of reduction of the incidence of myocardial infarction in patients taking a candidate drug in comparison with those taking an HMG-CoA reductase inhibitor (statin) or other LDL cholesterol-lowering agent, or reduction in the incidence of fractures in comparison with those taking a bisphosphonate. Use of surrogate end points significantly reduces cost and time required to complete trials, but there are many mitigating factors, including the significance of the surrogate end point to the disease that the candidate drug is intended to treat.

Some of the difficulties are well illustrated by recent experiences with ezetimibe, a drug that inhibits absorption of cholesterol from the GI tract and lowers LDL cholesterol concentrations in plasma, especially when used in combination with a statin. Lowering of LDL cholesterol was assumed to be an appropriate surrogate end point for the effectiveness of ezetimibe to reduce myocardial infarction and stroke. Surprisingly, the ENHANCE trial demonstrated that the combination of ezetimibe and a statin did not reduce intima-media thickness of carotid arteries (a more direct measure of subendothelial cholesterol accumulation) compared with the statin alone, despite the fact that the drug
combination lowered LDL cholesterol concentrations substantially more than did either drug alone. Critics of ENHANCE argue that the patients in the study had familial hypercholesterolemia, had been treated with statins for years, and did not have carotid artery thickening at the initiation of the study. Should ezetimibe have been approved? Must we return to measurement of true clinical end points (e.g., myocardial infarction) before approval of drugs that lower cholesterol by novel mechanisms? The costs involved in such extensive and expensive trials must be borne somehow (see below). Such a study (IMPROVE-IT) is now in progress.

The drug torcetrapib provides a related example in the same therapeutic area. Torcetrapib elevates HDL cholesterol (the “good cholesterol”), and higher levels of HDL cholesterol are statistically associated with (are a surrogate end point for) a lower incidence of myocardial infarction. Surprisingly, clinical administration of torcetrapib caused a significant increase in mortality from cardiovascular events, ending a development path of 15 years and $800 million. In this case, approval of the drug based on this secondary end point would have been a mistake.

No drug is totally safe; all drugs produce unwanted effects in at least some people at some dose. Many unwanted and serious effects of drugs occur so infrequently, perhaps only once in several thousand patients, that they go undetected in the relatively small populations (a few thousand) in the standard phase III clinical trial (see Table 1–1).

To detect and verify that such events are in fact drug-related would require administration of the drug to tens or hundreds of thousands of people during clinical trials, adding enormous expense and time to drug development and delaying access to potentially beneficial therapies. In general, the true spectrum and incidence of untoward effects becomes known only after a drug is released to the broader market and used by a large number of people (phase IV, postmarketing surveillance). Drug development costs and drug prices could be reduced substantially if the public were willing to accept more risk. This would require changing the way we think about a pharmaceutical company’s liability for damages from an unwanted effect of a drug that was not detected in clinical trials deemed adequate by the FDA.
While the concept is obvious, many lose sight of the fact that extremely severe unwanted effects of a drug, including death, may be deemed acceptable if its therapeutic effect is sufficiently unique and valuable. Such dilemmas are not simple and can become issues for great debate.

Several strategies exist to detect adverse reactions after marketing of a drug. Formal approaches for estimation of the magnitude of an adverse drug response include the follow-up or “cohort” study of patients who are receiving a particular drug; the “case-control” study, where the frequency of drug use in cases of adverse responses is compared to controls; and meta-analysis of pre- and post-marketing studies. Additional approaches also must be used. Spontaneous reporting of adverse reactions has proven to be an effective way to generate an early signal that a drug may be causing an adverse event. Recently, considerable effort has gone into improving the reporting system in the U.S., called MedWatch (see Appendix I). The primary sources for the reports are responsible, alert physicians; other useful sources are nurses, pharmacists, and students in these disciplines. In addition, hospital-based pharmacy and therapeutics committees and quality assurance committees frequently are charged with monitoring adverse drug reactions in hospitalized patients. The simple forms for reporting may be obtained 24 h a day, 7 days a week by calling 800-FDA-1088; alternatively, adverse reactions can be reported directly using the Internet (www.fda.gov/medwatch). Health professionals also may contact the pharmaceutical manufacturer, who is legally obligated to file reports with the FDA.

PUBLIC POLICY CONSIDERATIONS AND CRITICISMS OF THE PHARMACEUTICAL INDUSTRY

Drugs can save lives, prolong lives, and improve the quality of people’s lives. However, in a free-market economy, access to drugs is not equitable. Not surprisingly, there is tension between those who treat drugs as entitlements and those who view drugs as high-tech products of a capitalistic society. Supporters of the entitlement position argue that a constitutional right to life should guarantee access to drugs and other healthcare, and they are critical of pharmaceutical companies and others who profit from the business of making and selling drugs. Free-marketers point out that, without a profit motive, it would be difficult to generate the resources and innovation required for new
drug development. Given the public interest in the pharmaceutical industry, drug development is both a scientific process and a political one in which attitudes can change quickly. Little more than a decade ago Merck was named as America’s most admired company by *Fortune* magazine 7 years in a row—a record that still stands. In the 2011 survey, no pharmaceutical company ranked in the top 10 most admired companies in the U.S.

Critics of the pharmaceutical industry frequently begin from the position that people (and animals) need to be protected from greedy and unscrupulous companies and scientists. In the absence of a government-controlled drug development enterprise, our current system relies predominantly on investor-owned pharmaceutical companies that, like other companies, have a profit motive and an obligation to shareholders. The price of prescription drugs causes great consternation among consumers, especially as many health insurers seek to control costs by choosing not to cover certain “brand-name” products. Further, a few drugs (especially for treatment of cancer) have been introduced to the market in recent years at prices that greatly exceeded the costs of development, manufacture, and marketing of the product. Many of these products were discovered in government laboratories or in university laboratories supported by federal grants. The U.S. is the only large country that places no controls on drug prices and where price plays no role in the drug approval process. Many U.S. drugs cost much more in the U.S. than overseas; thus, U.S. consumers subsidize drug costs for the rest of the world, and they are irritated by that fact.

The drug development process is long, expensive, and risky (see Figure 1–1 and Table 1–1). Consequently, drugs must be priced to recover the substantial costs of invention and development, and to fund the marketing efforts needed to introduce new products to physicians and patients. Nevertheless, as U.S. healthcare spending continues to rise at an alarming pace, prescription drugs account for only ~10% of total healthcare expenditures, and a significant fraction of this drug cost is for low-priced nonproprietary medicines. Although the increase in prices is significant in certain classes of drugs (e.g., anticancer agents), the total price of prescription drugs is growing at a slower rate than other healthcare costs. Even drastic reductions in drug prices that would severely limit new drug invention would not lower the overall healthcare budget by more than a few percent.

Are profit margins excessive among the major pharmaceutical companies? There
is no objective answer to this question. Pragmatic answers come from the markets and from company survival statistics. The costs to bring products to market are enormous; the success rate is low (accounting for much of the cost); effective patent protection is only about a decade (see “Intellectual Property and Patents”), requiring every company to completely reinvent itself on a roughly 10-year cycle; regulation is stringent; product liability is great; competition is fierce; with mergers and acquisitions, the number of companies in the pharmaceutical world is shrinking.

WHO PAYS?

The cost of prescription drugs is borne by consumers ("out-of-pocket"), private insurers, and public insurance programs such as Medicare, Medicaid, and the State Children’s Health Insurance Program (SCHIP). Recent initiatives by major retailers and mail-order pharmacies run by private insurers to offer consumer incentives for purchase of generic drugs have helped to contain the portion of household expenses spent on pharmaceuticals; however, more than one-third of total retail drug costs in the U.S. are paid with public funds—tax dollars.

Healthcare in the U.S. is more expensive than everywhere else, but it is not, on average, demonstrably better than everywhere else. Forty-five million Americans are uninsured and seek routine medical care in emergency rooms. Solutions to these real problems must recognize both the need for effective ways to incentivize innovation and to permit, recognize, and reward compassionate medical care.

INTELLECTUAL PROPERTY AND PATENTS

Drug invention produces intellectual property eligible for patent protection, protection that is important for innovation. The U.S. patent protection system provides protection for only 20 years from the time the patent is filed. During this period, the patent owner has exclusive rights to market and sell the drug. When the patent expires, equivalent (generic) products can come on the market; a generic product must be
therapeutically equivalent to the original, contain equal amounts of the same active chemical ingredient, and achieve equal concentrations in blood when administered by the same routes. These generic preparations are sold much more cheaply than the original drug, and without the huge development costs borne by the original patent holder.

The long time course of drug development, usually >10 years (see Figure 1–1), reduces the time during which patent protection functions as intended. The Drug Price Competition and Patent Term Restoration Act of 1984 (the “Hatch-Waxman Act”) permits a patent holder to apply for extension of a patent term to compensate for delays in marketing caused by FDA approval processes; nonetheless, the average new drug brought to market now enjoys only ~10-12 years of patent protection. Some argue that patent protection for drugs should be shortened, so that earlier generic competition will lower healthcare costs. The counterargument is that new drugs would have to bear higher prices to provide adequate compensation to companies during a shorter period of protected time. If that is true, lengthening patent protection would actually permit lower prices. Recall that patent protection is worth little if a superior competitive product is invented and brought to market.

The Bayh-Dole Act (35 U.S.C. § 200) of 1980 created strong incentives for scientists at academic medical centers to approach drug invention with an entrepreneurial spirit. The Act transferred intellectual property rights to the researchers and their respective institutions in order to encourage partnerships with industry that would bring new products to market for the public’s benefit. This encouragement of public-private research collaborations has given rise to concerns about conflicts of interest by scientists and universities.

**DRUG PROMOTION**

In an ideal world, physicians would learn all they need to know about drugs from the medical literature, and good drugs would thereby sell
themselves. Instead, we have print advertising and visits from salespeople directed at physicians, and extensive direct-to-consumer advertising aimed at the public (in print, on the radio, and especially on television). There are roughly 100,000 pharmaceutical sales representatives in the U.S. who target ~10 times that number of physicians. It has been noted that college cheerleading squads are attractive sources for recruitment of this sales force. The amount spent on promotion of drugs approximates or perhaps even exceeds that spent on research and development. Pharmaceutical companies have been especially vulnerable to criticism for some of their marketing practices.

Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. In addition, there must be an acceptable balance between presentation of therapeutic claims for a product and discussion of unwanted effects. Nevertheless, direct-to-consumer advertising of drugs remains controversial and is permitted only in the U.S. and New Zealand. Physicians frequently succumb with misgivings to patients’ advertising-driven requests for specific medications. The counterargument is that patients are educated by such marketing efforts and in many cases will then seek medical care, especially for conditions that they may have been denying (e.g., depression). The major criticism of drug marketing involves some of the unsavory approaches used to influence physician behavior. Gifts of value (e.g., sports tickets) are now forbidden, but dinners where drug-prescribing information is presented are widespread. Large numbers of physicians are paid as “consultants” to make presentations in such settings. The acceptance of any gift, no matter how small, from a drug company by a physician, is now forbidden at many academic medical centers and by law in several states. The board of directors of the Pharmaceutical Research and Manufacturers of America has adopted an enhanced code on relationships with U.S. healthcare professionals that prohibits the distribution of noneducational items, prohibits company sales representatives from providing restaurant meals to healthcare professionals, and requires companies to ensure that their representatives are trained about laws and regulations that govern interactions with healthcare professionals.
EXPLOITATION OR “MEDICAL IMPERIALISM”

There is concern about the degree to which U.S. and European patent protection laws have restricted access to potentially lifesaving drugs in developing countries. Because development of new drugs is so expensive, private-sector investment in pharmaceutical innovation naturally has focused on products that will have lucrative markets in wealthy countries such as the U.S., which combines patent protection with a free-market economy. To lower costs, companies increasingly test their experimental drugs outside the U.S. and the E.U., in countries such as China, India, and Mexico, where there is less regulation and easier access to large numbers of patients. If the drug is successful in obtaining marketing approval, consumers in these countries often cannot afford the drugs.

Some ethicists have argued that this practice violates the justice principle articulated in the Belmont Report (1979), which states that “research should not unduly involve persons from groups unlikely to be among the beneficiaries of subsequent applications of the research.” Conversely, the conduct of trials in developing nations also frequently brings needed medical attention to underserved populations.

PRODUCT LIABILITY

Product liability laws are intended to protect consumers from defective products. Pharmaceutical companies can be sued for faulty design or manufacturing, deceptive promotional practices, violation of regulatory requirements, or failure to warn consumers of known risks. So-called “failure to warn” claims can be made against drug makers even when the product is approved by the FDA. With greater frequency, courts are finding companies that market prescription drugs directly to consumers responsible when these advertisements fail to provide an adequate warning of potential adverse effects.

Although injured patients are entitled to pursue legal remedies, the negative
effects of product liability lawsuits against pharmaceutical companies may be considerable. First, fear of liability may cause pharmaceutical companies to be overly cautious about testing, delaying access to the drug. Second, the cost of drugs increases for consumers when pharmaceutical companies increase the length and number of trials they perform to identify even the smallest risks, and when regulatory agencies increase the number or intensity of regulatory reviews. Third, excessive liability costs create disincentives for development of orphan drugs, pharmaceuticals that benefit a small number of patients. Should pharmaceutical companies be liable for failure to warn when all of the rules were followed and the product was approved by the FDA but the unwanted effect was not detected because of its rarity or another confounding factor? The only way to find “all” of the unwanted effects that a drug may have is to market it—to conduct a phase IV “clinical trial” or observational study. This basic friction between risk to patients and the financial risk of drug development does not seem likely to be resolved except on a case-by-case basis.

The U.S. Supreme Court added further fuel to these fiery issues in 2009 in the case Wyeth v. Levine. A patient (Levine) suffered gangrene of an arm following inadvertent arterial administration of the drug promethazine. The healthcare provider had intended to administer the drug by so-called intravenous push. The FDA-approved label for the drug warned against but did not prohibit administration by intravenous push. The state courts and then the U.S. Supreme Court held both the healthcare provider and the company liable for damages. FDA approval of the label apparently neither protects a company from liability nor prevents individual states from imposing regulations more stringent than those required by the federal government.

“ME TOO” VERSUS TRUE INNOVATION: THE PACE OF NEW DRUG DEVELOPMENT

“Me-too drug” is a term used to describe a pharmaceutical that is usually structurally similar to a drug already on the market. Other names used are derivative medications, molecular modifications, and follow-up drugs. In some cases, a me-too drug is a different molecule developed deliberately by a competitor company to take market share from the company with existing drugs on the market. When the
market for a class of drugs is especially large, several companies can share the market and make a profit. Other me-too drugs result coincidentally from numerous companies developing products simultaneously without knowing which drugs will be approved for sale.

Some me-too drugs are only slightly altered formulations of a company’s own drug, packaged and promoted as if it really offers something new. An example of this type of me-too is the heartburn medication esomeprazole, marketed by the same company that makes omeprazole. Omeprazole is a mixture of 2 stereoisomers; esomeprazole contains only 1 of the isomers and is eliminated less rapidly. Development of esomeprazole created a new period of market exclusivity, although generic versions of omeprazole are marketed, as are branded congeners of omeprazole/esomeprazole.

There are valid criticisms of me-too drugs. First, an excessive emphasis on profit may stifle true innovation. Of the 487 drugs approved by the FDA between 1998 and 2003, only 67 (14%) were considered by the FDA to be new molecular entities. Second, some me-too drugs are more expensive than the older versions they seek to replace, increasing the costs of healthcare without corresponding benefit to patients. Nevertheless, for some patients, me-too drugs may have better efficacy or fewer side effects or promote compliance with the treatment regimen. For example, the me-too that can be taken once a day rather than more frequently is convenient and promotes compliance. Some me-too drugs add great value from a business and medical point of view. Atorvastatin was the seventh statin to be introduced to market; it subsequently became the best-selling drug in the world. Now that nonproprietary versions of simvastatin are available, sales of atorvastatin are declining. Billions of dollars might be saved, likely with little loss of benefit, if nonproprietary simvastatin were substituted for proprietary atorvastatin, with appropriate adjustment of dosages.

Critics argue that pharmaceutical companies are not innovative and do not take risks and, further, that medical progress is actually slowed by their excessive concentration on me-too products. Figure 1–2 summarizes a few of the facts behind this and other arguments. Clearly, smaller numbers of new molecular entities reached FDA approval over the past decade, despite the industry’s enormous investment in research and development. This disconnect has occurred
at a time when combinatorial chemistry was blooming, the human genome was being sequenced, highly automated techniques of screening were being developed, and new techniques of molecular biology and genetics were offering novel insights into the pathophysiology of human disease. Despite their innovations and successes (e.g., insulin, growth hormone, erythropoietin, and monoclonal antibodies to extracellular targets), the biotechnology companies have not, on balance, been more efficient at drug invention or discovery than the traditional major pharmaceutical companies.

Figure 1–2 *The cost of drug invention is rising dramatically while productivity is declining.* The peak in the mid-1990s was caused by the advent of PDUFA (see text), which facilitated elimination of a backlog.

The trends evident in *Figure 1–2* must be reversed. The current path will not sustain today’s companies as they face a major wave of patent expirations over the next several years. There are arguments, some almost counterintuitive, that development of much more targeted, individualized drugs, based on a new generation of molecular diagnostic techniques and improved understanding of disease in individual patients, could improve both medical care and the survival of pharmaceutical companies. Finally, many of the advances in genetics and molecular biology are still new, particularly when measured in the time frame required for drug development. One can hope that modern molecular medicine will sustain the development of more efficacious and more specific
pharmacological treatments for an ever wider spectrum of human diseases.
The absorption, distribution, metabolism (biotransformation), and elimination of drugs (ADME) are the processes of pharmacokinetics (Figure 2–1). Understanding and employing pharmacokinetic principles can increase the probability of therapeutic success and reduce the occurrence of adverse drug effects in the body.

**Figure 2-1** The interrelationship of the absorption, distribution, binding, metabolism, and excretion of a drug and its concentration at its sites of action. Possible distribution and binding of metabolites in relation to their potential actions at receptors are not depicted.

**PHYSICOCHEMICAL FACTORS IN TRANSFER OF DRUGS ACROSS MEMBRANES**

The absorption, distribution, metabolism, excretion, and action of a drug involve its passage across cell membranes. Mechanisms by which drugs cross membranes and the physicochemical properties of molecules and membranes that influence this transfer are critical to
understanding the disposition of drugs in the human body. The characteristics of a drug that predict its movement and availability at sites of action are its molecular size and structural features, degree of ionization, relative lipid solubility of its ionized and nonionized forms, and its binding to serum and tissue proteins. Although barriers to drug movement may be a single layer of cells (e.g., intestinal epithelium) or several layers of cells and associated extracellular protein (e.g., skin), the plasma membrane represents the common barrier to drug distribution.

The plasma membrane consists of a bilayer of amphipathic lipids with their hydrocarbon chains oriented inward to the center of the bilayer to form a continuous hydrophobic phase, with their hydrophilic heads oriented outward. Individual lipid molecules in the bilayer vary according to the particular membrane and can move laterally and organize themselves with cholesterol (e.g., sphingolipids), endowing the membrane with fluidity, flexibility, organization, high electrical resistance, and relative impermeability to highly polar molecules. Membrane proteins embedded in the bilayer serve as structural anchors, receptors, ion channels, or transporters to transduce electrical or chemical signaling pathways and provide selective targets for drug actions. Membranes are highly ordered and compartmented. Membrane proteins may be associated with caveolin and sequestered within caveolae, excluded from caveolae, or be organized in signaling domains rich in cholesterol and sphingolipid not containing caveolin or other scaffolding proteins (i.e., lipid rafts). Cell membranes are relatively permeable to water either by diffusion or by flow resulting from hydrostatic or osmotic differences across the membrane, and bulk flow of water can carry with it small drug molecules (<200 Da). Paracellular passage through intercellular gaps is sufficiently large that transfer across capillary endothelium is generally limited by blood flow (Figure 2–2). Capillaries of the central nervous system (CNS) and a variety of epithelial tissues have tight junctions. Bulk-flow transfer is limited when the molecular mass of the solute exceeds 100-200 Da. Accordingly, most large lipophilic drugs must pass through the cell membrane itself (see Figure 2–2) by passive and active processes.
Figure 2-2 The variety of ways drugs move across cellular barriers in their passage throughout the body. See details in Figure 5-4.

PASSIVE MEMBRANE TRANSPORT. In passive transport, the drug molecule usually penetrates by diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. Such transfer is directly proportional to the magnitude of the concentration gradient across the membrane, to the lipid-water partition coefficient of the drug, and to the membrane surface area exposed to the drug. At steady state, the concentration of the unbound drug is the same on both sides of the membrane if the drug is a nonelectrolyte. For ionic compounds, the steady-state concentrations depend on the electrochemical gradient for the ion and on differences in pH across the membrane, which will influence the state of ionization of the molecule disparately on either side of the membrane and can effectively trap drug on one side of the membrane.

WEAK ELECTROLYTES AND THE INFLUENCE OF pH. Many drugs are weak acids or bases that are present in solution as both the lipid-soluble and diffusible nonionized form, and the relatively lipid-insoluble nondiffusible ionized species. The transmembrane distribution of a weak electrolyte is influenced by its $pK_a$ and the pH gradient across the membrane. The $pK_a$ is the pH at which half the drug (weak acid or base electrolyte) is in its ionized form. The ratio of
nonionized to ionized drug at any pH may be calculated from the Henderson-Hasselbalch equation:

\[
\log \frac{[\text{protonated form}]}{[\text{unprotonated form}]} = pK_a - \text{pH} \quad \text{(Equation 2–1)}
\]

Equation 2–1 relates the pH of the medium around the drug and the drug’s acid dissociation constant \((pK_a)\) to the ratio of the protonated (HA or BH+) and unprotonated (A– or B) forms, where HA \(\leftrightarrow\) A– + H+ \((K_a = [A–][H+]/[HA])\) describes the dissociation of an acid, and BH+ \(\leftrightarrow\) B + H+ \((K_a = [B][H+]/[BH+])\) describes the dissociation of the protonated form of a base. At steady state, an acidic drug will accumulate on the more basic side of the membrane and a basic drug on the more acidic side. This phenomenon, known as ion trapping, is an important process in drug distribution (Figure 2–3).

![Figure 2-3 Influence of pH on the distribution of a weak acid \((pK_a = 4.4)\) between plasma and gastric juice separated by a lipid barrier. Dissociation of the weak acid in plasma \((\text{pH 7.4})\) and gastric acid \((\text{pH 1.4})\). The uncharged form, HA, equilibrates across the membrane. Blue numbers in brackets show relative concentrations of HA and A–, as calculated from Equation 2-1.](image)

CARRIER-MEDIATED MEMBRANE TRANSPORT. Active transport and facilitated diffusion are carrier-mediated processes. Pharmacologically important transporters may mediate either drug uptake or efflux and often facilitate vectorial transport across polarized cells. An important efflux transporter is the P-glycoprotein encoded by the multidrug resistance-1 (MDR1) gene (see Table}
5–4). P-glycoprotein localized in the enterocyte limits the absorption of some orally administered drugs because it exports compounds into the lumen of the GI tract subsequent to their absorption. The P-glycoprotein also can confer resistance to some cancer chemotherapeutic agents (see Chapters 60–63). Transporters and their roles in drug action are presented in detail in Chapter 5.

**DRUG ABSORPTION, BIOAVAILABILITY, AND ROUTES OF ADMINISTRATION**

*Absorption* is the movement of a drug from its site of administration into the central compartment (see Figure 2–1). For solid dosage forms, absorption first requires dissolution of the tablet or capsule, thus liberating the drug. The clinician is concerned primarily with bioavailability rather than absorption. *Bioavailability* describes the fractional extent to which a dose of drug reaches its site of action or a biological fluid from which the drug has access to its site of action.

For example, a drug given orally must be absorbed first from the GI tract, but net absorption may be limited by the characteristics of the dosage form, the drug’s physicochemical properties, by intestinal metabolism, and by export into the intestinal lumen. The absorbed drug then passes through the liver, where metabolism and biliary excretion may occur before the drug enters the systemic circulation. Accordingly, a fraction of the administered and absorbed dose of drug will be inactivated or diverted in the intestine and liver before it can reach the general circulation and be distributed to its sites of action. If the metabolic or excretory capacity of the liver and the intestine for the drug is large, bioavailability will be reduced substantially (*first-pass effect*). This decrease in availability is a function of the anatomical site from which absorption takes place; other anatomical, physiological, and pathological factors can influence bioavailability (described later), and the choice of the route of drug administration must be based on an understanding of these conditions.

**ORAL (ENTERAL) VERSUS PARENTERAL ADMINISTRATION.** Some characteristics of the major routes employed for systemic drug effect are compared in Table 2–1.

| Table 2–1 |
Some Characteristics of Common Routes of Drug Administration

<table>
<thead>
<tr>
<th>ROUTE</th>
<th>ABSORPTION PATTERN</th>
<th>SPECIAL UTILITY</th>
<th>LIMITATIONS AND PRECAUTIONS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Subcutaneous</td>
<td>Prompt from aqueous solution. Slow and sustained from repository preparations.</td>
<td>Suitable for some poorly soluble suspensions and slow-release implants.</td>
<td>Not suitable for large volumes. Possible pain or necrosis from irritants.</td>
</tr>
<tr>
<td>Intramuscular</td>
<td>Prompt from aqueous solution. Slow and sustained from repository preparations.</td>
<td>Suitable for moderate volumes, oily vehicles, and some irritants. Appropriate for self-administration (e.g., insulin).</td>
<td>Precluded during anticoagulant therapy. May interfere with interpretation of certain diagnostic tests (e.g., creatine kinase).</td>
</tr>
<tr>
<td>Oral ingestion</td>
<td>Variable, depends on many factors (see text).</td>
<td>Most convenient and economical; usually more safe.</td>
<td>Requires patient compliance. Bioavailability potentially erratic and incomplete.</td>
</tr>
</tbody>
</table>

*See text for discussion and for other routes.

**Oral ingestion** is the most common method of drug administration. It is also the safest, most convenient, and most economical. Its disadvantages include limited absorption of some drugs because of their physical characteristics (e.g., low water solubility or poor membrane permeability), emesis as a result of irritation to the GI mucosa, destruction of some drugs by digestive enzymes or low gastric pH, irregularities in absorption or propulsion in the presence of food or other drugs, and the need for cooperation on the part of the patient. In addition, drugs in the GI tract may be metabolized by the enzymes of the intestinal flora, mucosa, or liver before they gain access to the general circulation.

**Parenteral injection** of drugs has distinct advantages over oral administration. In some instances, parenteral administration is essential for the drug to be delivered in its active form, as in the case of monoclonal antibodies. Availability usually is more rapid, extensive, and predictable when a drug is given by injection; the effective dose can be delivered more accurately. In emergency therapy and when
a patient is unconscious, uncooperative, or unable to retain anything given by mouth, parenteral therapy may be necessary. Parenteral administration also has its disadvantages: asepsis must be maintained, especially when drugs are given over time (e.g., intravenous or intrathecal administration); pain may accompany the injection; and it is sometimes difficult for patients to perform the injections themselves if self-medication is necessary.

**ORAL ADMINISTRATION.** Absorption from the GI tract is governed by factors such as surface area for absorption, blood flow to the site of absorption, the physical state of the drug (solution, suspension, or solid dosage form), its water solubility, and the drug’s concentration at the site of absorption. For drugs given in solid form, the rate of dissolution may limit their absorption. Because most drug absorption from the GI tract occurs by passive diffusion, absorption is favored when the drug is in the nonionized, more lipophilic form. Based on the pH-partition concept (Figure 2–3), one would predict that drugs that are weak acids would be better absorbed from the stomach (pH 1-2) than from the upper intestine (pH 3-6), and vice versa for weak bases. However the epithelium of the stomach is lined with a thick mucus layer, and its surface area is small; by contrast, the villi of the upper intestine provide an extremely large surface area (~200 m²). Accordingly, the rate of absorption of a drug from the intestine will be greater than that from the stomach even if the drug is predominantly ionized in the intestine and largely nonionized in the stomach. Thus, any factor that accelerates gastric emptying will generally increase the rate of drug absorption, whereas any factor that delays gastric emptying is expected to have the opposite effect. Gastric emptying rate is influenced by numerous factors, including the caloric content of food; volume, osmolality, temperature, and pH of ingested fluid; diurnal and interindividual variation; metabolic state (rest or exercise); and the ambient temperature. Gastric emptying is influenced in women by the effects of estrogen (i.e., compared to men, it is slower for premenopausal women and those taking estrogen replacement therapy).

Drugs that are destroyed by gastric secretions and low pH or that cause gastric irritation sometimes are administered in dosage forms with an enteric coating that prevents dissolution in the acidic gastric contents. Enteric coatings are useful for drugs such as aspirin, which can cause gastric irritation, and for presenting a drug such as mesalamine to sites of action in the ileum and colon (see Figure 47–4).
**Controlled-Release Preparations.** The rate of absorption of a drug administered as a tablet or other solid oral dosage form is partly dependent on its rate of dissolution in GI fluids. This is the basis for *controlled-release, extended-release, sustained-release, and prolonged-action* pharmaceutical preparations that are designed to produce slow, uniform absorption of the drug for 8 h or longer. Potential advantages of such preparations are reduction in the frequency of administration compared with conventional dosage forms (often with improved compliance by the patient), maintenance of a therapeutic effect overnight, and decreased incidence and/or intensity of undesired effects (by dampening of the peaks in drug concentration) and nontherapeutic blood levels of the drug (by elimination of the troughs in concentration) that often occur after administration of immediate-release dosage forms. Controlled-release dosage forms are most appropriate for drugs with short half-lives ($t_{1/2} < 4$ h) or in selected patient groups such as those receiving antiepileptics.

**Sublingual Administration.** Venous drainage from the mouth is to the superior vena cava, bypassing the portal circulation and thereby protecting the drug from rapid intestinal and hepatic first-pass metabolism. For example, nitroglycerin (see Chapter 27) is effective when retained sublingually because it is nonionic and has very high lipid solubility.

**Transdermal Absorption.** Absorption of drugs able to penetrate the intact skin is dependent on the surface area over which they are applied and their lipid solubility (see Chapter 65). Systemic absorption of drugs occurs much more readily through abraded, burned, or denuded skin. Toxic effects result from absorption through the skin of highly lipid-soluble substances (e.g., a lipid-soluble insecticide in an organic solvent). Absorption through the skin can be enhanced by suspending the drug in an oily vehicle and rubbing the resulting preparation into the skin. Hydration of the skin with an occlusive dressing may be used to facilitate absorption. Controlled-release topical patches have become increasingly available, including nicotine for tobacco-smoking withdrawal, scopolamine for motion sickness, nitroglycerin for angina pectoris, testosterone and estrogen for replacement therapy, various estrogens and progestins for birth control, and fentanyl for pain relief.

**Rectal Administration.** Approximately 50% of the drug that is absorbed from the rectum will bypass the liver; thus reducing hepatic first-pass
metabolism. However, rectal absorption can be irregular and incomplete, and certain drugs can cause irritation of the rectal mucosa.

**PARENTERAL INJECTION.** The major routes of parenteral administration are intravenous, subcutaneous, and intramuscular. Absorption from subcutaneous and intramuscular sites occurs by simple diffusion along the gradient from drug depot to plasma. The rate is limited by the area of the absorbing capillary membranes and by the solubility of the substance in the interstitial fluid. Relatively large aqueous channels in the endothelial membrane account for the indiscriminate diffusion of molecules regardless of their lipid solubility. Larger molecules, such as proteins, slowly gain access to the circulation by way of lymphatic channels. Drugs administered into the systemic circulation by any route, excluding the intraarterial route, are subject to possible first-pass elimination in the lung prior to distribution to the rest of the body. The lungs also serve as a filter for particulate matter that may be given intravenously and provide a route of elimination for volatile substances.

*Intravenous.* Factors limiting absorption are circumvented by intravenous injection of drugs in aqueous solution because bioavailability is complete and rapid. Also, drug delivery is controlled and achieved with an accuracy and immediacy not possible by any other procedure. Certain irritating solutions can be given only in this manner because the drug, when injected slowly, is greatly diluted by the blood.

There are advantages and disadvantages to intravenous administration. Unfavorable reactions can occur because high concentrations of drug may be attained rapidly in plasma and tissues. There are therapeutic circumstances where it is advisable to administer a drug by bolus injection (e.g., tissue plasminogen activator) and other circumstances where slower administration of drug is advisable (e.g., antibiotics). Intravenous administration of drugs warrants close monitoring of the patient’s response; once the drug is injected, there is often no retreat. Repeated intravenous injections depend on the ability to maintain a patent vein. Drugs in an oily vehicle, those that precipitate blood constituents or hemolyze erythrocytes, and drug combinations that cause precipitates to form
must not be given by this route.

**Subcutaneous.** Injection into a subcutaneous site can be done only with drugs that are not irritating to tissue; otherwise, severe pain, necrosis, and tissue sloughing may occur. The rate of absorption following subcutaneous injection of a drug often is sufficiently constant and slow to provide a sustained effect. Moreover, altering the period over which a drug is absorbed may be varied intentionally, as is accomplished with insulin for injection using particle size, protein complexation, and pH. The incorporation of a vasoconstrictor agent in a solution of a drug to be injected subcutaneously also retards absorption. Absorption of drugs implanted under the skin in a solid pellet form occurs slowly over a period of weeks or months; some hormones (e.g., contraceptives) are administered effectively in this manner.

**Intramuscular.** Drugs in aqueous solution are absorbed rapidly after intramuscular injection depending on the rate of blood flow to the injection site. This may be modulated to some extent by local heating, massage, or exercise. Generally, the rate of absorption following injection of an aqueous preparation into the deltoid or vastus lateralis is faster than when the injection is made into the gluteus maximus. The rate is particularly slower for females after injection into the gluteus maximus. This has been attributed to the different distribution of subcutaneous fat in males and females and because fat is relatively poorly perfused. Slow, constant absorption from the intramuscular site results if the drug is injected in solution in oil or suspended in various other repository (depot) vehicles.

**Intraarterial.** Occasionally, a drug is injected directly into an artery to localize its effect in a particular tissue or organ, such as in the treatment of liver tumors and head and neck cancers. Diagnostic agents sometimes are administered by this route (e.g., technetium-labeled human serum albumin).

**Intrathecal.** The blood-brain barrier and the blood-cerebrospinal fluid (CSF) barrier often preclude or slow the entrance of drugs into the CNS. Therefore, when local and rapid effects of drugs on the meninges or cerebrospinal axis are desired, drugs sometimes are injected directly into the spinal subarachnoid space. Brain tumors also may be treated by direct intraventricular drug administration.
PULMONARY ABSORPTION. Gaseous and volatile drugs may be inhaled and absorbed through the pulmonary epithelium and mucous membranes of the respiratory tract. Access to the circulation is rapid by this route because the lung’s surface area is large. In addition, solutions of drugs can be atomized and the fine droplets in air (aerosol) inhaled. Advantages are the almost instantaneous absorption of a drug into the blood, avoidance of hepatic first-pass loss, and in the case of pulmonary disease, local application of the drug at the desired site of action (see Chapters 19 and 36).

TOPICAL APPLICATION

Mucous Membranes. Drugs are applied to the mucous membranes of the conjunctiva, nasopharynx, oropharynx, vagina, colon, urethra, and urinary bladder primarily for their local effects.

Eye. Topically applied ophthalmic drugs are used primarily for their local effects (see Chapter 64).

BIOEQUIVALENCE

Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredients and are identical in strength or concentration, dosage form, and route of administration. Two pharmaceutically equivalent drug products are considered to be bioequivalent when the rates and extents of bioavailability of the active ingredient in the 2 products are not significantly different under suitable test conditions. However, brand name and generic forms of the same drug are not always legally equivalent; law suits that have succeeded against the makers of brand name drugs have failed against the producers of the equivalent generic forms (see recent cases involving Phenergan and generic promethazine). Generic versus brand name prescribing is further discussed in connection with drug nomenclature and the choice of drug name in writing prescription orders (see Appendix I).

DISTRIBUTION OF DRUGS
Following absorption or systemic administration into the bloodstream, a drug distributes into interstitial and intracellular fluids depending on the particular physicochemical properties of the individual drug. Cardiac output, regional blood flow, capillary permeability, and tissue volume determine the rate of delivery and potential amount of drug distributed into tissues. Initially, liver, kidney, brain, and other well-perfused organs receive most of the drug; delivery to muscle, most viscera, skin, and fat is slower. This second distribution phase may require minutes to several hours before the concentration of drug in tissue is in equilibrium with that in blood. The second phase also involves a far larger fraction of body mass (e.g., muscle) than does the initial phase and generally accounts for most of the extravascularly distributed drug. With exceptions such as the brain, diffusion of drug into the interstitial fluid occurs rapidly because of the highly permeable nature of the capillary endothelial membrane. Thus, tissue distribution is determined by the partitioning of drug between blood and the particular tissue.

**PLASMA PROTEINS.** Many drugs circulate in the bloodstream bound to plasma proteins. Albumin is a major carrier for acidic drugs; α₁-acid glycoprotein binds basic drugs. Nonspecific binding to other plasma proteins generally occurs to a much smaller extent. The binding is usually reversible. In addition, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of estrogen or testosterone to sex hormone-binding globulin or the binding of thyroid hormone to thyroxin-binding globulin.

The fraction of total drug in plasma that is bound is determined by the drug concentration, the affinity of binding sites for the drug, and the number of binding sites. For most drugs, the therapeutic range of plasma concentrations is limited; thus, the extent of binding and the unbound fraction are relatively constant. The extent of plasma protein binding also may be affected by disease-related factors (e.g., hypoalbuminemia). Conditions resulting in the acute-phase reaction (e.g., cancer, arthritis, myocardial infarction, Crohn disease) lead to elevated levels of α₁-acid glycoprotein and enhanced binding of basic drugs. Changes in protein binding caused by disease states and drug-drug
interactions are clinically relevant mainly for a small subset of so-called high-clearance drugs of narrow therapeutic index that are administered intravenously, such as lidocaine. When changes in plasma protein binding occur in patients, unbound drug rapidly equilibrates throughout the body and only a transient significant change in unbound plasma concentration will occur. Only drugs that show an almost instantaneous relationship between free plasma concentration and effect (e.g., anti-arrhythmics) will show a measureable effect. Thus, unbound plasma drug concentrations will exhibit significant changes only when either drug input or clearance of unbound drug occurs, as a consequence of metabolism or active transport. A more common problem resulting from competition of drugs for plasma protein-binding sites is misinterpretation of measured concentrations of drugs in plasma because most assays do not distinguish free drug from bound drug.

Binding of a drug to plasma proteins limits its concentration in tissues and at its site of action because only unbound drug is in equilibrium across membranes. Accordingly, after distribution equilibrium is achieved, the concentration of active, unbound drug in intracellular water is the same as that in plasma except when carrier-mediated transport is involved. Binding of a drug to plasma protein also limits the drug’s glomerular filtration. Drug transport and metabolism also are limited by binding to plasma proteins, except when these are especially efficient, and drug clearance, calculated on the basis of unbound drug, exceeds organ plasma flow.

**TISSUE BINDING.** Many drugs accumulate in tissues at higher concentrations than those in the extracellular fluids and blood. Tissue binding of drugs usually occurs with cellular constituents such as proteins, phospholipids, or nuclear proteins and generally is reversible. A large fraction of drug in the body may be bound in this fashion and serve as a reservoir that prolongs drug action in that same tissue or at a distant site reached through the circulation. Such tissue binding and accumulation also can produce local toxicity.

**FAT AS A RESERVOIR.** Many lipid-soluble drugs are stored by physical solution in the neutral fat. In obese persons, the fat content of the body may be as high as 50%, and even in lean individuals, fat constitutes 10% of body weight; hence, fat may serve as a reservoir for lipid-soluble drugs. Fat is a rather stable reservoir because it has a relatively low blood flow.
BONE. The tetracycline antibiotics (and other divalent metal-ion chelating agents) and heavy metals may accumulate in bone by adsorption onto the bone crystal surface and eventual incorporation into the crystal lattice. Bone can become a reservoir for the slow release of toxic agents such as lead or radium; their effects thus can persist long after exposure has ceased. Local destruction of the bone medulla also may lead to reduced blood flow and prolongation of the reservoir effect because the toxic agent becomes sealed off from the circulation; this may further enhance the direct local damage to the bone. A vicious cycle results, whereby the greater the exposure to the toxic agent, the slower is its rate of elimination. The adsorption of drug onto the bone crystal surface and incorporation into the crystal lattice have therapeutic advantages for the treatment of osteoporosis.

REDISTRIBUTION. Termination of drug effect after withdrawal of a drug usually is by metabolism and excretion but also may result from redistribution of the drug from its site of action into other tissues or sites. Redistribution is a factor in terminating drug effect primarily when a highly lipid-soluble drug that acts on the brain or cardiovascular system is administered rapidly by intravenous injection or inhalation, such as intravenous anesthetic thiopental, a highly lipid-soluble drug. Because blood flow to the brain is so high, thiopental reaches its maximal concentration in brain within a minute of its intravenous injection. After injection is concluded, the plasma and brain concentrations decrease as thiopental redistributes to other tissues, such as muscle. The concentration of the drug in brain follows that of the plasma because there is little binding of the drug to brain constituents. Thus, both the onset and termination of thiopental anesthesia are rapid and both are related directly to the concentration of drug in the brain.

CNS AND CEREBROSPINAL FLUID. The brain capillary endothelial cells have continuous tight junctions; therefore, drug penetration into the brain depends on transcellular rather than paracellular transport. The unique characteristics of brain capillary endothelial cells and pericapillary glial cells constitute the blood-brain barrier. At the choroid plexus, a similar blood-CSF barrier is present, formed by epithelial cells that are joined by tight junctions. The lipid solubility of the nonionized and unbound species of a drug is therefore an important determinant of its uptake by the brain; the more lipophilic a drug, the more likely it is to cross the blood-brain barrier. Pharmaceutical chemists
have used this fact to regulate the extent to which drugs penetrate into the CNS (e.g., compare first- and second-generation antihistamines; see Chapter 32). In general, the blood-brain barrier’s function is well maintained; however, meningeal and encephalic inflammation increase local permeability. Drugs may also be imported to and exported from the CNS by specific transporters (see Chapter 5).

**PLACENTAL TRANSFER OF DRUGS.** The transfer of drugs across the placenta is of critical importance because drugs may cause anomalies in the developing fetus. Lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are important general determinants in drug transfer across the placenta. The fetal plasma is slightly more acidic than that of the mother (pH 7.0-7.2 versus 7.4), so that ion trapping of basic drugs occurs. The view that the placenta is an absolute barrier to drugs is inaccurate, in part because a number of influx transporters are also present. The fetus is to some extent exposed to all drugs taken by the mother.

**EXCRETION OF DRUGS**

Drugs are eliminated from the body either unchanged or as metabolites. Excretory organs, the lung excluded, eliminate polar compounds more efficiently than substances with high lipid solubility. Lipid-soluble drugs thus are not readily eliminated until they are metabolized to more polar compounds. The kidney is the most important organ for excreting drugs and their metabolites. Renal excretion of unchanged drug is a major route of elimination for 25-30% of drugs administered to humans. Substances excreted in the feces are principally unabsorbed orally ingested drugs or drug metabolites excreted either in the bile or secreted directly into the intestinal tract and not reabsorbed. Excretion of drugs in breast milk is important not because of the amounts eliminated, but because the excreted drugs may affect the nursing infant. Excretion from the lung is important mainly for the elimination of anesthetic gases (see Chapter 19).

**RENAL EXCRETION.** Excretion of drugs and metabolites in the urine involves
3 distinct processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption. Changes in overall renal function generally affect all 3 processes to a similar extent. In neonates, renal function is low compared with body mass but matures rapidly within the first few months after birth. During adulthood, there is a slow decline in renal function, ~1% per year, so that in elderly patients a substantial degree of functional impairment may be present.

The amount of drug entering the tubular lumen by filtration depends on the glomerular filtration rate and the extent of plasma binding of the drug; only unbound drug is filtered. In the proximal renal tubule, active, carrier-mediated tubular secretion also may add drug to the tubular fluid (see Chapter 5). Membrane transporters, mainly located in the distal renal tubule, also are responsible for any active reabsorption of drug from the tubular lumen back into the systemic circulation; however, in the proximal and distal tubules, the nonionized forms of weak acids and bases undergo net passive reabsorption. The concentration gradient for back diffusion is created by the reabsorption of water with Na⁺ and other inorganic ions. Because the tubular cells are less permeable to the ionized forms of weak electrolytes, passive reabsorption of these substances depends on the pH. When the tubular urine is made more alkaline, weak acids are largely ionized and thus are excreted more rapidly and to a greater extent; conversely, acidification of the urine will reduce fractional ionization and excretion of weak acids. Alkalization and acidification of the urine have the opposite effects on the excretion of weak bases. In the treatment of drug poisoning, the excretion of some drugs can be hastened by appropriate alkalization or acidification of the urine.

**BILIARY AND FECAL EXCRETION.** Transporters present in the canalicular membrane of the hepatocyte (see Chapter 5) actively secrete drugs and metabolites into bile. P-gp and BCRP (breast cancer resistance protein, or ABCG2) transport a plethora of amphipathic lipid-soluble drugs, whereas MRP2 is mainly involved in the secretion of conjugated metabolites of drugs (e.g., glutathione conjugates, glucuronides, and some sulfates). Ultimately, drugs and metabolites present in bile are released into the GI tract during the digestive process. Subsequently, drugs and metabolites can be reabsorbed into the body from the intestine, which, in the case of conjugated metabolites, such as glucuronides, may require their enzymatic hydrolysis by the intestinal microflora. Such *enterohepatic recycling*, if extensive, may prolong significantly
the presence of a drug (or toxin) and its effects within the body prior to elimination by other pathways. For this reason, drugs may be given orally to bind substances excreted in the bile.

EXCRETION BY OTHER ROUTES. Excretion of drugs into sweat, saliva, and tears is quantitatively unimportant. Elimination by these routes depends mainly on diffusion of the nonionized lipid-soluble form of drugs through the epithelial cells of the glands and on the pH. The same principles apply to excretion of drugs in breast milk. Because milk is more acidic than plasma, basic compounds may be slightly concentrated in this fluid; conversely, the concentration of acidic compounds in the milk is lower than in plasma. Nonelectrolytes (e.g., ethanol and urea) readily enter breast milk and reach the same concentration as in plasma, independent of the pH of the milk. Thus, the administration of drugs to breast-feeding women carries the general caution that the suckling infant will be exposed to some extent to the medication and/or its metabolites. In certain cases, such as treatment with the β-blocker atenolol, the infant may be exposed to significant amounts of drug. Although excretion into hair and skin is quantitatively unimportant, sensitive methods of detection of drugs in these tissues have forensic significance.

METABOLISM OF DRUGS

The majority of therapeutic agents are lipophilic compounds filtered through the glomerulus and reabsorbed into the systemic circulation during passage through the renal tubules. The metabolism of drugs and other xenobiotics into more hydrophilic metabolites is essential for their elimination from the body, as well as for termination of their biological and pharmacological activity. In general, biotransformation reactions generate more polar, inactive metabolites that are readily excreted from the body. However, in some cases, metabolites with potent biological activity or toxic properties are generated. Many of the enzyme systems that transform drugs to inactive metabolites also generate biologically active metabolites of endogenous compounds, as in steroid biosynthesis.

The enzyme systems involved in the biotransformation of drugs are localized
primarily in the liver. Other organs with significant drug metabolizing capacity include the GI tract, kidneys, and lungs. Prodrugs are pharmacologically inactive compounds designed to maximize the amount of the active species that reaches its site of action. Inactive prodrugs are converted rapidly to biologically active metabolites often by the hydrolysis of an ester or amide linkage (see Chapter 6 for details of drug metabolism).

CLINICAL PHARMACOKINETICS

Clinical pharmacokinetics rely on a relationship between the pharmacological effects of a drug and an accessible concentration of the drug (e.g., in blood or plasma). In most cases, the concentration of drug at its sites of action will be related to the concentration of drug in the systemic circulation (see Figure 2–1). The pharmacological effect that results may be the clinical effect desired, or an adverse or toxic effect. The 4 most important parameters governing drug disposition are bioavailability, the fraction of drug absorbed as such into the systemic circulation; volume of distribution, a measure of the apparent space in the body available to contain the drug based on how much is given versus what is found in the systemic circulation; clearance, a measure of the body’s efficiency in eliminating drug from the systemic circulation; and elimination t\(_1/2\), a measure of the rate of removal of drug from the systemic circulation.

For some drugs, no clear or simple relationship has been found between pharmacological effect and concentration in plasma, whereas for other drugs, routine measurement of drug concentration is impractical as part of therapeutic monitoring.

CLEARANCE

Clearance is the most important concept to consider when designing a rational regimen for long-term drug administration. The clinician usually wants to maintain steady-state concentrations of a drug within a therapeutic window or range associated with therapeutic efficacy
and a minimum of toxicity for a given agent. Assuming complete bioavailability, the steady-state concentration of drug in the body will be achieved when the rate of drug elimination equals the rate of drug administration (Equation 2–2). Thus:

\[
\text{Dosing rate} = CL \cdot C_{ss} \quad (\text{Equation 2–2})
\]

where \( CL \) is clearance of drug from the systemic circulation and \( C_{ss} \) is the steady-state concentration of drug. If the desired steady-state concentration of drug in plasma or blood is known, the rate of clearance of drug by the patient will dictate the rate at which the drug should be administered.

Metabolizing enzymes and transporters usually are not saturated, and thus the absolute rate of elimination of the drug is essentially a linear function of its concentration in plasma (first-order kinetics), where a constant fraction of drug in the body is eliminated per unit of time. If mechanisms for elimination of a given drug become saturated, the kinetics approach zero order (the case for ethanol), in which a constant amount of drug is eliminated per unit of time. With first-order kinetics, clearance (\( CL \)) will vary with the concentration of drug, often according to Equation 2–3:

\[
CL = \frac{v_m}{K_m + C} \quad (\text{Equation 2–3})
\]

where \( K_m \) represents the concentration at which half the maximal rate of elimination is reached (in units of mass/volume) and \( v_m \) is equal to the maximal rate of elimination (in units of mass/time). Thus, clearance is derived in units of volume/time. This equation is analogous to the Michaelis-Menten equation for enzyme kinetics.

Clearance of a drug is its rate of elimination by all routes normalized to the concentration of drug \( C \) in some biological fluid where measurement can be made:

\[
CL = \frac{\text{rate of elimination}}{C} \quad (\text{Equation 2–4})
\]

Thus, when clearance is constant, the rate of drug elimination is directly
proportional to drug concentration. Clearance indicates the volume of biological fluid such as blood or plasma from which drug would have to be completely removed to account for the clearance per unit of body weight (e.g., mL/min per kg). Clearance can be defined further as blood clearance ($CL_b$), plasma clearance ($CL_p$), or clearance based on the concentration of unbound drug ($CL_u$), depending on the measurement made ($C_b$, $C_p$, or $C_u$). Clearance of drug by several organs is additive. Elimination of drug from the systemic circulation may occur as a result of processes that occur in the kidney, liver, and other organs. Division of the rate of elimination by each organ by a concentration of drug (e.g., plasma concentration) will yield the respective clearance by that organ. Added together, these separate clearances will equal systemic clearance:

$$CL_{\text{renal}} + CL_{\text{hepatic}} + CL_{\text{other}} = CL$$

(Equation 2–5)

Systemic clearance may be determined at steady state by using **Equation 2–2**. For a single dose of a drug with complete bioavailability and first-order kinetics of elimination, systemic clearance may be determined from mass balance and the integration of **Equation 2–4** over time:

$$CL = Dose/AUC$$

(Equation 2–6)

$AUC$ is the total area under the curve that describes the measured concentration of drug in the systemic circulation as a function of time (from zero to infinity), as in **Figure 2–6**.

**Examples.** The plasma clearance for the antibiotic cephalexin is 4.3 mL/min/kg, with 90% of the drug excreted unchanged in the urine. For a 70-kg man, the clearance from plasma would be 301 mL/min, with renal clearance accounting for 90% of this elimination. In other words, the kidney is able to excrete cephalexin at a rate such that the drug is completely removed (cleared) from ~270 mL of plasma every minute (renal clearance = 90% of total clearance). Because clearance usually is assumed to remain constant in a medically stable patient (e.g., no acute decline in kidney function), the rate of elimination of cephalexin will depend on the concentration of drug in the plasma (see **Equation 2–4**).
The β adrenergic receptor antagonist propranolol is cleared from the blood at a rate of 16 mL/min/kg (or 1120 mL/min in a 70-kg man), almost exclusively by the liver. Thus, the liver is able to remove the amount of propranolol contained in 1120 mL of blood in 1 min. Even though the liver is the dominant organ for elimination, the plasma clearance of some drugs exceeds the rate of blood flow to this organ. Often this is so because the drug partitions readily into red blood cells (RBCs) and the rate of drug delivered to the eliminating organ is considerably higher than expected from measurement of its concentration in plasma. The parent text has a more extended presentation of clearance in Chapter 2 and Appendix II.

**HEPATIC CLEARANCE.** For a drug that is removed efficiently from the blood by hepatic processes (metabolism and/or excretion of drug into the bile), the concentration of drug in the blood leaving the liver will be low, the extraction ratio will approach unity, and the clearance of the drug from blood will become limited by hepatic blood flow. Drugs that are cleared efficiently by the liver (e.g., drugs with systemic clearances >6 mL/min/kg, such as diltiazem, imipramine, lidocaine, morphine, and propranolol) are restricted in their rate of elimination not by intrahepatic processes but by the rate at which they can be transported in the blood to the liver.

**RENAL CLEARANCE.** Renal clearance of a drug results in its appearance in the urine. The rate of filtration of a drug depends on the volume of fluid that is filtered in the glomerulus and the unbound concentration of drug in plasma, because drug bound to protein is not filtered. The rate of secretion of drug by the kidney will depend on the drug’s intrinsic clearance by the transporters involved in active secretion as affected by the drug’s binding to plasma proteins, the degree of saturation of these transporters, and the rate of delivery of the drug to the secretory site. In addition, processes involved in drug reabsorption from the tubular fluid must be considered. These factors are altered in renal disease.

**DISTRIBUTION**

**VOLUME OF DISTRIBUTION.** The volume of distribution (V) relates the amount of drug in the body to the concentration of drug (C) in the blood or plasma depending on the fluid measured. This volume does not necessarily refer to an identifiable physiological volume but
rather to the fluid volume that would be required to contain all of the
drug in the body at the same concentration measured in the blood or
plasma:

\[
\frac{\text{Amount of drug in body}}{V} = C \quad \text{or} \quad V = \frac{\text{amount of drug in body}}{C} \quad \text{(Equation 2–7)}
\]

A drug’s volume of distribution therefore reflects the extent to
which it is present in extravascular tissues and not in the plasma. View
\( V \) as an imaginary volume, because for many drugs \( V \) exceeds the
known volume of any and all body compartments. For example, the
value of \( V \) for the highly lipophilic antimalarial chloroquine is some
15,000 L, yet the plasma volume of a typical 70-kg man is 3 L, blood
volume is \(~5.5\) L, extracellular fluid volume outside the plasma is 12
L, and the volume of total-body water is \(~42\) L.

Many drugs exhibit volumes of distribution far in excess of these values. For
example, if 500 \( \mu \)g of the cardiac glycoside digoxin were in the body of a 70-kg
subject, a plasma concentration of \(~0.75\) ng/mL would be observed. Dividing the
amount of drug in the body by the plasma concentration yields a volume of
distribution for digoxin of \(~667\) L, or a value \(~15\) times greater than the total-
body volume of a 70-kg man. In fact, digoxin distributes preferentially to muscle
and adipose tissue and to its specific receptors \((\text{Na}^+, \text{K}^+\text{-ATPase})\), leaving a very
small amount of drug in the plasma to be measured. For drugs that are bound
extensively to plasma proteins but are not bound to tissue components, the
volume of distribution will approach that of the plasma volume because drug
bound to plasma protein is measurable in the assay of most drugs. In contrast,
certain drugs have high volumes of distribution even though most of the drug in
the circulation is bound to albumin because these drugs are also sequestered
elsewhere.

The volume of distribution may vary widely depending on the relative degrees of
binding to high-affinity receptor sites, plasma and tissue proteins, the partition
coefficient of the drug in fat, and accumulation in poorly perfused tissues. The
volume of distribution for a given drug can differ according to patient’s age,
gender, body composition, and presence of disease. Total-body water of infants
younger than 1 year of age, for example, is \(75\)% to \(80\)% of body weight, whereas
that of adult males is 60% and that of females is 55%.

The volume of distribution defined in Equation 2–7 considers the body as a single homogeneous compartment. In this one-compartment model, all drug administration occurs directly into the central compartment, and distribution of drug is instantaneous throughout the volume (V). Clearance of drug from this compartment occurs in a first-order fashion, as defined in Equation 2–4; that is, the amount of drug eliminated per unit of time depends on the amount (concentration) of drug in the body compartment. Figure 2–4A and Equation 2–8 describe the decline of plasma concentration with time for a drug introduced into this central compartment:

![Figure 2–4](image)

**Figure 2–4** Plasma concentration-time curves following intravenous administration of a drug (500 mg) to a 70-kg patient. **A.** Drug concentrations are measured in plasma at 2-hour intervals following drug administration. The semilogarithmic plot of plasma concentration (C_p) versus time suggests that the drug is eliminated from a single compartment by a first-order process (see Equation 2–8) with a t_{1/2} of 4 h (k = 0.693/t_{1/2} = 0.173 hr^{-1}). The volume of distribution (V) may be determined from the value of C_p obtained by extrapolation to 0-time. Volume of distribution (see Equation 2–7) for the one-compartment model is 31.3 L, or 0.45 L/Kg \( (V = \frac{dose}{C_p}) \). The clearance for this drug is 90 mL/min; for a one-compartment model, \( CL = kV \). **B.** Sampling before 2 h indicates that in fact the drug follows multiexponential kinetics. The terminal disposition \( t_{1/2} \) is 4 h, clearance is 84 mL/min (see Equation 2–6), \( V_{area} \) is 29 L.
(see Equation 2–8), and $V_{ss}$ is 26.8 L. The initial or “central” distribution volume for the drug ($V = \frac{\text{dose}}{C^0}$) is 16.1 L. The example indicates that multicompartment kinetics may be overlooked when sampling at early times is neglected. In this particular case, there is only a 10% error in the estimate of clearance when the multicompartment characteristics are ignored. For many drugs, multicompartment kinetics may be observed for significant periods of time, and failure to consider the distribution phase can lead to significant errors in estimates of clearance and in predictions of the appropriate dosage. Also, the difference between the “central” distribution volume and other terms reflecting wider distribution is important in deciding a loading dose strategy.

$$C = \left[\frac{\text{dose}}{V}\right]e^{-kt} \quad \text{(Equation 2–8)}$$

where $k$ is the rate constant for elimination that reflects the fraction of drug removed from the compartment per unit of time. This rate constant is inversely related to the $t_{1/2}$ of the drug [$kt_{1/2} = \ln 2 = 0.693$]. The idealized one-compartment model does not describe the entire time course of the plasma concentration. That is, certain tissue reservoirs can be distinguished from the central compartment, and the drug concentration appears to decay in a manner that can be described by multiple exponential terms (Figure 2–4B).

**RATE OF DISTRIBUTION.** In many cases, groups of tissues with similar perfusion-to-partition ratios all equilibrate at essentially the same rate such that only one apparent phase of distribution is seen (rapid initial decrease in concentration of intravenously injected drug, as in Figure 2–4B). It is as though the drug starts in a “central” volume (see Figure 2–1), which consists of plasma and tissue reservoirs that are in rapid equilibrium, and distributes to a “final” volume, at which point concentrations in plasma decrease in a log-linear fashion with a rate constant of $k$ (see Figure 2–4B). The multicompartment model of drug disposition can be viewed as though the blood and highly perfused lean organs such as heart, brain, liver, lung, and kidneys cluster as a single central compartment, whereas more slowly perfused tissues such as muscle, skin, fat, and bone behave as the final compartment (the tissue compartment).

**STEADY STATE.** Equation 2–2 (dosing rate $= CL \cdot C_{ss}$) indicates that a steady-state concentration eventually will be achieved when a drug is administered at a constant rate. At this point, drug elimination (the product of clearance and
concentration; Equation 2–4) will equal the rate of drug availability. This concept also extends to regular intermittent dosage (e.g., 250 mg of drug every 8 h). During each interdose interval, the concentration of drug rises with absorption and falls by elimination. At steady state, the entire cycle is repeated identically in each interval (Figure 2–5). Equation 2–2 still applies for intermittent dosing, but it now describes the average steady-state drug concentration \( \bar{C}\) during an interdose interval, where \( F \) is fractional bioavailability of the dose and \( T \) is dosage interval (time). By substitution of infusion rate for \( F \cdot \text{dose} / T \), the formula is equivalent to Equation 2–2 and provides the concentration maintained at steady state during continuous intravenous infusion.

![Figure 2-5](image)

**Figure 2-5** Fundamental pharmacokinetic relationships for repeated administration of drugs. The red line is the pattern of drug accumulation during repeated administration of a drug at intervals equal to its elimination half-time when drug absorption is 10 times as rapid as elimination. As the rate of absorption increases, the concentration maxima approach 2 and the minima approach 1 during the steady state. The blue line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based on the one-compartment model. Average drug concentration at steady state \( \bar{C}\) is given by Equation 2-10, where dosing rate is dose per time interval
(T), \( F \) is fractional bioavailability, and \( CL \) is clearance. Substituting infusion rate for \( F \cdot \text{dose}/T \) provides the concentration maintained at steady state during continuous intravenous infusion.

**HALF-LIFE.** The \( t_{1/2} \) is the time it takes for the plasma concentration to be reduced by 50%. For a one-compartment model (Figure 2–4A), \( t_{1/2} \) may be determined readily by inspection and used to make decisions about drug dosage. However, as indicated in Figure 2–4B, drug concentrations in plasma often follow a multiexponential pattern of decline, reflecting the changing amount of drug in the body. When using pharmacokinetics to calculate drug dosing in disease, note in Equation 2–9 that \( t_{1/2} \) changes as a function of both clearance and volume of distribution:

\[
t_{1/2} \approx 0.693 \cdot \frac{V_{ss}}{CL}
\]

(Equation 2–9)

This \( t_{1/2} \) reflects the decline of systemic drug concentrations during a dosing interval at steady-state as depicted in Figure 2–5.

*Clearance* is the measure of the body’s ability to eliminate a drug; thus, as clearance decreases, owing to a disease process, for example, \( t_{1/2} \) would be expected to increase as long as the volume of distribution remains unchanged. For example, the \( t_{1/2} \) of diazepam increases with increasing age; however, it is not clearance that changes as a function of age but rather the volume of distribution. Similarly, changes in protein binding of a drug may affect its clearance as well as its volume of distribution, leading to unpredictable changes in \( t_{1/2} \) as a function of disease. The \( t_{1/2} \) defined in Equation 2–9 provides an approximation of the time required to reach steady state after a dosage regimen is initiated or changed (e.g., 4 half-lives to reach \(~94\%\) of a new steady state) and a means to estimate the appropriate dosing interval.

**EXTENT AND RATE OF ABSORPTION**

**BIOAVAILABILITY.** It is important to distinguish between the rate and extent of drug absorption and the amount of drug that ultimately reaches the systemic circulation. This depends not only on the administered dose but also on the fraction of the dose \((F)\) that is absorbed and escapes any first-pass elimination. This fraction is the
drug’s bioavailability.

When drugs are administered by a route that is subject to first-pass loss, the equations presented previously that contain the terms dose or dosing rate (see Equations 2–2, 2–6, and 2–8) also must include the bioavailability term $F$ such that the available dose or dosing rate is used. For example, Equation 2–2 is modified to Equation 2–10:

$$F \cdot \text{dosing rate} = CL \cdot C_{ss} \quad \text{(Equation 2–10)}$$

where the value of $F$ is between 0 and 1. The value of $F$ varies widely for drugs administered by mouth, and successful therapy can still be achieved for some drugs with $F$ values as low as 0.03 (e.g., etidronate and aliskiren).

**RATE OF ABSORPTION.** Although the rate of drug absorption does not, in general, influence the average steady-state concentration of the drug in plasma, it may still influence drug therapy. If a drug is absorbed rapidly (e.g., a dose given as an intravenous bolus) and has a small “central” volume, the concentration of drug initially will be high. It will then fall as the drug is distributed to its “final” (larger) volume (see Figure 2–4B). If the same drug is absorbed more slowly (e.g., by slow infusion), a significant amount of the drug will be distributed while it is being administered, and peak concentrations will be lower and will occur later. Controlled-release oral preparations are designed to provide a slow and sustained rate of absorption in order to produce smaller fluctuations in the plasma concentration-time profile during the dosage interval compared with more immediate-release formulations. Because the beneficial, nontoxic effects of drugs are based on knowledge of an ideal or desired plasma concentration range, maintaining that range while avoiding large swings between peak and trough concentrations can improve therapeutic outcome.

**NONLINEAR PHARMACOKINETICS**

Nonlinearity in pharmacokinetics (i.e., changes in such parameters as clearance, volume of distribution, and $t_{1/2}$ as a function of dose or concentration of drug) is usually caused by saturation of either protein binding, hepatic metabolism, or active renal transport of the drug.
SATURABLE PROTEIN BINDING. As the molar concentration of drug increases, the unbound fraction eventually also must increase (as all binding sites become saturated when drug concentrations in plasma are in the range of tens to hundreds of μg/mL). For a drug that is metabolized by the liver with a low intrinsic clearance-extraction ratio, saturation of plasma-protein binding will cause both $V$ and $CL$ to increase as drug concentrations increase; $t_{1/2}$ thus may remain constant (see Equation 2–9). For such a drug, $C_{ss}$ will not increase linearly as the rate of drug administration is increased. For drugs that are cleared with high intrinsic clearance-extraction ratios, $C_{ss}$ can remain linearly proportional to the rate of drug administration. In this case, hepatic clearance will not change, and the increase in $V$ will increase the half-time of disappearance by reducing the fraction of the total drug in the body that is delivered to the liver per unit of time. Most drugs fall between these 2 extremes.

SATURABLE ELIMINATION. In this situation, the Michaelis-Menten equation (see Equation 2–3) usually describes the nonlinearity. All active processes are undoubtedly saturable, but they will appear to be linear if values of drug concentrations encountered in practice are much less than $K_m$. When drug concentrations exceed $K_m$, nonlinear kinetics are observed. The major consequences of saturation of metabolism or transport are the opposite of those for saturation of protein binding. Saturation of protein binding will lead to increased $CL$ because $CL$ increases as drug concentration increases, whereas saturation of metabolism or transport may decrease $CL$. Saturable metabolism causes oral first-pass metabolism to be less than expected (higher fractional bioavailability), and there is a greater fractional increase in $C_{ss}$ than the corresponding fractional increase in the rate of drug administration. The parent text includes a more detailed treatment.

DESIGN AND OPTIMIZATION OF DOSAGE REGIMENS
The intensity of a drug’s effect is related to its concentration above a minimum effective concentration, whereas the duration of the drug’s effect reflects the length of time the drug level is above this value (Figure 2–6). These considerations, in general, apply to both desired and undesired (adverse) drug effects; as a result, a therapeutic window exists that reflects a concentration range that provides efficacy without
unacceptable toxicity.

Figure 2–6 Temporal characteristics of drug effect and relationship to the therapeutic window (e.g., single dose, oral administration). A lag period is present before the plasma drug concentration ($C_p$) exceeds the minimum effective concentration (MEC) for the desired effect. Following onset of the response, the intensity of the effect increases as the drug continues to be absorbed and distributed. This reaches a peak, after which drug elimination results in a decline in $C_p$ and in the effect's intensity. Effect disappears when the drug concentration falls below the MEC. The duration of a drug’s action is determined by the time period over which concentrations exceed the MEC. An MEC exists for each adverse response, and if the drug concentration exceeds this, toxicity will result. The therapeutic goal is to obtain and maintain concentrations within the therapeutic window for the desired response with a minimum of toxicity. Drug response below the MEC for the desired effect will be subtherapeutic; above the MEC for an adverse effect, the probability of toxicity will increase. Increasing or decreasing drug dosage shifts the response curve up or down the intensity scale and is used to modulate the drug’s effect. Increasing the dose also prolongs a drug’s duration of action but at the risk of increasing the likelihood of adverse effects. Unless the drug is nontoxic (e.g., penicillins), increasing the dose is not a useful strategy for extending the duration of action. Instead, another dose of drug should be given, timed to
maintain concentrations within the therapeutic window. The area under the blood concentration-time curve (area under the curve, or AUC, shaded in red) can be used to calculate the clearance (see Equation 2–6) for first-order elimination. The AUC is also used as a measure of bioavailability (defined as 100% for an intravenously administered drug). Bioavailability will be less than 100% for orally administered drugs, due mainly to incomplete absorption and first-pass metabolism and elimination.

Similar considerations apply after multiple dosing associated with long-term therapy, and they determine the amount and frequency of drug administration to achieve an optimal therapeutic effect. In general, the lower limit of a drug’s therapeutic range is approximately equal to the drug concentration that produces about half the greatest possible therapeutic effect, and the upper limit of the therapeutic range is such that no more than 5-10% of patients will experience a toxic effect. For some drugs, this may mean that the upper limit of the range is no more than twice the lower limit. Of course, these figures can be highly variable, and some patients may benefit greatly from drug concentrations that exceed the therapeutic range, whereas others may suffer significant toxicity at much lower values (e.g., with digoxin).

For a limited number of drugs, some effect of the drug is easily measured (e.g., blood pressure, blood glucose) and can be used to optimize dosage using a trial-and-error approach. Even in an ideal case, certain quantitative issues arise, such as how often to change dosage and by how much. These usually can be settled with simple rules of thumb based on the principles discussed (e.g., change dosage by no more than 50% and no more often than every 3-4 half-lives). Alternatively, some drugs have very little dose-related toxicity, and maximum efficacy usually is desired. In such cases, doses well in excess of the average required will ensure efficacy (if this is possible) and prolong drug action. Such a “maximal dose” strategy typically is used for penicillins. For many drugs, however, the effects are difficult to measure (or the drug is given for prophylaxis), toxicity and lack of efficacy are both potential dangers, or the therapeutic index is narrow. In these circumstances, doses must be titrated carefully, and drug dosage is limited by toxicity rather than efficacy.

MAINTENANCE DOSE

In most clinical situations, drugs are administered in a series of
repetitive doses or as a continuous infusion to maintain a steady-state concentration of drug associated with the therapeutic window. Calculation of the appropriate maintenance dosage is a primary goal. To maintain the chosen steady-state or target concentration, the rate of drug administration is adjusted such that the rate of input equals the rate of loss. This relationship is expressed here in terms of the desired target concentration:

\[ \text{Dosing rate} = \text{target } C_p \cdot \frac{CL}{F} \quad \text{(Equation 2–11)} \]

If the clinician chooses the desired concentration of drug in plasma and knows the clearance and bioavailability for that drug in a particular patient, the appropriate dose and dosing interval can be calculated. An example of calculating the maintenance dose for oral digoxin appears in the parent text.

**DOsing INTERVAL FOR INTERMITTENT DOSAGE**

In general, marked fluctuations in drug concentrations between doses are not desirable. If absorption and distribution were instantaneous, fluctuations in drug concentrations between doses would be governed entirely by the drug’s elimination \( t_{1/2} \). If the dosing interval \( T \) were chosen to be equal to the \( t_{1/2} \), then the total fluctuation would be 2-fold; this is often a tolerable variation.

Pharmacodynamic considerations modify this. For some drugs with a narrow therapeutic range, it may be important to estimate the maximal and minimal concentrations that will occur for a particular dosing interval. The minimal steady-state concentration \( C_{ss,\text{min}} \) may be reasonably determined as:

\[
C_{ss,\text{min}} = \frac{F \cdot \text{dose}/V_{ss}}{1 - \exp(-kT)} \cdot \exp(-kT) \quad \text{(Equation 2–12)}
\]

where \( k \) equals 0.693 divided by the clinically relevant plasma \( t_{1/2} \), and \( T \) is the dosing interval. The term \( \exp(-kT) \) is, in fact, the fraction of the last dose (corrected for bioavailability) that remains in the body at the end of a dosing interval. The parent text gives examples
employing Equation 2–12.

LOADING DOSE

The *loading dose* is one or a series of doses that may be given at the onset of therapy with the aim of achieving the target concentration rapidly. The appropriate magnitude for the loading dose is:

\[
\text{Loading dose} = \text{target } C_p \cdot \frac{V_{ss}}{F} \quad \text{(Equation 2–13)}
\]

A loading dose may be desirable if the time required to attain steady state by the administration of drug at a constant rate (4 elimination \( t_{1/2} \) values) is long relative to the temporal demands of the condition being treated as is the case for treatment of arrhythmias and cardiac failure. The use of a loading dose also has significant disadvantages. First, the particularly sensitive individual may be exposed abruptly to a toxic concentration of a drug that may take a long time to decrease (i.e., long \( t_{1/2} \)). Loading doses tend to be large, and they are often given parenterally and rapidly; this can be particularly dangerous if toxic effects occur as a result of actions of the drug at sites that are in rapid equilibrium with plasma. It is therefore usually advisable to divide the loading dose into a number of smaller fractional doses that are administered over a period of time. Alternatively, the loading dose should be administered as a continuous intravenous infusion over a period of time using computerized infusion pumps. See the parent text for sample calculations.

THERAPEUTIC DRUG MONITORING

The major use of measured concentrations of drugs (at steady state) is to refine the estimate of \( CL/F \) for the patient being treated, using Equation 2–10 as rearranged:

\[
\frac{CL}{F} \text{ (patient)} = \frac{\text{dosing rate}}{C_{ss} \text{ (measured)}} \quad \text{(Equation 2–14)}
\]

The new estimate of \( CL/F \) can be used in Equation 2–11 to adjust the maintenance dose to achieve the desired target concentration. See the parent text for a fuller presentation of details, precautions, and pitfalls associated with therapeutic drug monitoring.
Pharmacodynamics is the study of the biochemical and physiological effects of drugs and their mechanisms of action. The effects of most drugs result from their interaction with macromolecular components of the organism. The term drug receptor or drug target denotes the cellular macromolecule or macromolecular complex with which the drug interacts to elicit a cellular response. Drugs commonly alter the rate or magnitude of an intrinsic cellular response rather than create new responses. Drug receptors are often located on the surface of cells, but may also be located in specific intracellular compartments such as the nucleus.

Many drugs also interact with acceptors (e.g., serum albumin) within the body. Acceptors are entities that do not directly cause any change in biochemical or physiological response. However, interactions of drugs with acceptors can alter the pharmacokinetics of a drug’s actions.

**PHYSIOLOGICAL RECEPTORS**

Many drug receptors are proteins that normally serve as receptors for endogenous regulatory ligands. These drug targets are termed physiological receptors. Drugs that bind to physiological receptors and mimic the regulatory effects of the endogenous signaling compounds are termed agonists. If the drug binds to the same recognition site as the endogenous agonist, the drug is said to be a primary agonist. Allosteric (or allotopic) agonists bind to a different region on the receptor referred to as an allosteric or allotopic site. Drugs that block or reduce the action of an agonist are termed antagonists. Antagonism generally results from competition with an
agonist for the same or overlapping site on the receptor (a syntopic interaction), but can also occur by interacting with other sites on the receptor (allosteric antagonism), by combining with the agonist (chemical antagonism), or by functional antagonism by indirectly inhibiting the cellular or physiological effects of the agonist. Agents that are only partly as effective as agonists are termed partial agonists. Many receptors exhibit some constitutive activity in the absence of a regulatory ligand; drugs that stabilize such receptors in an inactive conformation are termed inverse agonists (Figure 3–1). In the presence of a full agonist, partial and inverse agonists will behave as competitive antagonists.

![Figure 3–1](Image)

**Figure 3–1** Regulation of the activity of a receptor with conformation-selective drugs. The ordinate is the activity of the receptor produced by $R_a$, the active receptor conformation (e.g., stimulation of adenylyl cyclase by a β adrenergic receptor). If a drug $L$ selectively binds to $R_a$, it will produce a maximal response. If $L$ has equal affinity for $R_i$ and $R_a$, it will not perturb the equilibrium between them and will have no effect on net activity; $L$ would appear as an inactive compound. If the drug selectively binds to $R_i$, then the net amount of $R_a$ will be diminished. If $L$ can bind to receptor in an active conformation $R_a$ but also bind
to inactive receptor $R_i$ with lower affinity, the drug will produce a partial response; $L$ will be a partial agonist. If there is sufficient $R_a$ to produce an elevated basal response in the absence of ligand (agonist-independent constitutive activity), then activity will be inhibited; $L$ will then be an inverse agonist. Inverse agonists selectively bind to the inactive form of the receptor and shift the conformational equilibrium toward the inactive state. In systems that are not constitutively active, inverse agonists will behave like competitive antagonists, which helps explain why the properties of inverse agonists and the number of such agents previously described as competitive antagonists were only recently appreciated. Receptors that have constitutive activity and are sensitive to inverse agonists include benzodiazepine, histamine, opioid, cannabinoid, dopamine, bradykinin, and adenosine receptors.

**SPECIFICITY OF DRUG RESPONSES**

The strength of the reversible interaction between a drug and its receptor, as measured by the *dissociation constant*, is defined as the affinity of one for the other. Both the affinity of a drug for its receptor and its *intrinsic activity* are determined by its chemical structure. The chemical structure of a drug also contributes to the drug’s *specificity*. A drug that interacts with a single type of receptor that is expressed on only a limited number of differentiated cells will exhibit high specificity. Conversely, drugs acting on a receptor expressed ubiquitously throughout the body will exhibit widespread effects.

Many clinically important drugs exhibit a broad (low) specificity because they interact with multiple receptors in different tissues. Such broad specificity might enhance the clinical utility of a drug, but also contribute to a spectrum of adverse side effects because of off-target interactions. One example of a drug that interacts with multiple receptors is amiodarone, an agent used to treat cardiac arrhythmias. Amiodarone also has a number of serious toxicities, some of which are caused by the drug’s structural similarity to thyroid hormone and its ability to interact with nuclear thyroid receptors. Amiodarone’s salutary effects and toxicities may also be mediated through interactions with receptors that are poorly characterized or unknown. Some drugs are administered as racemic mixtures of stereoisomers. The stereoisomers can exhibit different
pharmacodynamic as well as pharmacokinetic properties. For example, the anti-arrhythmic drug sotalol is prescribed as a racemic mixture; the \( \text{D} \)- and \( \text{L} \)-enantiomers are equipotent as \( \text{K}^+ \) channel blockers, but the \( \text{L} \)-enantiomer is a much more potent - adrenergic antagonist (see Chapter 29). A drug may have multiple mechanisms of action that depend on receptor specificity, the tissue-specific expression of the receptor(s), drug access to target tissues, drug concentration in different tissues, pharmacogenetics, and interactions with other drugs.

Chronic administration of a drug may cause a downregulation of receptors or desensitization of response that can require dose adjustments to maintain adequate therapy. Chronic administration of nitrovasodilators to treat angina results in the rapid development of complete tolerance, a process known as tachyphylaxis. Drug resistance may also develop because of pharmacokinetic mechanisms (i.e., the drug is metabolized more rapidly with chronic exposure), the development of mechanisms that prevent the drug from reaching its receptor (i.e., increased expression of the multidrug resistance transporter in drug-resistant cancer cells; see Chapter 5), or the clonal expansion of cancer cells containing drug-resistant mutations in the drug receptor.

Some drug effects do not occur by means of macromolecular receptors; aluminum and magnesium hydroxides \([\text{Al(OH)}_3\text{ and Mg(OH)}_2]\) reduce gastric acid chemically, neutralizing \( \text{H}^+ \) with \( \text{OH}^- \) and raising gastric pH. Mannitol acts osmotically to cause changes in the distribution of water to promote diuresis, catharsis, expansion of circulating volume in the vascular compartment, or reduction of cerebral edema (see Chapter 25). Anti-infective drugs such as antibiotics, antivirals, and antiparasitics target receptors or cell processes that are critical for the growth or survival of the infective agent but are nonessential or lacking in the host organism. Resistance to antibiotics, antivirals, and other drugs can result through a variety of mechanisms including mutation of the target receptor, increased expression of enzymes that degrade or increase efflux of the drug from the infective agent, and development of alternative biochemical pathways that circumvent the drug’s effects on the infective agent.

**STRUCTURE-ACTIVITY RELATIONSHIPS AND DRUG DESIGN**
The receptors responsible for the clinical effects of many drugs have yet to be identified. Conversely, sequencing of the entire human genome has identified novel genes related by sequence to known receptors, for which endogenous and exogenous ligands are unknown; these are called *orphan receptors*.

Both the affinity of a drug for its receptor and its intrinsic activity are determined by its chemical structure. This relationship frequently is quite stringent. Relatively minor modifications in the drug molecule may result in major changes in its pharmacological properties based on altered affinity for 1 or more receptors. Exploitation of structure-activity relationships has frequently led to the synthesis of valuable therapeutic agents. Because changes in molecular configuration need not alter all actions and effects of a drug equally, it is sometimes possible to develop a congener with a more favorable ratio of therapeutic to adverse effects, enhanced selectivity among different cells or tissues, or more acceptable secondary characteristics than those of the parent drug. Therapeutically useful antagonists of hormones or neurotransmitters have been developed by chemical modification of the structure of the physiological agonist.

With information about the molecular structures and pharmacological activities of a relatively large group of congeners, it is possible to use computer analysis to identify the chemical properties (i.e., the pharmacophore) required for optimal action at the receptor: size, shape, position, and orientation of charged groups or hydrogen bond donors, and so on. Advances in molecular modeling of organic compounds and the methods for drug target (receptor) discovery and biochemical measurement of the primary actions of drugs at their receptors have enriched the quantitation of structure-activity relationships and its use in drug design. Such information increasingly is allowing the optimization or design of chemicals that can bind to a receptor with improved affinity, selectivity, or regulatory effect. Similar structure-based approaches also are used to improve pharmacokinetic properties of drugs, particularly if knowledge of their metabolism is known. Knowledge of the structures of receptors and of drug-receptor complexes, determined at atomic resolution by X-ray crystallography, is even more helpful in the design of ligands and in understanding the molecular basis of drug resistance and circumventing it. Emerging technology in the field of pharmacogenetics (see Chapter 7) is improving our understanding of the
nature of and variation in receptors.

**QUANTITATIVE ASPECTS OF DRUG INTERACTIONS WITH RECEPTORS**

Receptor occupancy theory assumes that response emanates from a receptor occupied by a drug, a concept that has its basis in the law of mass action. The *dose-response curve* depicts the observed effect of a drug as a function of its concentration in the receptor compartment. Figure 3–2 shows a typical dose-response curve.

**Figure 3–2** Graded responses (y axis as a percentage of maximal response) expressed as a function of the concentration of drug A present at the receptor. The hyperbolic shape of the curve in panel A becomes sigmoid when plotted semi-logarithmically, as in panel B. The concentration of drug that produces 50% of the maximal response quantifies drug activity and is referred to as the $EC_{50}$ (effective concentration for 50% response). The range of concentrations needed to fully depict the dose-response relationship (~3 $\log_{10} [10]$ units) is too wide to be useful in the linear format of Figure 3–2A; thus, most dose-response curves use log [Drug] on the x axis, as in Figure 3–2B. Dose-response curves presented in this way are sigmoidal in shape and have 3 properties: threshold, slope, and maximal asymptote. These 3 parameters quantitate the activity of the drug.

Some drugs cause low-dose stimulation and high-dose inhibition of response. These U-shaped relationships for some receptor systems are said to display hormesis. Several drug-receptor systems can display this property (e.g., prostaglandins, endothelin, and purinergic and serotonergic agonists), which may be at the root of some drug toxicities.
AFFINITY, EFFICACY, AND POTENCY. In general, the drug-receptor interaction is characterized by (1) binding of drug to receptor and (2) generation of a response in a biological system, as illustrated in Equation 3–1 where the drug or ligand is denoted as $L$ and the inactive receptor as $R$. The first reaction, the reversible formation of the ligand-receptor complex $LR$, is governed by the chemical property of affinity.

\[ L + R \xrightleftharpoons[k_{-1}]{k_{+1}} LR \xrightleftharpoons[k_{-2}]{k_{+2}} LR^* \]  

(Equation 3–1)

$LR^*$ is produced in proportion to [LR] and leads to a response. This simple relationship illustrates the reliance of the affinity of the ligand ($L$) with receptor ($R$) on both the forward or association rate ($k_{+1}$) and the reverse or dissociation rate ($k_{-1}$). At any given time, the concentration of ligand-receptor complex [LR] is equal to the product of $k_{+1}[L][R]$, the rate of formation of the bimolecular complex $LR$, minus the product $k_{-1}[LR]$, the rate dissociation of $LR$ into $L$ and $R$. At equilibrium (i.e., when $\delta[LR]/\delta t = 0$), $k_{+1}[L][R] = k_{-1}[LR]$. The equilibrium dissociation constant ($K_D$) is then described by ratio of the off and on rate constants ($k_{-1}/k_{+1}$).

Thus, at equilibrium,

\[ K_D = \frac{[L][R]}{[LR]} = \frac{k_{-1}}{k_{+1}} \]  

(Equation 3–2)

The affinity constant or equilibrium association constant ($K_A$) is the reciprocal of the equilibrium dissociation constant (i.e., $K_A = 1/K_D$); thus, a high-affinity drug has a low $K_D$ and will bind a greater number of a particular receptor at a low concentration than a low-affinity drug. As a practical matter, the affinity of a drug is influenced most often by changes in its off-rate ($k_{-1}$) rather than its on-rate ($k_{+1}$).
Equation 3–2 permits us to write an expression of the fractional occupancy \( f \) of receptors by agonist:

\[
    f = \frac{[\text{ligand-receptor complexes}]}{[\text{total receptors}]} - \frac{[LR]}{[R] + [LR]}
\]  

(Equation 3–3)

This can be expressed in terms of \( K_A \) (or \( K_D \)) and \([L]\):

\[
    f = \frac{K_A[L]}{1 + K_A[L]} = \frac{[L]}{[L] + K_D}
\]  

(Equation 3–4)

From this relationship, it follows that when the concentration of drug equals the \( K_D \) (or \( 1/K_A \)), \( f = 0.5 \), that is, the drug will occupy 50% of the receptors. This relationship describes only receptor occupancy, not the eventual response that may be amplified by the cell. Many signaling systems reach a full biological response with only a fraction of receptors occupied.

Potency is defined by example in Figure 3–3. Basically, when 2 drugs produce equivalent responses, the drug whose dose-response curve (plotted as in Figure 3–3A) lies to the left of the other (i.e., the concentration producing a half-maximal effect [EC\(_{50}\)] is smaller) is said to be the more potent.
Figure 3–3 Two ways of quantifying agonism. A. The relative potency of 2 agonists (Drug X, red line; Drug Y, purple line) obtained in the same tissue is a function of their relative affinities and intrinsic efficacies. The \( EC_{50} \) of Drug X occurs at a concentration that is one-tenth the \( EC_{50} \) of Drug Y. Thus, Drug X is more potent than Drug Y. B. In systems where the 2 drugs do not both produce the maximal response characteristic of the tissue, the observed maximal response is a nonlinear function of their relative intrinsic efficacies. Drug X is more efficacious than Drug Y; their asymptotic fractional responses are 100% (Drug X) and 50% (Drug Y).

Efficacy reflects the capacity of a drug to activate a receptor and generate a cellular response. Thus, a drug with high efficacy may be a full agonist, eliciting, at some concentration, a full response. A drug with a lower efficacy at the same receptor may not elicit a full response at any dose (see Figure 3–1). A drug with a low intrinsic efficacy will be a partial agonist. A drug that binds to a receptor and exhibits zero efficacy is an antagonist.
QUANTIFYING AGONISM. When the relative potency of 2 agonists of equal efficacy is measured in the same biological system, and downstream signaling events are the same for both drugs, the comparison yields a relative measure of the affinity and efficacy of the 2 agonists (see Figure 3–3). We often describe agonist response by determining the half-maximally effective concentration ($EC_{50}$) for producing a given effect. We can also compare maximal asymptotes in systems where the agonists do not produce maximal response (Figure 3–3B). The advantage of using maxima is that this property depends solely on efficacy, whereas drug potency is a mixed function of both affinity and efficacy.

QUANTIFYING ANTAGONISM. Characteristic patterns of antagonism are associated with certain mechanisms of blockade of receptors. One is straightforward competitive antagonism, whereby a drug with affinity for a receptor but lacking intrinsic efficacy competes with the agonist for the primary binding site on the receptor. The characteristic pattern of such antagonism is the concentration-dependent production of a parallel shift to the right of the agonist dose-response curve with no change in the maximal response (Figure 3–4A). The magnitude of the rightward shift of the curve depends on the concentration of the antagonist and its affinity for the receptor. A competitive antagonist will reduce the response to zero.
Figure 3–4 Mechanisms of receptor antagonism. A. Competitive antagonism occurs when the agonist A and antagonist I compete for the same binding site on the receptor. Response curves for the agonist are shifted to the right in a concentration-related manner by the antagonist such that the $EC_{50}$ for the agonist increases (e.g., $L$ versus $L'$, $L''$, and $L'''$) with the concentration of the antagonist. B. If the antagonist binds to the same site as the agonist but does so irreversibly or pseudo-irreversibly (slow dissociation but no covalent bond), it causes a shift of the dose-response curve to the right, with further depression of the maximal response. Allosteric effects occur when an allosteric ligand I or P binds to a different site on the receptor to either inhibit (I) the response (see panel C) or potentiate (P) the response (see panel D). This effect is saturable; inhibition or
potentiation reaches a limiting value when the allosteric site is fully occupied.

A partial agonist similarly can compete with a “full” agonist for binding to the receptor. However, increasing concentrations of a partial agonist will inhibit response to a finite level characteristic of the drug’s intrinsic efficacy. Partial agonists may be used therapeutically to buffer a response by inhibiting excessive receptor stimulation without totally abolishing receptor stimulation.

An antagonist may dissociate so slowly from the receptor that its action is exceedingly prolonged. In the presence of a slowly dissociating antagonist, the maximal response to the agonist will be depressed at some antagonist concentrations (Figure 3–4B). Operationally, this is referred to as noncompetitive antagonism, although the molecular mechanism of action cannot be inferred unequivocally from the effect. An irreversible antagonist competing for the same binding site as the agonist can produce the pattern of antagonism shown in Figure 3–4B. Noncompetitive antagonism can be produced by an allosteric or allotopic antagonist, which binds to a site on the receptor distinct from that of the primary agonist, thereby changing the affinity of the receptor for the agonist. In the case of an allosteric antagonist, the affinity of the receptor for the agonist is decreased by the antagonist (Figure 3–4C). In contrast, a drug binding at an allosteric site could potentiate the effects of primary agonists (Figure 3–4D); such a drug would be referred to as an allosteric agonist or co-agonist.

The affinity of a competitive antagonist ($K_i$) for its receptor can be determined in radioligand binding assays or by measuring the functional response of a system to a drug in the presence of the antagonist. Concentration curves are run with the agonist alone and with the agonist plus an effective concentration of the antagonist (see Figure 3–4A). As more antagonist (I) is added, a higher concentration of the agonist (A) is needed to produce an equivalent response (the half-maximal or 50%, response is a convenient and accurately determined level of response). The extent of the rightward shift of the concentration-dependence curve is a measure of the affinity of the inhibitor, and a higher-affinity inhibitor will cause a greater rightward shift than a lower-affinity inhibitor at the same inhibitor concentration. Using Equations 3–3 and 3–4, one may write mathematical expressions of fractional occupancy ($f$) of the receptor by agonist for the agonist alone (control) and agonist in the presence of inhibitor.

For the agonist drug ($L$) alone,
For the case of agonist plus antagonist (I),

\[ f_{\text{control}} = \frac{[L]}{[L] + K_D} \quad \text{ (Equation 3–5)} \]

Assuming that equal responses result from equal fractional receptor occupancies in both the absence and presence of antagonist, one can set the fractional occupancies equal at agonist concentrations (\(L\) and \(L'\)) that generate equivalent responses in Figure 3–4A. Thus,

\[ \frac{L}{L + K_D} = \frac{L'}{L' + K_D \left(1 + \frac{[I]}{K_i}\right)} \quad \text{ (Equation 3–7)} \]

Simplifying, one gets:

\[ \frac{L'}{L} - 1 = \frac{[I]}{K_i} \quad \text{ (Equation 3–8)} \]

where all values are known except \(K_i\). Thus, one can determine the \(K_i\) for a reversible, competitive antagonist without knowing the \(K_D\) for the agonist and without needing to define the precise relationship between receptor and response.

**PHARMACODYNAMIC VARIABILITY: INDIVIDUAL AND POPULATION PHARMACODYNAMICS**

Individuals vary in the magnitude of their response to the same concentration of a single drug, and a given individual may not always respond in the same way to the same drug concentration. Drug responsiveness may change because of disease or because of previous drug administration. Receptors are dynamic, and their concentration and function may be up- or downregulated by endogenous and
Data on the correlation of drug levels with efficacy and toxicity must be interpreted in the context of the pharmacodynamic variability in the population (e.g., genetics, age, disease, and the presence of coadministered drugs). The variability in pharmacodynamic response in the population may be analyzed by constructing a quantal concentration-effect curve (Figure 3–5A). The dose of a drug required to produce a specified effect in 50% of the population is the median effective dose \((ED_{50})\); see Figure 3–5A. In preclinical studies of drugs, the median lethal dose \((LD_{50})\) is determined in experimental animals (Figure 3–5B). The \(LD_{50}/ED_{50}\) ratio is an indication of the therapeutic index, which is a statement of how selective the drug is in producing its desired effects versus its adverse effects. A similar term, the therapeutic window, is the range of steady-state concentrations of drug that provides therapeutic efficacy with minimal toxicity (Figures 2–6 and 3–6). In clinical studies, the dose, or preferably the concentration, of a drug required to produce toxic effects can be compared with the concentration required for therapeutic effects in the population to evaluate the clinical therapeutic index. The concentration or dose of drug required to produce a therapeutic effect in most of the population usually will overlap the concentration required to produce toxicity in some of the population, even though the drug’s therapeutic index in an individual patient may be large. Thus, a population therapeutic window expresses a range of concentrations at which the likelihood of efficacy is high and the probability of adverse effects is low (see Figure 3–6); it does not guarantee efficacy or safety. Therefore, use of the population therapeutic window to adjust dosage of a drug should be complemented by monitoring appropriate clinical and surrogate markers for drug effect(s).
Figure 3–5 Frequency distribution curves and quantal concentration-effect and dose-effect curves. **A. Frequency distribution curves.** An experiment was performed on 100 subjects, and the effective plasma concentration that produced a quantal response was determined for each individual. The number of subjects who required each dose was plotted, giving a log-normal frequency distribution (*purple bars*). The normal frequency distribution, when summated, yields the cumulative frequency distribution—a sigmoidal curve that is a quantal concentration-effect curve (*red bars, red line*). **B. Quantal dose-effect curves.** Animals were injected with varying doses of a drug and the responses were determined and plotted. The calculation of the therapeutic index, the ratio of the \( LD_{50} \) to the \( ED_{50} \), is an indication of how selective a drug is in producing its desired effects relative to its toxicity. See text for additional explanation.
Figure 3–6 Relation of the therapeutic window of drug concentrations to therapeutic and adverse effects in the population. The ordinate is linear; the abscissa is logarithmic.

FACTORS MODIFYING DRUG ACTION. Numerous factors contribute to the wide patient-to-patient variability in the dose required for optimal therapy observed with many drugs (Figure 3–7). The effects of these factors on variability of drug pharmacokinetics are described more thoroughly in Chapters 2, 5, 6, and 7.
COMBINATION THERAPY. Marked alterations in the effects of some drugs can result from coadministration with other agents, including prescription and nonprescription drugs, as well as supplements and nutraceuticals. Such interactions can cause toxicity, or inhibit the drug effect and the therapeutic benefit. Drug interactions always should be considered when unexpected responses to drugs occur. Understanding the mechanisms of drug interactions provides a framework for preventing them. Drug interactions may be pharmacokinetic (the delivery of a drug to its site of action is altered by a second drug) or pharmacodynamic (the response of the drug target is modified by a second drug). Examples of pharmacokinetic interactions that can enhance or diminish the delivery of drug to its site of action are provided in Chapter 2. In a patient with multiple comorbidities requiring a variety of medications, it may be difficult to identify adverse effects due to medication interactions, and to determine whether these are pharmacokinetic, pharmacodynamic, or some combination of interactions.
Combination therapy constitutes optimal treatment for many conditions, including heart failure (see Chapter 28), hypertension (see Chapter 27), and cancer (see Chapters 60-63). However, some drug combinations produce pharmacodynamic interactions that result in adverse effects. For example, nitrovasodilators produce relaxation of vascular smooth muscle (vasodilation) via NO-dependent elevation of cyclic GMP in vascular smooth muscle. The pharmacologic effects of sildenafil, tadalafil, and vardenafil result from inhibition of the type 5 cyclic nucleotide phosphodiesterase (PDE5) that hydrolyzes cyclic GMP to 5’GMP in the vasculature. Thus, coadministration of an NO donor (e.g., nitroglycerin) with a PDE5 inhibitor can cause potentially catastrophic hypotension. The oral anticoagulant warfarin has a narrow margin between therapeutic inhibition of clot formation and bleeding complications and is subject to numerous important pharmacokinetic and pharmacodynamic drug interactions. Alterations in dietary vitamin K intake may significantly affect the pharmacodynamics of warfarin and mandate altered dosing; antibiotics that alter the intestinal flora reduce the bacterial synthesis of vitamin K, thereby enhancing the effect of warfarin; concurrent administration of nonsteroidal anti-inflammatory drugs (NSAIDs) with warfarin increases the risk of GI bleeding almost 4-fold compared with warfarin alone. By inhibiting platelet aggregation, aspirin increases the incidence of bleeding in warfarin-treated patients.

Most drugs are evaluated in young and middle-aged adults, and data on their use in children and the elderly are sparse. At the extremes of age, drug pharmacokinetics and pharmacodynamics can be altered, possibly requiring substantial alteration in the dose or dosing regimen to safely produce the desired clinical effect.

**Mechanisms of Drug Action**

**RECEPTORS THAT AFFECT CONCENTRATIONS OF ENDOGENOUS LIGANDS**

A large number of drugs act by altering the synthesis, storage, release, transport, or metabolism of endogenous ligands such as neurotransmitters, hormones, and other intercellular mediators. For example, some of the drugs acting on adrenergic neurotransmission
(see Chapters 8 and 12) include α-methyltyrosine [inhibits synthesis of norepinephrine (NE)], cocaine (blocks NE reuptake), amphetamine (promotes NE release), and selegiline (inhibits NE breakdown by MAO). There are similar examples for other neurotransmitter systems including acetylcholine (see Chapters 8 and 10), dopamine (DA), and serotonin (5HT) (see Chapters 13-15). Drugs that affect the synthesis of circulating mediators such as vasoactive peptides (e.g., angiotensin-converting enzyme inhibitors; see Chapter 26) and lipid-derived autocoids (e.g., cyclooxygenase inhibitors; see Chapter 33) are also widely used in the treatment of hypertension, inflammation, and myocardial ischemia.

**RECEPTORS THAT REGULATE THE IONIC MILIEU**

A relatively small number of drugs act by affecting the ionic milieu of blood, urine, and the GI tract. The receptors for these drugs are ion pumps and transporters, many of which are expressed only in specialized cells of the kidney and GI system. Most of the diuretics (e.g., furosemide, chlorothiazide, amiloride) act by directly affecting ion pumps and transporters in epithelial cells of the nephron that increase the movement of Na⁺ into the urine, or by altering the expression of ion pumps in these cells (e.g., aldosterone). Another therapeutically important target is the H⁺, K⁺-ATPase (proton pump) of gastric parietal cells. Irreversible inhibition of this proton pump by drugs such as esomeprazole reduces gastric acid secretion by 80-95% (see Chapter 45).

**CELLULAR PATHWAYS ACTIVATED BY PHYSIOLOGICAL RECEPTORS**

**SIGNAL TRANSDUCTION PATHWAYS.** Physiological receptors have 2 major functions, ligand binding and message propagation (i.e., signaling). These functions imply the existence of at least 2 functional domains within the receptor: a *ligand-binding domain* and an *effector*
The regulatory actions of a receptor may be exerted directly on its cellular target(s), on effector protein(s), or may be conveyed by intermediary cellular signaling molecules called transducers. The receptor, its cellular target, and any intermediary molecules are referred to as a receptor-effector system or signal transduction pathway. Frequently, the proximal cellular effector protein is not the ultimate physiological target but rather is an enzyme, ion channel, or transport protein that creates, moves, or degrades a small molecule (e.g., a cyclic nucleotide, inositol trisphosphate, or NO) or ion (e.g., Ca\(^{2+}\)) termed a second messenger. Second messengers can diffuse in the proximity of their synthesis or release and convey information to a variety of targets, which may integrate multiple signals. Even though these second messengers originally were thought of as freely diffusible molecules within the cell, imaging studies show that their diffusion and intracellular actions are constrained by compartmentation—selective localization of receptor-transducer-effector-signal termination complexes—established by protein-lipid and protein-protein interactions. All cells express multiple forms of proteins designed to localize signaling pathways by protein-protein interactions; these proteins are termed scaffolds or anchoring proteins.

Receptors and their associated effector and transducer proteins also act as integrators of information as they coordinate signals from multiple ligands with each other and with the differentiated activity of the target cell. For example, signal transduction systems regulated by changes in cyclic AMP (cAMP) and intracellular Ca\(^{2+}\) are integrated in many excitable tissues. In cardiac myocytes, an increase in cellular cAMP caused by activation of β adrenergic receptors enhances cardiac contractility by augmenting the rate and amount of Ca\(^{2+}\) delivered to the contractile apparatus; thus, cAMP and Ca\(^{2+}\) are positive contractile signals in cardiac myocytes. By contrast, cAMP and Ca\(^{2+}\) produce opposing effects on the contractility of smooth muscle cells: as usual, Ca\(^{2+}\) is a contractile signal, however, activation of β adrenergic receptors on these cells activates the cAMP-PKA pathway, which leads to relaxation through the phosphorylation of proteins that mediate Ca\(^{2+}\) signaling, such as myosin light chain kinase and ion channels that hyperpolarize the cell membrane.

Another important property of physiological receptors is their capacity to
significantly amplify a physiological signal. Neurotransmitters, hormones, and other extracellular ligands are often present at the ligand-binding domain of a receptor in very low concentrations (nM to μM levels). However, the effector domain or the signal transduction pathway often contains enzymes and enzyme cascades that catalytically amplify the intended signal. These signaling systems are excellent targets for drugs.

**STRUCTURAL AND FUNCTIONAL FAMILIES OF PHYSIOLOGICAL RECEPTORS**

Receptors for physiological regulatory molecules can be assigned to functional families that share common molecular structures and biochemical mechanisms. Table 3–1 outlines 6 major families of receptors with examples of their physiological ligands, signal transduction systems, and drugs that affect these systems.

Table 3–1

**Physiological Receptors**
### G Protein–Coupled Receptors (GPCRs)

GPCRs span the plasma membrane as a bundle of 7 α-helices (Figure 3–8). Among the ligands for GPCRs are neurotransmitters such as ACh, biogenic amines such as NE, all eicosanoids and other lipid-signaling molecules, peptide hormones, opioids, amino acids such as GABA, and many other peptide and protein ligands. GPCRs are important regulators of nerve activity in the CNS and are the receptors for the neurotransmitters of the peripheral autonomic nervous system. Because of their number and physiological importance, GPCRs are

**Figure 3–8** Stimulation of a G–protein coupled receptor by ligand, the activation of the G protein, and stimulation of selected effectors. In the absence of ligand, the receptor and G protein heterotrimer form a complex in the membrane with the G subunit bound to GDP. Following binding of ligand, the receptor and G protein subunit undergo a conformational change leading to release of GDP, binding of GTP, and dissociation of the complex. The activated GTP-bound G subunit and the freed dimer bind to and regulate effectors. The system is returned to the basal state by hydrolysis of the GTP on the subunit; a reaction that is markedly enhanced by the regulators of G protein signaling.
(RGS) proteins. Prolonged stimulation of the receptor can lead to downregulation of the receptor. This event is initiated by G protein receptor kinases (GRKs) that phosphorylate the C terminal tail of the receptor, leading to recruitment of proteins termed arrestins; arrestins bind to the receptor on the internal surface, displacing G proteins and inhibiting signaling. Detailed descriptions of these signaling pathways are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

**GPCR Subtypes.** There are multiple receptor subtypes within families of receptors. Ligand-binding studies initially identified receptor subtypes; molecular cloning has greatly accelerated the discovery and definition of additional receptor subtypes; their expression as recombinant proteins has facilitated the discovery of subtype-selective drugs. The distinction between classes and subtypes of receptors, however, is often arbitrary or historical. The α1, α2, and β adrenergic receptors differ from each other both in ligand selectivity and in coupling to G proteins (Gq, Gi, and Gs, respectively), yet s and are considered receptor classes and α1 and α2 are considered subtypes. Pharmacological differences among receptor subtypes are exploited therapeutically through the development and use of receptor-selective drugs. For example, β2 adrenergic agonists such as terbutaline are used for bronchodilation in the treatment of asthma in the hope of minimizing cardiac side effects caused by stimulation of the β1 adrenergic receptor (see Chapter 12). Conversely, the use of β1-selective antagonists minimizes the chance of bronchoconstriction in patients being treated for hypertension or angina (see Chapters 12 and 27).

**Receptor Dimerization.** GPCRs undergo both homo- and heterodimerization and possibly oligomerization. Dimerization of receptors may regulate the affinity and specificity of the complex for G proteins and the sensitivity of the receptor to phosphorylation by receptor kinases and the binding of arrestin, events important in termination of the action of agonists and removal of receptors from the cell surface. Dimerization also may permit binding of receptors to other regulatory proteins such as transcription factors.

**G PROTEINS.** GPCRs couple to a family of heterotrimeric GTP-binding regulatory proteins termed G proteins. G proteins are signal transducers that convey the information from the agonist-bound receptor to 1 or more effector proteins. G protein–regulated effectors include enzymes such as adenyllyl
cyclase, phospholipase C, cyclic GMP phosphodiesterase (PDE6), and membrane ion channels selective for Ca\textsuperscript{2+} and K\textsuperscript{+} (see Table 3–1 and Figure 3–8).

The G protein heterotrimer consists of a guanine nucleotide-binding α subunit, which confers specific recognition to both receptors and effectors, and an associated dimer of β and γ subunits that helps confer membrane localization of the G protein heterotrimer by prenylation of the γ subunit. In the basal state of the receptor-heterotrimer complex, the α subunit contains bound GDP and the α-GDP:βγ complex is bound to the unliganded receptor (see Figure 3–8). The α subunits fall into 4 families (Gs, Gi, Gq, and G12/13) which are responsible for coupling GPCRs to relatively distinct effectors. The Gs subunit uniformly activates adenylyl cyclase; the Gi subunit inhibits certain isoforms of adenylyl cyclase; the Gq subunit activates all forms of phospholipase C-β (PLCβ); and the G12/13 α subunits couple to guanine nucleotide exchange factors (GEFs), such as p115RhoGEF for the small GTP-binding proteins Rho and Rac. The signaling specificity of the large number of possible βγ combinations is not yet clear; nonetheless, it is known that K\textsuperscript{+} channels, Ca\textsuperscript{2+} channels, and PI-3 kinase (PI3K) are some of the effectors of free βγ dimer. Figure 3–8 and its legend summarize the basic activation/inactivation scheme for GPCR-linked systems.

SECOND MESSENGER SYSTEMS

CYCLIC AMP. Cyclic AMP is synthesized by adenylyl cyclase; stimulation is mediated by the Gs α subunit, inhibition by the Gi α subunit. There are 9 membrane-bound isoforms of adenylyl cyclase (AC) and 1 soluble isoform found in mammals. Cyclic AMP generated by adenylyl cyclases has 3 major targets in most cells, the cyclic AMP dependent protein kinase (PKA), cAMP-regulated guanine nucleotide exchange factors termed EPACs (exchange factors directly activated by cAMP), and via PKA phosphorylation, a transcription factor termed CREB (cAMP response element binding protein). In cells with specialized functions, cAMP can have additional targets such as cyclic nucleotide-gated ion channels, cyclic nucleotide-regulated phosphodiesterases (PDEs), and several ABC transporters (MRP4 and MRP5) (see Chapter 7).

PKA. The PKA holoenzyme consists of 2 catalytic (C) subunits reversibly bound to a regulatory (R) subunit dimer to form a heterotetramer complex
(R₂C₂). When AC is activated and cAMP concentrations are increased, 4 cyclic AMP molecules bind to the R₂C₂ complex, 2 to each R subunit, causing a conformational change in the R subunits that lowers their affinity for the C subunits, causing their activation. The active C subunits phosphorylate serine and threonine residues on specific protein substrates. There are multiple isoforms of PKA; molecular cloning has revealed α and β isoforms of both the regulatory subunits (RI and RII), as well as 3 C subunit isoforms Cα, Cβ, and Cγ. The R subunits exhibit different subcellular localization and binding affinities for cAMP, giving rise to PKA holoenzymes with different thresholds for activation. PKA function also is modulated by subcellular localization mediated by A-kinase anchoring proteins (AKAPs).

PKG. Stimulation of receptors that raise intracellular cyclic GMP concentrations (see Figure 3–11) leads to the activation of the cyclic GMP-dependent protein kinase G (PKG) that phosphorylates some of the same substrates as PKA and some that are PKG-specific. Unlike the heterotetramer (R₂C₂) structure of the PKA holoenzyme, the catalytic domain and cyclic nucleotide-binding domains of PKG are expressed as a single polypeptide, which dimerizes to form the PKG holoenzyme.
Figure 3–11 Cyclic GMP signaling pathways. Formation of cyclic GMP is regulated by cell surface receptors with intrinsic guanylyl cyclase (GC) activity and by soluble forms of GC. The cell surface receptors respond to natriuretic peptides such as atrial natriuretic peptide (ANP) with an increase in cyclic GMP. Soluble GC responds to nitric oxide (NO) generated from L-arginine by NO synthase (NOS). Cellular effects of cyclic GMP are carried out by PKG and cyclic GMP-regulated phosphodiesterases (PDEs). In this diagram, NO is produced by a Ca^{2+}/calmodulin-dependent NOS in an adjacent endothelial cell. Detailed descriptions of these signaling pathways are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

PKG exists in 2 homologous forms, PKG-I and PKG-II. PKG-I has an acetylated N terminus, is associated with the cytoplasm, and has 2 isoforms (Iα and Iβ) that arise from alternate splicing. PKG-II has a myristylated N terminus, is membrane-associated, and can be localized by PKG-anchoring proteins in a manner analogous to that known for PKA, although the docking domains of
PKA and PKG are very different structurally. Pharmacologically important effects of elevated cyclic GMP include modulation of platelet activation and relaxation of smooth muscle. Receptors linked to cGMP synthesis are covered below in a separate section.

**PDEs.** Cyclic nucleotide PDEs form another family of important signaling proteins whose activities are regulated via the rate of gene transcription as well as by second messengers (cyclic nucleotides or Ca\(^{2+}\)) and interactions with other signaling proteins such as β arrestin and protein kinases. PDEs hydrolyze the cyclic 3’,5’-phosphodiester bond in cAMP and cGMP, thereby terminating their action. The enzymes comprise a superfamily with >50 different PDE proteins. The substrate specificities of the different PDEs include those specific for cAMP hydrolysis, cGMP hydrolysis, and some that hydrolyze both cyclic nucleotides. PDEs (mainly PDE3 forms) are drug targets for treatment of diseases such as asthma, cardiovascular diseases such as heart failure, atherosclerotic coronary and peripheral arterial disease, and neurological disorders. PDE5 inhibitors (e.g., sildenafil) are used in treating chronic obstructive pulmonary disease and erectile dysfunction.

**G\(_q\)-PLC-DAG/IP\(_3\)-CA\(^{2+}\) PATHWAY.** Calcium is an important messenger in all cells and can regulate diverse responses including gene expression, contraction, secretion, metabolism, and electrical activity. Ca\(^{2+}\) can enter the cell through Ca\(^{2+}\) channels in the plasma membrane (see “Ion Channels,” below) or be released by hormones or growth factors from intracellular stores. In keeping with its role as a signal, the basal Ca\(^{2+}\) level in cells is maintained in the 100 nM range by membrane Ca\(^{2+}\) pumps that extrude Ca\(^{2+}\) to the extracellular space and a sarcoplasmic reticulum (SR) Ca\(^{2+}\)-ATPase (SERCA) in the membrane of the endoplasmic reticulum (ER) that accumulates Ca\(^{2+}\) into its storage site in the ER/SR.

Hormones and growth factors release Ca\(^{2+}\) from its intracellular storage site, the ER, via a signaling pathway that begins with activation of phospholipase C (PLC) at the plasma membrane, of which there are 2 primary forms, PLCβ and PLCγ. GPCRs that couple to G\(_q\) or G\(_i\) activate PLCβ by activating the G protein α subunit (see Figure 3–8) and releasing the βγ dimer. Both the active, G\(_q\)-GTP bound α subunit and the βγ dimer can activate certain isoforms of PLCβ. PLCγ isoforms are activated by tyrosine phosphorylation, including phosphorylation
by receptor and nonreceptor tyrosine kinases.

PLCs are cytosolic enzymes that translocate to the plasma membrane upon receptor stimulation. When activated they hydrolyze a minor membrane phospholipid, phosphatidylinositol-4, 5-bisphosphate, to generate 2 intracellular signals, inositol-1,4,5-trisphosphate (IP$_3$) and the lipid diacylglycerol (DAG). DAG directly activates members of the protein kinase C (PKC) family. IP$_3$ diffuses to the ER where it activates the IP$_3$ receptor in the ER membrane causing release of stored Ca$^{2+}$ from the ER. Release of Ca$^{2+}$ from these intracellular stores raises Ca$^{2+}$ levels in the cytoplasm manyfold within seconds and activates calmodulin-sensitive enzymes such as cyclic AMP PDE and a family of Ca$^{2+}$/calmodulin-sensitive protein kinases (e.g., phosphorylase kinase, myosin light chain kinase, and CaM kinases II and IV). Depending on the cell’s differentiated function, the Ca$^{2+}$/calmodulin kinases and PKC may regulate the bulk of the downstream events in the activated cells.

ION CHANNELS

Changes in the flux of ions across the plasma membrane are critical regulatory events in both excitable and nonexcitable cells. To establish the electrochemical gradients required to maintain a membrane potential, all cells express ion transporters for Na$^+$, K$^+$, Ca$^{2+}$, and Cl$^-$. For example, the Na$^+$, K$^+$-ATPase expends cellular ATP to pump Na$^+$ out of the cell and K$^+$ into the cell. The electrochemical gradients thus established are used by excitable tissues such as nerve and muscle to generate and transmit electrical impulses, by nonexcitable cells to trigger biochemical and secretory events, and by all cells to support a variety of secondary symport and antiport processes (see Chapter 5). Because of their roles as regulators of cell function, these proteins are important drug targets. The diverse ion channel family can be divided into subfamilies based on the mechanisms that open the channels, their architecture, and the ions they conduct. They can also be classified as voltage-activated, ligand-activated, store-activated, stretch-activated, and temperature-activated channels.
VOLTAGE-GATED CHANNELS. Humans express multiple isoforms of voltage-gated channels for Na⁺, K⁺, Ca²⁺, and Cl⁻ ions. In nerve and muscle cells, voltage-gated Na⁺ channels are responsible for the generation of robust action potentials that depolarize the membrane from its resting potential of –70 mV up to a potential of +20 mV within a few msec. These Na⁺ channels are composed of 3 subunits, a pore-forming α subunit and 2 regulatory β subunits (Figure 3–9A). The voltage-activated Na⁺ channels in pain neurons are targets for local anesthetics such as lidocaine and tetracaine, which block the pore, inhibit depolarization, and thus block the sensation of pain. They are also the targets of the naturally occurring marine toxins, tetrodotoxin and saxitoxin (see Chapter 20). Voltage-activated Na⁺ channels are also important targets of many drugs used to treat cardiac arrhythmias (see Chapter 29).

Figure 3–9 Two types of ion channels regulated by receptors and drugs. A. Diagram of a voltage-activated Na⁺ channel with the pore in the open and closed state. The pore-forming P loops are shown in blue, angled into the pore to form...
Voltage-gated Ca\(^{2+}\) channels have a similar architecture to voltage-gated Na\(^+\) channels with a large α subunit (4 domains of 5 membrane-spanning helices) and 3 regulatory subunits (the β, δ, and γ subunits). Ca\(^{2+}\) channels can be responsible for initiating an action potential (as in the pacemaker cells of the heart), but are more commonly responsible for modifying the shape and duration of an action potential initiated by fast voltage-gated Na\(^+\) channels. These channels initiate the influx of Ca\(^{2+}\) that stimulates the release of neurotransmitters in the central, enteric, and autonomic nervous systems, and that control heart rate and impulse conduction in cardiac tissue (see Chapters 8, 14, and 27). The L-type voltage-gated Ca\(^{2+}\) channels are subject to additional regulation via phosphorylation by PKA. Voltage-gated Ca\(^{2+}\) channels expressed in smooth muscle regulate vascular tone; the intracellular concentration of Ca\(^{2+}\) is critical to regulating the phosphorylation state of the contractile apparatus via the activity of the Ca\(^{2+}\)/calmodulin-sensitive myosin light chain kinase. Ca\(^{2+}\) channel antagonists such as nifedipine, diltiazem, and verapamil are effective vasodilators and are widely used to treat angina, cardiac arrhythmias, and hypertension.

Voltage-gated K\(^+\) channels are the most numerous and structurally diverse members of the voltage-gated channel family and include the voltage-gated K\(_v\) channels, the inwardly rectifying K\(^+\) channel, and the tandem or 2-pore domain “leak” K\(^+\) channels. The inwardly rectifying channels and the 2-pore channels are voltage insensitive, regulated by G proteins and H\(^+\) ions, and greatly stimulated by general anesthetics. Increasing K\(^+\) conductance through these
channels drives the membrane potential more negative (closer to the equilibrium potential for K\(^+\)); thus, these channels are important in regulating resting membrane potential and restoring the resting membrane at \(~70\) to \(~90\) mV following depolarization.

**LIGAND-GATED CHANNELS.** Channels activated by the binding of a ligand to a specific site in the channel protein have a diverse architecture and set of ligands. Major ligand-gated channels in the nervous system are those that respond to excitatory neurotransmitters such as acetylcholine (Figure 3–9B) or glutamate (or agonists such as AMPA and NMDA) and inhibitory neurotransmitters such as glycine or γ-aminobutyric acid (GABA). Activation of these channels is responsible for the majority of synaptic transmission by neurons both in the CNS and in the periphery (see Chapters 8, 11, and 14). In addition, there are a variety of more specialized ion channels that are activated by intracellular small molecules, and are structurally distinct from conventional ligand-gated ion channels. These include ion channels that are formally members of the K\(_v\) family, such as the hyperpolarization and cyclic nucleotide-gated (HCN) channel expressed in the heart (see Chapter 29), and the cyclic nucleotide-gated (CNG) channels important for vision (see Chapter 64). The intracellular small molecule category of ion channels also includes the IP\(_3\)-sensitive Ca\(^{2+}\) channel responsible for release of Ca\(^{2+}\) from the ER and the sulfonylurea “receptor” (SUR1) that associates with the K\(_i\)6.2 channel to regulate the ATP-dependent K\(^+\) channel (K\(_{ATP}\)) in pancreatic beta cells. The K\(_{ATP}\) channel is the target of oral hypoglycemic drugs such as sulfonylureas and meglitinides that stimulate insulin release from pancreatic β cells and are used to treat type 2 diabetes (see Chapter 43).

**TRANSMEMBRANE RECEPTORS LINKED TO INTRACELLULAR ENZYMES**

**RECEPTOR TYROSINE KINASES.** The receptor tyrosine kinases include receptors for hormones such as insulin, for multiple growth factors such EGF, platelet-derived growth factor (PDGF), nerve growth factor (NGF), fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), and ephrins. With the exception of the insulin receptor, which has α and β chains (see Chapter 43), these macromolecules consist of single polypeptide chains with large, cysteine-rich extracellular domains, short transmembrane domains, and an
intracellular region containing 1 or 2 protein tyrosine kinase domains. Activation of growth factor receptors leads to cell survival, cell proliferation, and differentiation. Activation of the ephrin receptors leads to neuronal angiogenesis, axonal migration, and guidance.

The inactive state of growth factor receptors is monomeric; binding of ligand induces dimerization of the receptor and cross-phosphorylation of the kinase domains on multiple tyrosine residues (Figure 3–10A). The phosphorylation of other tyrosine residues forms docking sites for the SH2 domains contained in a large number of signaling proteins. Molecules recruited to phosphotyrosine-containing proteins by their SH2 domains include PLCγ, which raises intracellular levels of Ca²⁺ and activates PKC. The α and β isoforms of PI3K contain SH2 domains, dock at the phosphorylated receptor, are activated, and increase the level of phosphatidylinositol 3,4,5 trisphosphate (PIP₃) and protein kinase B (PKB, also known as Akt). PKB can regulate the mammalian target of rapamycin (mTOR) in the various signaling pathways and the bad protein that is important in apoptosis.
Figure 3–10 Mechanism of activation of a receptor tyrosine kinase and a cytokine receptor. A. Activation of the EGF receptor. The extracellular structure of the unliganded receptor (a) contains 4 domains (I-IV), which rearrange significantly upon binding 2 EGF molecules. (b). The conformational changes lead to activation of the cytoplasmic tyrosine kinase domains and tyrosine phosphorylation of intracellular regions to form SH2 binding sites. (c). The adapter molecule Grb2 binds to the phosphorylated tyrosine residues and activates the Ras-MAP kinase cascade. B. Activation of a cytokine receptor. Binding of the cytokine causes dimerization of the receptor and recruits the Janus kinases (JAKs) to the cytoplasmic tails of the receptor. JAKs transphosphorylate and lead to the phosphorylation of the signal transducers and
activators of transcription (STATs). The phosphorylated STATS translocate to the nucleus and regulate transcription. There are proteins termed suppressors of cytokine signaling (SOCS) that inhibit the JAK-STAT pathway.

In addition to recruiting enzymes, phosphotyrosine-presenting proteins can interact with SH2 domain-containing adaptor molecules without activity (e.g., Grb2), which in turn attract guanine nucleotide exchange factors (GEFs) such as Sos that can activate the small GTP-binding protein, Ras. The small GTP-binding proteins Ras and Rho belong to a large family of small monomeric GTPases. All of the small GTPases are activated by GEFs that are regulated by a variety of mechanisms and inhibited by GTPase-activating proteins (GAPs). Activation of members of the Ras family leads in turn to activation of a protein kinase cascade termed the mitogen-activated protein kinase (MAP kinase or MAPK) pathway. Activation of the MAPK pathway is one of the major routes used by growth factor receptors to signal to the nucleus and stimulate cell growth.

**JAK-STAT RECEPTOR PATHWAY.** Cells express a family of receptors for cytokines such as C-interferon and hormones like growth hormone and prolactin, which signal to the nucleus by a more direct manner than the receptor tyrosine kinases. These receptors have no intrinsic enzymatic activity, rather the intracellular domain binds a separate, intracellular tryosine kinase termed a Janus kinase (JAK). Upon dimerization induced by ligand binding, JAKs phosphorylate other proteins termed signal transducers and activators of transcription (STATs), which translocate to the nucleus and regulate transcription (Figure 3–10B). The entire pathway is termed the JAK-STAT pathway. There are 4 JAKs and 5 STATs in mammals that, depending on the cell type and signal, combine differently to activate gene transcription.

**RECEPTOR SERINE-THREONINE KINASES.** Protein ligands such as TGF-β activate a family of receptors that are analogous to the receptor tyrosine kinases except that they have a serine/threonine kinase domain in the cytoplasmic region of the protein. There are 2 isoforms of the monomeric receptor protein, type I (7 forms) and type II (5 forms). In the basal state, these proteins exist as monomers; upon binding an agonist ligand, they dimerize, leading to phosphorylation of the kinase domain of the type I monomer, which activates the receptor. The activated receptor then phosphorylates a gene regulatory protein termed a Smad. Once phosphorylated by the activated
receptor on a serine residue, Smad dissociates from the receptor, migrates to the nucleus, associates with transcription factors, and regulates genes leading to morphogenesis and transformation. There are also inhibitory Smads (the Smad6 or Smad7 isoforms) that compete with the phosphorylated Smads to terminate signaling.

**TOLL-LIKE RECEPTORS.** Signaling related to the innate immune system is carried out by a family of >10 single membrane-spanning receptors termed *Toll-like receptors* (TLR), which are highly expressed in hematopoietic cells. In a single polypeptide chain, these receptors contain a large extracellular ligand-binding domain, a short membrane-spanning domain, and a cytoplasmic region termed the TIR domain that lacks intrinsic enzymatic activity. Ligands for TLR are comprised of a multitude of pathogen products including lipids, peptidoglycans, lipopeptides, and viruses. Activation of these receptors produces an inflammatory response to the pathogenic microorganisms.

The first step in activation of TLR by ligands is dimerization, which in turn causes signaling proteins to bind to the receptor to form a signaling complex. Ligand-induced dimerization recruits a series of adaptor proteins including Mal and the myeloid differentiation protein 88 (MyD88) to the intracellular TIR domain, which in turn recruit the interleukin-associated kinases termed IRAKs. The IRAKs autophosphorylate in the complex and subsequently form a more stable complex with MyD88. The phosphorylation event also recruits TRAF6 to the complex, which facilitates interaction with a ubiquitin ligase that attaches a polyubiquitin molecule to TRAF6. This complex can now interact with the protein kinase TAK1 and the adaptor TAB1. TAK1 is a member of the MAP kinase family, which activates the NF-κB kinases; phosphorylation of the NF-κB transcription factors causes their translocation to the nucleus and transcriptional activation of a variety of inflammatory genes.

**TNF-α RECEPTORS.** The mechanism of action of tumor necrosis factor α (TNF-α) signaling to the NF-κB transcription factors is very similar to that used by Toll-like receptors in that the intracellular domain of the receptor has no enzymatic activity. The TNF-α receptor is another single membrane-spanning receptor with an extracellular ligand-binding domain, a transmembrane domain, and a cytoplasmic domain termed the death domain. TNF-α binds a complex composed of TNF-receptor 1 and TNF-receptor 2. On trimerization, the death domains bind the adaptor protein TRADD, which recruits the receptor
interacting protein 1 (RIP1) to form a receptor-adaptor complex at the membrane. RIP1 is polyubiquinated, resulting in recruitment of the TAK1 kinase and the IκB kinase (IKK) complex to the ubiquinated molecules. The activation loop of IKK is phosphorylated in the complex eventually resulting in IκBα being released from the complex allowing the p50/p65 heterodimer of the complex to translocate to the nucleus and activate the transcription of inflammatory genes. Humanized monoclonal antibodies to TNF-α itself, such as infliximab and adalimumab, are important for the treatment of rheumatoid arthritis and Crohn disease (see Chapters 35 and 47).

**RECEPTORS THAT STIMULATE SYNTHESIS OF CYCLIC GMP.** The signaling pathways that regulate the synthesis of cyclic GMP in cells include hormonal regulation of transmembrane guanylyl cyclases such as the atrial natriuretic peptide (ANP) receptor and the activation of soluble forms of guanylyl cyclase by NO. The downstream effects of cyclic GMP are carried out by multiple isoforms of PKG, cyclic GMP-gated ion channels, and cyclic GMP-modulated PDEs that degrade cyclic AMP.

**Natriuretic Peptide Receptors: Ligand-Activated Guanylyl Cyclases.** The class of membrane receptors with intrinsic enzymatic activity includes the receptors for 3 small peptide ligands released from cells in cardiac tissues and the vascular system, the natriuretic peptides: atrial natriuretic peptide (ANP), released from atrial storage granules following expansion of intravascular volume or stimulation with pressor hormones; brain natriuretic peptide (BNP), synthesized and released in large amounts from ventricular tissue in response to volume overload; and C-type natriuretic peptide (CNP), synthesized in the brain and endothelial cells. Like BNP, CNP is not stored in granules; rather, its synthesis and release are increased by growth factors and sheer stress on vascular endothelial cells. The major physiological effects of these hormones are to decrease blood pressure (ANP, BNP), to reduce cardiac hypertrophy and fibrosis (BNP), and to stimulate long bone growth (CNP). The transmembrane receptors for ANP, BNP, and CNP are ligand-activated guanylyl cyclases. The ANP receptor (NPR-A) is the molecule that responds to ANP and BNP. The NPR-B receptor responds to CNP. The natriuretic peptide C receptor (NPR-C) has an extracellular domain similar to those of NPR-A and NPR-B but does not contain the intracellular kinase or guanylyl cyclase domains. It has no enzymatic activity and is thought to function as a clearance receptor, removing excess natriuretic
peptide from the circulation.

**NO Synthase and Soluble Guanylyl Cyclase.** NO is produced locally in cells by the enzyme NO synthase (NOS). NO stimulates the soluble form of guanylyl cyclase to produce cyclic GMP. There are 3 forms of NO synthase, neuronal NOS (nNOS or NOS1), endothelial NOS (eNOS or NOS3), and inducible NOS (iNOS or NOS2). All 3 forms of this enzyme are widely expressed but are especially important in the cardiovascular system, where they are found in myocytes, vascular smooth muscle cells, endothelial cells, hematopoietic cells, and platelets. Elevated cell Ca\(^{2+}\), acting via calmodulin, markedly activates nNOS and eNOS; the inducible form is less sensitive to Ca\(^{2+}\) but synthesis of iNOS protein in cells can be induced > 1000-fold by inflammatory stimuli such as endotoxin, TNF-α, interleukin-1β, and interferon-γ.

NOS produces NO by catalyzing the oxidation of the guanido nitrogen of L-arginine, producing L-citrulline and NO. NO activates the soluble guanylyl cyclase (sGC), a heterodimer that contains a protoporphyrin-IX heme domain. NO binds to this domain at low nM concentrations and produces a 200- to 400-fold increase in the \(V_{\text{max}}\) of guanylyl cyclase, leading to an elevation of cellular cyclic GMP. The cellular effects of cyclic GMP on the vascular system are mediated by a number of mechanisms, but especially by PKG. In vascular smooth muscle, activation of PKG leads to vasodilation by:

- Inhibiting IP\(_3\)-mediated Ca\(^{2+}\) release from intracellular stores
- Phosphorylating voltage-gated Ca\(^{2+}\) channels to inhibit Ca\(^{2+}\) influx
- Phosphorylating phospholamban, a modulator of the sarcoplasmic Ca\(^{2+}\) pump, leading to a more rapid reuptake of Ca\(^{2+}\) into intracellular stores
- Phosphorylating and opening the Ca\(^{2+}\)-activated K\(^+\) channel leading to hyperpolarization of the cell membrane, which closes L-type Ca\(^{2+}\) channels and reduces the flux of Ca\(^{2+}\) into the cell.

**NUCLEAR HORMONE RECEPTORS AND TRANSCRIPTION FACTORS**

Nuclear hormone receptors comprise a superfamily of 48 receptors that respond to a diverse set of ligands. The receptor proteins are transcription factors able to regulate the expression of genes
controlling numerous physiological processes such as reproduction, development, and metabolism. Members of the family include receptors for circulating steroid hormones such as androgens, estrogens, glucocorticoids, thyroid hormone, and vitamin D. Other members of the family are receptors for a diverse group of fatty acids, bile acids, lipids, and lipid metabolites.

Examples include the retinoic acid receptor (RXR); the liver X receptor (LXR—the ligand is 22-OH cholesterol); the farnesoid X receptor (FXR—the ligand is chenodeoxycholic acid); and the peroxisome proliferator-activated receptors (PPARs α, β, and γ; 15 deoxy prostaglandin J2 is a possible ligand for PPARγ; the cholesterol-lowering fibrates bind to and regulate PPARγ). In the inactive state, receptors for steroids such as glucocorticoids reside in the cytoplasm and translocate to the nucleus upon binding ligand. Other members of the family such as the LXR and FXR receptors reside in the nucleus and are activated by changes in the concentration of hydrophobic lipid molecules.

Nuclear hormone receptors contain 4 major domains in a single polypeptide chain. The N-terminal domain can contain an activation region (AF-1) essential for transcriptional regulation followed by a very conserved region with 2 zinc fingers that bind to DNA (the DNA-binding domain). The N-terminal activation region (AF-1) is subject to regulation by phosphorylation and other mechanisms that stimulate or inhibit transcription. The C terminal half of the molecule contains a hinge region (which can be involved in binding DNA), the domain responsible for binding the hormone or ligand (the ligand-binding domain or LBD), and specific sets of amino acid residues for binding coactivators and corepressors in a second activation region (AF-2). The LBD is formed from a bundle of 12 helices; ligand binding induces a major conformational change in helix 12 that affects the binding of the coregulatory proteins essential for activation of the receptor-DNA complex (Figure 3–12).
Figure 3–12 Activation of nuclear hormone receptors. A nuclear hormone receptor (OR) is shown in complex with the retinoic acid receptor (RXR). When an agonist (yellow triangle) and coactivator bind, a conformational change occurs in helix 12 (black bar) and gene transcription is stimulated. If corepressors are bound, activation does not occur. See text for details; see also Figure 6–13.

When bound to DNA, most of the nuclear hormone receptors act as dimers—some as homodimers, others as heterodimers. Steroid hormone receptors such as the glucocorticoid receptor are commonly homodimers, whereas those for lipids are heterodimers with the RXR receptor. The receptor dimers bind to repetitive DNA sequences, either direct repeat sequences or an inverted repeat termed hormone response elements (HRE) that are specific for each type of receptor. The hormone response elements in DNA are found upstream of the regulated genes or in some cases within the regulated genes. An agonist-bound nuclear hormone receptor often activates a large number of genes to carry out a program of cellular differentiation or metabolic regulation. An important property of these receptors is that they must bind their ligand, the appropriate HRE, and a coregulator to regulate their target genes. The activity of the nuclear hormone receptors in a given cell depends not only on the ligand, but the ratio of coactivators and corepressors recruited to the complex. Coactivators recruit enzymes to the transcription complex that modify chromatin, such as histone acetylase that serves to unravel DNA for transcription. Corepressors recruit proteins such as histone deacetylase that keeps DNA tightly packed and inhibits transcription.

APOPTOSIS

Organ development and renewal requires a balance between survival
and expansion of the cell population, and cell death and removal. The process by which cells are genetically programmed for death is termed *apoptosis*.

Apoptosis is a highly regulated program of biochemical reactions that leads to cell rounding, shrinking of the cytoplasm, condensation of the nucleus and nuclear material, and changes in the cell membrane that eventually lead to presentation of phosphatidylserine on the outer surface of the cell. Phosphatidylserine is recognized as a sign of apoptosis by macrophages, which engulf and phagocytize the dying cell. During this process, the membrane of the apoptotic cell remains intact and the cell does not release its cytoplasm or nuclear material. Thus, unlike necrotic cell death, the apoptotic process does not initiate an inflammatory response. Alterations in apoptotic pathways are implicated in a variety of diseases such as cancer, and neurodegenerative and autoimmune diseases.

Two major signaling pathways induce apoptosis. Apoptosis can be initiated by external signals that have features in common with those used by ligands such as TNF-α or by an internal pathway activated by DNA damage, improperly folded proteins, or withdrawal of cell survival factors (*Figure 3–13*). The apoptotic program is carried out by a large family of cysteine proteases termed *caspases*. The caspases are highly specific cytoplasmic proteases that are inactive in normal cells but become activated by apoptotic signals.
Figure 3–13 Two pathways leading to apoptosis. Apoptosis can be initiated by external ligands such as TNF, Fas, or TNF-related apoptosis-inducing ligand (TRAIL) at specific transmembrane receptors (left half of figure). Activation leads to trimerization of the receptor, and binding of adaptor molecules such as TRADD, to the intracellular death domain. The adaptors recruit caspase 8, activate it leading to cleavage and activation of the effector caspase, caspase 3, which activates the caspase pathway, leading to apoptosis. Apoptosis can also be initiated by an intrinsic pathway regulated by Bcl-2 family members such as Bax and Bcl-2. Bax is activated by DNA damage or malformed proteins via p53 (right half of figure). Activation of this pathway leads to release of cytochrome c from the mitochondria, formation of a complex with Apaf-1 and caspase 9. Caspase 9 is activated in the complex and initiates apoptosis thru activation of caspase 3. Either the extrinsic or the intrinsic pathway can overwhelm the inhibitors of apoptosis proteins (IAPs) that otherwise keep apoptosis in check.

The external apoptosis signaling pathway can be activated by ligands such as TNF, Fas (also called Apo-1), or the TNF-related apoptosis-inducing ligand (TRAIL). The receptors for Fas and TRAIL are transmembrane receptors with no enzymatic activity, similar to the organization of the TNF receptor described above. Upon binding TNF, Fas ligand, or TRAIL, these receptors form a
receptor, undergo a conformational change, and recruit adapter proteins to the death domain. The adaptor proteins then recruit the receptor-interacting protein kinase (RIP1) and caspase 8 to form a complex that results in the activation of caspase 8. Activation of caspase 8 leads to the activation of caspase 3, which initiates the apoptotic program. The final steps of apoptosis are carried out by caspase 6 and 7, leading to degradation of enzymes, structural proteins, and DNA fragmentation characteristic of cell death (see Figure 3–13).

The internal apoptosis pathway can be activated by signals such as DNA damage leading to increased transcription of the p53 gene and involves damage to the mitochondria by pro-apoptotic members of the Bcl-2 family of proteins. This family includes proapoptotic members such as Bax, Bak, and Bad, which induce damage at the mitochondrial membrane. There are also anti-apoptotic Bcl-2 members, such as Bcl-2, Bcl-X, and Bcl-W, which serve to inhibit mitochondrial damage and are negative regulators of the system. When DNA damage occurs, p53 transcription is activated and holds the cell at a cell cycle checkpoint until the damage is repaired. If the damage cannot be repaired, apoptosis is initiated through the pro-apoptotic Bcl-2 members such as Bax. Bax is activated, translocates to the mitochondria, overcomes the anti-apoptotic proteins, and induces the release of cytochrome c and a protein termed the second mitochondria-derived activator of caspase (SMAC). SMAC binds to and inactivates the inhibitors of apoptosis proteins (IAPs) that normally prevent caspase activation. Cytochrome C combines in the cytosol with another protein, apoptotic activating protease factor -1 (Apaf-1), and with caspase 9. This complex leads to activation of caspase 9 and ultimately to the activation of caspase 3. Once activated, caspase 3 activates the same downstream pathways as the external pathway described above, leading to the cleavage of proteins, cytoskeletal elements, DNA repair proteins, with subsequent DNA condensation and membrane blebbing that eventually lead to cell death and engulfment by macrophages (see Figure 3–13).

**RECEPTOR DESENSITIZATION AND REGULATION OF RECEPTORS**

Receptors are almost always subject to feedback regulation by their own signaling outputs. Continued stimulation of cells with agonists generally results in a state of desensitization (also referred to as adaptation, refractoriness, or downregulation) such that the effect that follows continued or subsequent
exposure to the same concentration of drug is diminished. This phenomenon, called *tachyphylaxis*, occurs rapidly and is important therapeutically; an example is attenuated response to the repeated use of β adrenergic receptor agonists as bronchodilators for the treatment of asthma (see Chapters 12 and 36).

Desensitization can result from temporary inaccessibility of the receptor to agonist or from fewer receptors being synthesized (e.g., downregulation of receptor number). Phosphorylation of GPCR receptors by specific GPCR kinases (GRKs) plays a key role in triggering rapid desensitization. Phosphorylation of agonist-occupied GPCRs by GRKs facilitates the binding of cytosolic proteins termed *arrestins* to the receptor, resulting in the uncoupling of G protein from the receptor. The β arrestins recruit proteins, such as PDE4, that limit cyclic AMP signaling, and clathrin and β 2-adaptin, that promote sequestration of receptor from the membrane (*internalization*), thereby providing a scaffold that permits additional signaling steps.

Conversely, *supersensitivity* to agonists also frequently follows chronic reduction of receptor stimulation. Such situations can result, e.g., following withdrawal from prolonged receptor blockade (e.g., the long-term administration of a adrenergic receptor antagonists such as metoprolol) or in the case where chronic denervation of a preganglionic fiber induces an increase in neurotransmitter release per pulse, indicating post-ganglionic neuronal supersensitivity.

**DISEASES RESULTING FROM RECEPTOR MALFUNCTION.** Alteration in receptors and their immediate signaling effectors can be the cause of disease. The loss of a receptor in a highly specialized signaling system may cause a phenotypic disorder (e.g., deficiency of the androgen receptor and testicular feminization syndrome; see Chapter 41). The expression of constitutively active, aberrant, or ectopic receptors, effectors, and coupling proteins potentially can lead to supersensitivity, subsensitivity, or other untoward responses.

**PHYSIOLOGICAL SYSTEMS INTEGRATE MULTIPLE SIGNALS**

Consider the vascular wall of an arteriole (Figure 3–14). Several cell types interact at this site, including vascular smooth muscle cells (SMCs), endothelial cells (ECs), platelets, and post-ganglionic sympathetic neurons. A variety of
physiological receptors and ligands are present, including ligands that cause SMCs to contract (angiotensin II [AngII], norepinephrine [NE]) and relax (nitric oxide [NO], B-type natriuretic peptide [BNP], and epinephrine), as well as ligands that alter SMC gene expression (platelet-derived growth factor [PDGF], AngII, NE, and eicosanoids).

Figure 3–14 Interaction of multiple signaling systems regulating vascular smooth muscle cells. See text for explanation of signaling and contractile pathways and abbreviations.

AngII has both acute and chronic effects on SMC. Interaction of AngII with AT$_1$ receptors (AT$_1$R) mobilizes stored Ca$^{2+}$ via G$_q$-PLC-IP$_3$-Ca$^{2+}$ pathway. The Ca$^{2+}$ binds and activates calmodulin and its target protein, myosin light-chain kinase (MLCK). The activation of MLCK results in the phosphorylation of myosin, leading to smooth muscle cell contraction. Activation of the sympathetic nervous system also regulates SMC tone through release of NE from post-ganglionic sympathetic neurons. NE binds $\alpha_1$ adrenergic receptors that also activate the G$_q$-PLC-IP$_3$-Ca$^{2+}$ pathway, resulting in SMC contraction, an effect that is additive to that of AngII.

The contraction of SMCs is opposed by mediators that promote relaxation, including NO, BNP, and catecholamines acting at $\beta_2$ receptors. NO is formed in ECs by eNOS when the G$_q$-PLC-IP$_3$-Ca$^{2+}$ pathway is activated, and by iNOS
when that isoform is induced. The NO formed in ECs diffuses into SMCs, and activates the soluble form of guanylyl cyclase (sGC), which catalyzes the formation of cyclic GMP, which leads to activation of PKG and phosphorylation of proteins in SMCs that reduce intracellular concentrations of Ca$^{2+}$ and thereby promote relaxation. Intracellular concentrations of cyclic GMP are also increased by activation of the transmembrane BNP receptor (BNP-R), whose guanylyl cyclase activity is increased when BNP binds.

As a consequence of the variety of pathways that affect arteriolar tone, a patient with hypertension may be treated with 1 or several drugs that alter signaling through these pathways. Drugs commonly used to treat hypertension include β$_1$ antagonists to reduce secretion of renin (the rate-limiting first step in AngII synthesis), a direct renin inhibitor (aliskiren) to block the rate-limiting step in AngII production, angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril) to reduce the concentrations of circulating AngII, AT$_1$ receptor blockers (e.g., losartan) to block AngII binding to AT$_1$Rs on SMCs, R$_1$ adrenergic blockers to block NE binding to SMCs, sodium nitroprusside to increase the quantities of NO produced, or a Ca$^{2+}$ channel blocker (e.g., nifedipine) to block Ca$^{2+}$ entry into SMCs. β$_1$ antagonists would also block the baroreceptor reflex increase in heart rate and blood pressure elicited by a drop in blood pressure induced by the therapy. ACE inhibitors also inhibit the degradation of a vasodilating peptide, bradykinin (see Chapter 26). Thus, the choices and mechanisms are complex, and the appropriate therapy in a given patient depends on many considerations, including the diagnosed causes of hypertension in the patient, possible side effects of the drug, efficacy in a given patient, and cost.
Pharmacology intersects with *toxicology* when the physiological response to a drug is an *adverse effect*. A *poison* is any substance, including any drug, that has the capacity to harm a living organism. *Poisoning* generally implies that damaging physiological effects result from exposure to pharmaceuticals, illicit drugs, or chemicals.

**DOSE-RESPONSE**

There is a graded dose-response relationship in an *individual* and a quantal dose-response relationship in the *population* (see Chapters 2 and 3). Graded doses of a drug given to an individual usually result in a greater magnitude of response as the dose increases. In a quantal dose-response relationship, the percentage of the population affected increases as the dose is raised; the relationship is quantal in that the effect is judged to be either present or absent in a given individual. This quantal dose-response phenomenon is used to determine the *median lethal dose* (*LD*₅₀) of drugs, as defined in Figure 4–1.
**Figure 4–1 Dose-response relationships.** The $LD_{50}$ of a compound is determined experimentally, usually by administration of the chemical to mice or rats (orally or intraperitoneally). The midpoint of the curve representing percent of population responding (response here is death) versus dose (log scale) represents the $LD_{50}$, or the dose of drug that is lethal in 50% of the population. The $LD_{50}$ values for both compounds are the same (~10 mg/kg); however, the slopes of the dose-response curves are quite different. Thus, at a dose equal to one-half the $LD_{50}$ (5 mg/kg), less than 5% of the animals exposed to compound B would die, but 30% of the animals given compound A would die.

One can also determine a quantal dose-response curve for the therapeutic effect of a drug to generate a median effective dose ($ED_{50}$), the concentration of drug at which 50% of the population will have the desired response, and a quantal dose-response curve for lethality by the same agent. These 2 curves can be used to generate a *therapeutic index* (TI), which quantifies the relative safety of a drug:

$$TI = \frac{LD_{50}}{ED_{50}}$$

Clearly, the higher the ratio, the safer the drug.

Values of TI vary widely, from 1-2 to >100. Drugs with a low TI must be administered with caution (e.g., cardiac glycoside digitalis and cancer chemotherapeutic agents). Agents with very high TI (e.g., penicillin) are extremely safe in the absence of a known allergic response in a given patient. Note that use of median doses fails to consider that the slopes of the dose-response curves for therapeutic and lethal (toxic) effects may differ (Figure 4–1). As an alternative the $ED_{99}$ for the therapeutic effect can be compared to the $LD_{1}$ for lethality (toxic effect), to yield a *margin of safety*.

$$Margin\ of\ Safety = \frac{LD_{1}}{ED_{99}}$$

These quantal dose-response relationships are typical sigmoidal dose-response curves. However, not all dose-response curves follow this shape. *U-shaped dose-response curves* can be observed for essential metals and vitamins (Figure 4–2). At low dose, adverse effects are observed since there is a deficiency of these nutrients to maintain homeostasis. As dose increases, homeostasis is achieved, and the bottom of the U-shaped dose-response curve is reached. As dose
increases to surpass the amount required to maintain homeostasis, overdose toxicity can ensue. Thus, adverse effects are seen at both low and high dose.

![Figure 4–2](image)

**Figure 4–2** *U-Shaped dose-response curve for essential metals and vitamins.* Vitamins and essential metals are essential for life and their lack can cause adverse responses (plotted on the vertical axis), as can their excess, giving rise to a U-shaped dose-dependence curve.

**PHARMACOKINETICS VERSUS TOXICOKINETICS**

Absorption, distribution, metabolism, and elimination (ADME; *see Chapters 2, 5, and 6*) may differ significantly after poisoning, and these differences can profoundly alter treatment decisions and prognosis. The pharmacokinetics of a drug under circumstances that produce toxicity or excessive exposure are referred to as *toxicokinetics*. Ingesting larger than therapeutic doses of a pharmaceutical may prolong its absorption, alter its protein binding and apparent volume of distribution, and change its metabolic fate. When confronted with a potential poisoning, 2 questions should be foremost in the clinician’s mind:

- *How long will an asymptomatic patient need to be monitored (drug absorption and dynamics)?*
- *How long will it take an intoxicated patient to get better (drug elimination and dynamics)?*
DRUG ABSORPTION. Aspirin poisoning is a leading cause of overdose morbidity and mortality as reported to U.S. poison control centers. In therapeutic dosing, aspirin reaches peak plasma concentrations in ~1 h. However, aspirin overdose may cause spasm of the pyloric valve, delaying entry of the drug into the small intestine. Aspirin, especially enteric-coated forms, may coalesce into bezoars, reducing the effective surface area for absorption. Peak plasma salicylate concentrations from aspirin overdose may not be reached for 4-35 h after ingestion.

DRUG ELIMINATION. After therapeutic dosing, valproic acid has an elimination $t_\frac{1}{2}$ of ~14 h. Valproic acid poisoning may lead to coma. In predicting the duration of coma, it is important to consider that, after overdose, first-order metabolic processes appear to become saturated and the apparent elimination $t_\frac{1}{2}$ may exceed 30-45 h. Table 4–1 lists some pharmaceuticals notorious for their predilection to have initial symptoms develop after a typical 4-6 h emergency medical observation period.

*Drugs co-ingested with agents having anticholinergic activity, manifest by diminished GI motility, may also exhibit delayed onset of action.

TYPES OF THERAPEUTIC DRUG TOXICITY
In therapeutics, a drug typically produces numerous effects, but usually only 1 is sought as the primary goal of treatment; most of the other effects are undesirable effects for that therapeutic indication (Figure 4–3). Side effects of drugs usually are bothersome but not deleterious. Other undesirable effects may be characterized as toxic effects.

**Figure 4–3** Spectrum of the effects of pharmaceuticals.

**DOSE-DEPENDENT REACTIONS.** Toxic effects of drugs may be classified as pharmacological, pathological, or genotoxic. Typically, the incidence and seriousness of the toxicity is proportionately related to the concentration of the drug in the body and to the duration of the exposure.

*Pharmacological Toxicity.* The CNS depression produced by barbiturates is largely predictable in a dose-dependent fashion. The progression of clinical effects goes from anxiolysis to sedation to somnolence to coma. Similarly, the degree of hypotension produced by nifedipine is related to the dose of the drug administered. Tardive dyskinesia (see Chapter 16), an extrapyramidal motor disorder associated with use of antipsychotic medications, seems to be dependent on duration of exposure. Pharmacological toxicity can also occur.
when the correct dose is given: there is phototoxicity associated with exposure to sunlight in patients treated with tetracyclines, sulfonamides, chlorpromazine, and nalidixic acid.

*Pathological Toxicity.* Acetaminophen is metabolized to nontoxic glucuronide and sulfate conjugates, and to a highly reactive metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI) via CYP isoforms. At therapeutic dose, NAPQI binds to nucleophilic glutathione; but, in overdose, glutathione depletion may lead to the pathological finding of hepatic necrosis (Figure 4–4).

![Pathways of acetaminophen metabolism and toxicity](image)

**Figure 4–4** Pathways of acetaminophen metabolism and toxicity. The toxic intermediate NAPQI is *N*-acetyl-*p*-benzoquinoneimine.

*Genotoxic Effects.* Ionizing radiation and many environmental chemicals are known to injure DNA, and may lead to mutagenic or carcinogenic toxicities. Many of the cancer chemotherapeutic agents (see Chapters 60-63) may be genotoxic (see Chapters 6 and 7).
ALLERGIC REACTIONS. An allergy is an adverse reaction, mediated by the immune system, that results from previous sensitization to a particular chemical or to 1 that is structurally similar. Allergic responses have been divided into 4 general categories based on the mechanism of immunological involvement.

TYPE I: ANAPHYLACTIC REACTIONS. Anaphylaxis is mediated by IgE antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils. If the Fab portion of the antibody molecule then binds an antigen, various mediators (e.g., histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the GI tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed immediate hypersensitivity reactions.

TYPE II: CYTOLYTIC REACTIONS. Type II allergies are mediated by both IgG and IgM antibodies and usually are attributed to their capacity to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include penicillin-induced hemolytic anemia, quinidine-induced thrombocytopenic purpura, and sulfonamide-induced granulocytopenia. These autoimmune reactions to drugs usually subside within several months after removal of the offending agent.

TYPE III: ARTHUS REACTIONS. Type III allergic reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen-antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called serum sickness occurs. The clinical symptoms of serum sickness include urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. Several drugs, including commonly used antibiotics, can induce serum sickness-like reactions. These reactions usually last 6-12 days and then subside after the offending agent is eliminated.

TYPE IV: DELAYED HYPERSENSITIVITY REACTIONS. These reactions
are mediated by sensitized T-lymphocytes and macrophages. When sensitized cells come in contact with antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity is the contact dermatitis caused by poison ivy.

**IDIOSYNCRATIC REACTIONS; PHARMACOGENETIC CONTRIBUTIONS.** *Idiosyncrasy* is an abnormal reactivity to a chemical that is peculiar to a given individual; the idiosyncratic response may be extreme sensitivity to low doses or extreme insensitivity to high doses of drugs.

Many interindividual differences in drug responses have a *pharmacogenetic basis* (see Chapter 7). Some black males (~10%) develop a serious hemolytic anemia when they receive primaquine as an antimalarial therapy, due to a genetic deficiency of erythrocyte glucose-6-phosphate dehydrogenase. Variability in the anticoagulant response to warfarin is due to polymorphisms in CYP2C9 and VKORC1 (vitamin K epoxide reductase complex 1) (see Figure 30–6 and Table 30–2).

**DRUG–DRUG INTERACTIONS.** Patients are commonly treated with more than 1 drug, may also be using over-the-counter (OTC) medications, vitamins, and other “natural” supplements, and may have unusual diets; all of these factors can contribute to interactions of drugs, a failure of therapy, and toxicity. Figure 4–5 summarizes the mechanisms and types of interactions.
INTERACTION OF ABSORPTION. A drug may cause either an increase or a decrease in the absorption of another drug from the intestinal lumen. Ranitidine, an antagonist of histamine H$_2$ receptors, raises gastrointestinal pH and may increase the absorption of basic drugs such as triazolam. Conversely, the bile-acid sequestrant cholestyramine leads to significantly reduced serum concentrations of propranolol.

INTERACTION OF PROTEIN BINDING. Many drugs, such as aspirin, barbiturates, phenytoin, sulfonamides, valproic acid, and warfarin, are highly protein-bound in the plasma, and it is the free (unbound) drug that produces the clinical effects. These drugs may have enhanced toxicity in overdose if protein binding sites become saturated, in physiological states that lead to hypoalbuminemia, or when displaced from plasma proteins by other drugs.

INTERACTION OF METABOLISM. A drug can frequently influence the metabolism of 1 or several other drugs (see Chapter 6), especially when hepatic CYPs are involved. Acetaminophen is partially transformed by CYP2E1 to the toxic metabolite NAPQI (see Figure 4–4). Intake of ethanol, a potent inducer of CYP2E1, may lead to increased susceptibility to acetaminophen poisoning after overdose.
INTERACTION OF RECEPTOR BINDING. Buprenorphine is an opioid with partial agonist and antagonist receptor activities, commonly used to treat opioid addiction. The drug binds opioid receptors with high affinity, and can prevent euphoria from concomitant use of narcotic drugs of abuse.

INTERACTION OF THERAPEUTIC ACTION. Aspirin is an inhibitor of platelet aggregation and heparin is an anticoagulant; given together they may increase risk for bleeding. Sulfonylureas cause hypoglycemia by stimulating pancreatic insulin release, whereas biguanide drugs (metformin) lead to decreased hepatic glucose production, and these drugs can be used together to control diabetic hyperglycemia.

Such drug interactions are additive when the combined effect of 2 drugs equals the sum of the effect of each agent given alone and synergistic when the combined effect exceeds the sum of the effects of each drug given alone. Potentiation describes the creation of a toxic effect from 1 drug due to the presence of another drug. Antagonism is the interference of 1 drug with the action of another. Functional or physiological antagonism occurs when 2 chemicals produce opposite effects on the same physiological function. Chemical antagonism, or inactivation, is a reaction between 2 chemicals to neutralize their effects, such as is seen with chelation therapy. Dispositional antagonism is the alteration of the disposition of a substance (its absorption, biotransformation, distribution, or excretion) so that less of the agent reaches the target organ or its persistence in the target organ is reduced. Receptor antagonism is the blockade of the effect of 1 drug by another drug that competes at the receptor site.

DESCRIPTIVE TOXICITY TESTING IN ANIMALS

Two main principles or assumptions underlie all descriptive toxicity tests performed in animals.

First, those effects of chemicals produced in laboratory animals, when properly qualified, apply to human toxicity. When calculated on the basis of dose per unit of body surface, toxic effects in human beings usually are encountered in the same range of concentrations as those in experimental animals. On the basis of body weight, human beings generally are more vulnerable than experimental animals.
Second, exposure of experimental animals to toxic agents in high doses is a necessary and valid method to discover possible hazards to human beings who are exposed to much lower doses. This principle is based on the quantal dose-response concept. As a matter of practicality, the number of animals used in experiments on toxic materials usually will be small compared with the size of human populations potentially at risk. For example, 0.01% incidence of a serious toxic effect (such as cancer) represents 25,000 people in a population of 250 million. Such an incidence is unacceptably high. Yet, detecting an incidence of 0.01% experimentally probably would require a minimum of 30,000 animals. To estimate risk at low dosage, large doses must be given to relatively small groups. *The validity of the necessary extrapolation is clearly a crucial question.*

The parent text, 12th edition, briefly discusses the rationale, design, size, and duration of such toxicity studies.

**SAFETY PHARMACOLOGY AND CLINICAL TRIALS**

Fewer than one-third of the drugs tested in clinical trials reach the marketplace. U.S. federal law and ethical considerations require that the study of new drugs in humans be conducted in accordance with stringent guidelines.

Once a drug is judged ready to be studied in humans, a *Notice of Claimed Investigational Exemption for a New Drug (IND)* must be filed with the FDA. The IND includes: (1) information on the composition and source of the drug; (2) chemical and manufacturing information; (3) all data from animal studies; (4) proposed clinical plans and protocols; (5) the names and credentials of physicians who will conduct the clinical trials; and (6) a compilation of the key data relevant to study the drug in man made available to investigators and their institutional review boards (IRBs).

It often requires 4-6 years of clinical testing to accumulate and analyze all required data. Testing in humans is begun after sufficient acute and subacute animal toxicity studies have been completed. Chronic safety testing in animals, including carcinogenicity studies, is usually done concurrently with clinical trials. In each of the 3 formal phases of clinical trials, volunteers or patients must be informed of the investigational status of the drug as well as the possible risks
and must be allowed to decline or to consent to participate and receive the drug. These regulations are based on the ethical principles set forth in the Declaration of Helsinki. In addition, an interdisciplinary IRB at the facility where the clinical drug trial will be conducted must review and approve the scientific and ethical plans for testing in humans.

The prescribed phases, time lines, and costs for developing a new drug are presented in Table 1–1 and Figure 1–1.

**EPIDEMIOLOGY OF ADVERSE DRUG RESPONSES AND PHARMACEUTICAL POISONING**

Poisoning can occur in many ways following both therapeutic and nontherapeutic drug or chemical exposures (Table 4–2). In U.S., it is estimated that ~2 million hospitalized patients have serious adverse drug reactions each year, and ~100,000 suffer fatal adverse drug reactions. Use of good principles of prescribing, as described in Appendix I and Table 4–6, can aid in avoiding such adverse outcomes.

### Table 4–2

**Potential Scenarios for Poisoning**

- Therapeutic drug toxicity
- Exploratory exposure by young children
- Environmental exposure
- Occupational exposure
- Recreational abuse
- Medication error
  - Prescribing error
  - Dispensing error
  - Administration error
- Purposeful administration for self-harm
- Purposeful administration to harm another

Some toxicities of pharmaceuticals can be predicted based on their known pharmacological mechanism; however, it is often not until the postmarketing period that the therapeutic toxicity profile of a drug becomes fully appreciated. The Adverse Event Reporting System of the FDA relies on 2 signals to detect
rarer adverse drug events. First, the FDA requires drug manufacturers to perform postmarketing surveillance of prescription drugs and nonprescription products. Second, the FDA operates a voluntary reporting system (MedWatch, at http://www.fda.gov/Safety/MedWatch/default.htm) available to both health professionals and consumers. Hospitals may also support adverse drug event committees to investigate potential adverse drug events. Unfortunately, any national dataset will significantly underestimate the morbidity and mortality attributable to adverse drug events because of underreporting and because it is difficult to estimate the denominator of total patient exposures for each event reported once a drug is available on the open market.

Therapeutic drug toxicity is only a subset of poisoning, as noted in Table 4–2. Misuse and abuse of both prescription and illicit drugs is a major public health problem. The incidence of unintentional, noniatrogenic poisoning is bimodal, primarily affecting exploratory young children, ages 1-5 years, and the elderly. Intentional overdose with pharmaceuticals is most common in adolescence and through adulthood. The top 5 drugs involved in drug-related deaths reported in 2005 are presented in Table 4–3. The substances most frequently involved in human exposures and fatalities are presented in Tables 4–4 and 4–5.

Table 4–4

Substances Most Frequently Involved in Human Poisoning
REDUCTION OF MEDICATION ERRORS. Over the past decade considerable attention has been given to the reduction of medication errors and adverse drug events. Medication errors can occur in any part of the medication prescribing or use process, whereas adverse drug events (ADEs) are injuries related to the use or nonuse of medications. It is believed that medication errors are 50-100 times more common than ADEs. The “5 Rights” of safe medication administration attempt to help practitioners avoid medication errors:

**Right drug, right patient, right dose, right route, right time.**

In practice, accomplishing a reduction in medication errors involves scrutiny of
the systems involved in prescribing, documenting, transcribing, dispensing, administering, and monitoring a therapy, as presented in Appendix I. Good medication use practices have mandatory and redundant checkpoints (Figure 4–6), such as having a pharmacist, a doctor, and a nurse all review and confirm that an ordered dose of a medication is appropriate for a patient prior to the drug’s administration. Several practical strategies have can help to reduce medication errors within healthcare settings (Table 4–6).

![Image of the “Swiss cheese” model of medication error]

**Figure 4–6** The “Swiss cheese” model of medication error. Several checkpoints typically exist to identify and prevent an adverse drug event, and that adverse event can only occur if holes in several systems align. **A.** One systematic error does not lead to an adverse event, because it is prevented by another check in the system. **B.** Several systematic errors align to allow an adverse event to occur. (Adapted from Reason J, *Br Med J*, 2000;320:768–770.)

**Long Term**

- Implement technology-based safeguards:
  - Computerized order entry
  - Computerized dose and allergy checking
  - Computerized medication tracking
  - Use of bar codes or electronic readers for medication preparation and administration

**POISONING PREVENTION IN THE HOME.** Table 4–2 demonstrates that there are several contexts into which poisoning prevention can be directed. Depression and suicidal ideation need to be identified and treated. Exposure to hazards in the home, outdoor, and work environments need to be reduced to reasonably achievable levels.

Poisoning prevention strategies may be categorized as being *passive*, requiring no behavior change on the part of the individual, or *active*, requiring sustained adaptation to be successful. Passive prevention strategies are the most effective (Table 4–7). The incidence of poisoning in children has decreased dramatically over the past 4 decades. This favorable trend is largely due to improved safety packaging of drugs, drain cleaners, turpentine, and other household chemicals; improved medical training and care; and increased public awareness of potential poisons.

Table 4–7

**Passive Poisoning Prevention: Strategies and Examples**
PRINCIPLES OF TREATMENT OF POISONING

When toxicity is expected or occurs, the priorities of poisoning treatment are to:

- Maintain vital physiological functions from impairment
- Keep the concentration of poison in tissues as low as possible by preventing absorption and enhancing elimination
- Combat the toxicological effects of the poison at the effector sites

INITIAL STABILIZATION OF THE POISONED PATIENT. The “ABC” mnemonic of emergency care applies to the treatment of acute poisoning (Table 4–8). In severe cases, endotracheal intubation, mechanical ventilation, pharmacological blood pressure support, and/or extracorporeal circulatory support may be necessary and appropriate.

| Reduce manufacture/sale of poisons |
| Withdrawal of phenformin from U.S. market |
| Decrease amount of poison in a consumer product |
| Limiting of pills in bottle of baby aspirin |
| Prevent access to poison |
| Use of child-resistant packaging |
| Change product formulation |
| Removing ethanol from mouthwash |

Table 4–8

ABCDE: Initial Approach for Acute Poisoning
IDENTIFICATION OF CLINICAL PATTERNS OF TOXICITY. A medical history may allow for the creation of a list of available medications or chemicals that might be implicated in a poisoning event. Often, an observation of physical symptoms and signs may be the only additional clues to a poisoning diagnosis. Groups of physical signs and symptoms associated with specific poisoning syndromes are known as toxidromes (Table 4–9).

Common Toxidromes

Table 4–9
The urine drug toxicology test is an immunoassay designed to detect common drugs of abuse such as amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, and opiates. Acute poisoning with these substances can usually be determined on clinical grounds, and the results of these assays are infrequently available fast enough to guide stabilization. Additionally, detection of drugs or their metabolites on a urine immunoassay does not mean that the detected drug is responsible for the currently observed poisoning illness. When ingestion of acetaminophen or aspirin cannot clearly be excluded via the exposure history, serum quantification of these drugs is recommended. An ECG may be useful at detecting heart blocks, Na⁺ channel blockade, or K⁺ channel blockade associated with specific medication classes (Table 4–10). Further laboratory analysis should be tailored to the individual poisoning circumstance.

Table 4–10

Differential Poisoning Diagnosis (Partial Listing) for Electrocardiographic Manifestations of Toxicity
DECONTAMINATION OF THE POISONED PATIENT. Poisoning exposures may be by inhalation, by dermal or mucosal absorption, by injection, or by ingestion. The first step in preventing absorption of poison is to stop any ongoing exposure. If necessary, eyes and skin should be washed copiously. GI decontamination prevents or reduces absorption of a substance after it has been ingested. The strategies for GI decontamination are gastric emptying, adsorption of poison, and catharsis. Minimal indications for considering GI decontamination include: (1) the poison must be potentially dangerous; (2) the poison must still be unabsorbed in the stomach or intestine, so it must be soon after ingestion; and (3) the procedure must be able to be performed safely and with proper technique. Gastric emptying is rarely recommended anymore, but the administration of activated charcoal and the performance of whole bowel irrigation remain therapeutic options. Gastric emptying reduces drug absorption by ~1/3 under optimal conditions.

Based upon review of existing evidence, the American Academy of Pediatrics no longer recommends syrup of ipecac as part of its childhood injury prevention program, and the American Academy of Clinical Toxicology dissuades routine use of gastric emptying in the poisoned patient.

ADSORPTION. Adsorption of a poison refers to the binding of a
poison to the surface of another substance so that the poison is less available for absorption into the body. Fuller’s earth has been suggested as an adsorbent for paraquat, Prussian blue binds thallium and cesium, and sodium polystyrene can adsorb lithium. The most common adsorbent used in the treatment of acute drug overdose is activated charcoal.

**ACTIVATED CHARCOAL.** Charcoal is created through controlled pyrolysis of organic matter, and is *activated* through steam or chemical treatment that increases its internal pore structure and adsorptive surface capacity. The surface of activated charcoal contains carbon moieties that are capable of binding poisons. The recommended dose is typically 0.5–2 g/kg of body weight, up to a maximum tolerated dose of ~75-100 g. As a rough estimate, 10 g of activated charcoal is expected to bind ~1 g of drug. Alcohols, corrosives, hydrocarbons, and metals are not well adsorbed by charcoal. Complications of activated charcoal therapy include vomiting, constipation, pulmonary aspiration, and death. Nasogastric administration of charcoal increases the incidence of vomiting, and may increase the risk for pulmonary aspiration. Charcoal should not be given to patients with suspected GI perforation, or to patients who may be candidates for endoscopy.

**WHOLE BOWEL IRRIGATION.** Whole bowel irrigation (WBI) involves the enteral administration of large amounts of a high molecular weight, iso-osmotic polyethylene glycol electrolyte solution with the goal of passing poison by the rectum before it can be absorbed. Potential candidates for WBI include: (1) “body-packers” with intestinal packets of illicit drugs; (2) patients with iron overdose; (3) patients who have ingested patch pharmaceuticals; and (4) patients with overdoses of sustained-release or bezoar-forming drugs. Polyethylene glycol electrolyte solution is typically administered at a rate of 25 to 40 mL/kg/h until the rectal effluent is clear and no more drug is being passed. To achieve these high administration rates, a nasogastric tube may be used. WBI is contraindicated in the presence of bowel obstruction or perforation, and may be complicated by abdominal distention or pulmonary aspiration.

**CATHARTICS.** The 2 most common categories of simple cathartics are the magnesium salts, such as magnesium citrate and magnesium sulfate, and the nondigestible carbohydrates, such as sorbitol. The use of simple cathartics has
been abandoned as a GI decontamination strategy.

**Gastric Lavage.** The procedure for gastric lavage involves passing an orogastric tube into the stomach with the patient in the left-lateral decubitus position with head lower than feet. After withdrawing stomach contents, 10 to 15 mL/kg (up to 250 mL) of saline lavage fluid is administered and withdrawn. This process continues until the lavage fluid returns clear. Complications of the procedure include mechanical trauma to the stomach or esophagus, pulmonary aspiration of stomach contents, and vagus nerve stimulation.

**Syrup of Ipecac.** The alkaloids cephaeline and emetine within syrup of ipecac act as emetics because of both a local irritant effect on the enteric tract and a central effect on the chemoreceptor trigger zone in the area postrema of the medulla. Ipecac is given orally at a dose of 15 mL for children up to 12 years, and 30 mL for older children and adults. Administration of ipecac is typically followed by a drink of water, and reliably produces emesis in 15-30 min. Contraindications for syrup of ipecac administration include existing or impending CNS depression, ingestion of a corrosive or hydrocarbon drug (due to the emergence of chemical pneumonia), or presence of a medical condition that might be exacerbated by vomiting.

**ENHANCING THE ELIMINATION OF POISONS.** Once absorbed, the deleterious toxicodynamic effects of some drugs may be reduced by methods that hasten their elimination from the body, as described below.

**MANIPULATING URINARY pH: URINARY ALKALINIZATION.** Drugs subject to renal clearance are excreted into the urine by glomerular filtration and active tubular secretion; nonionized compounds may be reabsorbed far more rapidly than ionized polar molecules (see Chapter 2). Weakly acidic drugs are susceptible to “ion-trapping” in the urine. Aspirin is a weak acid with a $pK_a = 3.0$. As the pH of the urine increases, more salicylate is in its ionized form at equilibrium, and more salicylic acid is diffused into the tubular lumen of the kidney. Urinary alkalization is also believed to speed clearance of phenobarbital, chlorpropamide, methotrexate, and chlorophenoxy herbicides. The American Academy of Clinical Toxicologists recommends urine alkalization as first-line treatment only for moderately severe salicylate
poisoning that does not meet criteria for hemodialysis. To achieve alkalinization of the urine, 100-150 mEq of sodium bicarbonate in 1 L of D5W is infused intravenously at twice the maintenance fluid requirements and then titrated to effect. Hypokalemia should be treated since it will hamper efforts to alkalinize the urine due to H⁺-K⁺ exchange in the kidney. Urine alkalinization is contraindicated in renal failure, or if fluid administration may worsen pulmonary edema or congestive heart failure. Acetazolamide is not used to alkalinize urine as it promotes acidemia.

**MULTIPLE-DOSE ACTIVATED CHARCOAL.** Activated charcoal adsorbs drug to its surface and promotes enteral elimination. Multiple doses of activated charcoal can speed elimination of absorbed drug by 2 mechanisms. Charcoal may interrupt enterohepatic circulation of hepatically metabolized drug excreted in the bile, and charcoal may create a diffusion gradient across the GI mucosa and promote movement of drug from the bloodstream onto the charcoal in the intestinal lumen. Activated charcoal may be administered in multiple doses, 12.5 g/h every 1, 2, or 4 h (smaller doses may be used for children). Charcoal enhances the clearance of many drugs of low molecular weight, small volume of distribution, and long elimination \( t_{1/2} \). Multiple-dose activated charcoal is believed to have the most potential utility in overdoses of carbamazepine, dapsone, phenobarbital, quinine, theophylline, and yellow oleander.

**EXTRACORPOREAL DRUG REMOVAL.** The ideal drug amenable to removal by hemodialysis has a low molecular weight, a low volume of distribution, high solubility in water, and minimal protein binding. Hemoperfusion involves passing blood through a cartridge containing adsorbent particles. The most common poisonings for which hemodialysis is sometimes used include salicylate, methanol, ethylene glycol, lithium, carbamazepine, and valproic acid.

**ANTIDOTAL THERAPIES.** Antidotal therapy involves antagonism or chemical inactivation of an absorbed poison. Among the most common specific antidotes used are N-acetyl-L-cysteine for acetaminophen poisoning, opioid antagonists for opioid overdose, and chelating agents for poisoning from certain metal ions. A list of antidotes used is presented in Table 4–11.

</table>

The pharmacodynamics of a poison can be altered by competition at a receptor, as in the antagonism provided by naloxone therapy in the setting of heroin overdose. A physiological antidote may use a different cellular mechanism to overcome the effects of a poison, as in the use of glucagon to circumvent a blocked β adrenergic receptor and increase cellular cyclic AMP in the setting of propranolol overdose. Antivenoms and chelating agents bind and directly inactivate poisons. The biotransformation of a drug can also be altered by an antidote; for example, fomepizole will inhibit alcohol dehydrogenase and stop the formation of toxic acid metabolites from ethylene glycol and methanol. Many drugs used in the supportive care of a poisoned patient (anticonvulsants,
vasoconstricting agents, etc.) may be considered nonspecific functional antidotes.

*The mainstay of therapy for poisoning is good support of the airway, breathing, circulation, and vital metabolic processes of the poisoned patient until the poison is eliminated from the body.*

**IMPORTANT RESOURCES FOR INFORMATION RELATED TO DRUG TOXICITY AND POISONING**

Additional information on poisoning from drugs and chemicals can be found in many dedicated books of toxicology. A popular computer database for information on toxic substances is POISINDEX (Micromedex, Inc., Denver, CO). The National Library of Medicine offers information on toxicology and environmental health ([http://sis.nlm.nih.gov/enviro.html](http://sis.nlm.nih.gov/enviro.html)), including a link to ToxNet ([http://toxnet.nlm.nih.gov/](http://toxnet.nlm.nih.gov/)). Regional poison control centers are a resource for valuable poisoning information and may be contacted within the U.S. through a national PoisonHelp hotline: 1-800-222-1222.
**chapter 5**

Membrane Transporters and Drug Response

Transporters are membrane proteins that are present in all organisms. These proteins control the influx of essential nutrients and ions and the efflux of cellular waste, environmental toxins, drugs, and other xenobiotics (**Figure 5–1**), consistent with their critical roles in cellular homeostasis, ~2000 genes in the human genome, ~7% of the total number of genes, code for transporters or transporter-related proteins. The functions of membrane transporters may be facilitated (equilibrative, not requiring energy) or active (requiring energy). In considering the transport of drugs, pharmacologists generally focus on transporters from 2 major superfamilies, ABC (ATP binding cassette) and SLC (solute carrier) transporters.

![Figure 5–1 Membrane transporters in pharmacokinetic pathways](image)

**Figure 5–1** Membrane transporters in pharmacokinetic pathways. Membrane transporters (T) play roles in pharmacokinetic pathways (drug absorption, distribution, metabolism, and excretion), thereby setting systemic drug levels. Drug levels often drive therapeutic and adverse drug effects.

Most ABC proteins are primary active transporters, which rely on
ATP hydrolysis to actively pump their substrates across membranes. Among the best recognized transporters in the ABC superfamily are P-glycoprotein (Pgp, encoded by \textit{ABCB1}, also termed \textit{MDR1}) and the cystic fibrosis transmembrane regulator (CFTR, encoded by \textit{ABCC7}). The \textit{SLC} superfamily includes genes that encode facilitated transporters and ion-coupled secondary active transporters. Forty-eight \textit{SLC} families with \(\sim\)315 transporters have been identified in the human genome. Many \textit{SLC} transporters serve as drug targets or in drug absorption and disposition. Widely recognized \textit{SLC} transporters include the serotonin transporter, SERT, and the dopamine transporter, DAT, both targets for antidepressant medications.

**MEMBRANE TRANSPORTERS IN THERAPEUTIC DRUG RESPONSES**

**PHARMACOKINETICS.** Transporters important in pharmacokinetics generally are located in intestinal, renal, and hepatic epithelia, where they function in the selective absorption and elimination of endogenous substances and xenobiotics, including drugs. Transporters work in concert with drug-metabolizing enzymes to eliminate drugs and their metabolites (\textit{Figure 5–2}). In addition, transporters in various cell types mediate tissue-specific drug distribution (drug targeting). Conversely, transporters also may serve as protective barriers to particular organs and cell types. For example, P-glycoprotein in the blood-brain barrier protects the central nervous system (CNS) from a variety of structurally diverse drugs through its efflux mechanisms.
**PHARMACODYNAMICS: TRANSPORTERS AS DRUG TARGETS.** Membrane transporters are the targets of many clinically used drugs. SERT (SLC6A4) is a target for a major class of antidepressant drugs, the selective serotonin reuptake inhibitors (SSRIs). Other neurotransmitter reuptake transporters serve as drug targets for the tricyclic antidepressants, various amphetamines (including amphetamine-like drugs used in the treatment of attention deficit disorder in children), and anticonvulsants.

These transporters also may be involved in the pathogenesis of neuropsychiatric disorders, including Alzheimer and Parkinson diseases. Transporters that are nonneuronal also may be potential drug targets, e.g., cholesterol transporters in cardiovascular disease, nucleoside transporters in cancers, glucose transporters in metabolic syndromes, and Na\(^+\)-H\(^+\) antiporters in hypertension.

**DRUG RESISTANCE.** Membrane transporters play critical roles in the development of resistance to anticancer drugs, antiviral agents, and anticonvulsants. *Decreased uptake of drugs*, such as folate antagonists, nucleoside analogs, and platinum complexes, is mediated...
by reduced expression of influx transporters required for these drugs to access the tumor. *Enhanced efflux of hydrophobic drugs* is one mechanism of antitumor resistance in cellular assays of resistance.

For example, P-glycoprotein is overexpressed in tumor cells after exposure to cytotoxic anticancer agents. P-glycoprotein pumps out the anticancer drugs, rendering cells resistant to their cytotoxic effects. The over-expression of multidrug resistance protein 4 (MRP4) is associated with resistance to antiviral nucleoside analogs.

**MEMBRANE TRANSPORTERS AND ADVERSE DRUG RESPONSES**

As controllers of import and export, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs. Thus, transporters play crucial roles in the cellular toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into 3 categories (*Figure 5–3*).
Figure 5–3 *Major mechanisms by which transporters mediate adverse drug responses*. Three cases are given. The *left panel* of each case provides a representation of the mechanism; the *right panel* shows the resulting effect on drug levels. *(Top panel)* Increase in the plasma concentrations of drug due to a decrease in the uptake and/or secretion in clearance organs (e.g., liver and kidney). *(Middle panel)* Increase in the concentration of drug in toxicological target organs due to the enhanced uptake or reduced efflux. *(Bottom panel)* Increase in the plasma concentration of an endogenous compound (e.g., a bile acid) due to a drug’s inhibiting the influx of the endogenous compound in its eliminating or target organ. The diagram also may represent an increase in the concentration of the endogenous compound in the target organ owing to drug-
inhibited efflux of the endogenous compound.

Transporters expressed in the liver and kidney, as well as metabolic enzymes, are key determinants of drug exposure in the circulating blood, thereby affecting exposure, and hence toxicity, in all organs (Figure 5–3, top panel). For example, after oral administration of an HMG-CoA reductase inhibitor (e.g., pravastatin), the efficient first-pass hepatic uptake of the drug by the organic anion-transporting polypeptide OATP1B1 maximizes the effects of such drugs on hepatic HMG-CoA reductase. Uptake by OATP1B1 also minimizes the escape of these drugs into the systemic circulation, where they can cause adverse responses such as skeletal muscle myopathy.

Transporters expressed in tissues that may be targets for drug toxicity (e.g., brain) or in barriers to such tissues (e.g., the blood-brain barrier [BBB]) can tightly control local drug concentrations and thus control the exposure of these tissues to the drug (Figure 5–3, middle panel). For example, endothelial cells in the BBB are linked by tight junctions, and some efflux transporters are expressed on the blood-facing (luminal) side, thereby restricting the penetration of compounds into the brain. The interactions of loperamide and quinidine are a good example of transporter control of drug exposure at this site. Loperamide is a peripheral opioid used in the treatment of diarrhea and is a substrate of P-glycoprotein. Inhibition of P-glycoprotein-mediated efflux in the BBB would cause an increase in the concentration of loperamide in the CNS and potentiate adverse effects. Indeed, coadministration of loperamide and the potent P-glycoprotein inhibitor quinidine results in significant respiratory depression, an adverse response to the loperamide.

The case of oseltamivir (the antiviral drug TAMIFLU) provides an example that dysfunction of an active barrier may cause a CNS effect. Oseltamivir and its active form, Ro64-0802, undergo active efflux across the BBB by P-glycoprotein, organic anion transporter 3 (OAT3), and multidrug resistance-associated protein 4 (MRP4). Decreased activities of these transporters at the BBB can enhance the CNS exposure to oseltamivir and Ro64-0802, contributing to an adverse effect on the CNS.

Drug-induced toxicity sometimes is caused by the concentrative tissue distribution mediated by influx transporters. For example, biguanides (e.g., metformin and phenformin), used for the treatment of type 2 diabetes mellitus,
can produce lactic acidosis, a lethal side effect. Biguanides are substrates of the organic cation transporter 1 (OCT1), which is highly expressed in the liver. OCT1-mediated hepatic uptake of biguanides plays an important role in lactic acidosis. The organic anion transporter 1 (OAT1) and organic cation transporters (OCT1 and OCT2) provide other examples of transporter-related toxicity. OAT1 is expressed mainly in the kidney and is responsible for the renal tubular secretion of anionic compounds. Substrates of OAT1, such as cephaloridine (a β-lactam antibiotic), and adefovir and cidofovir (antiviral drugs), reportedly cause nephrotoxicity. In vitro experiments suggest that cephaloridine, adefovir, and cidofovir are substrates of OAT1 and that OAT1-expressing cells are more susceptible to the toxicity of these drugs than control cells. Exogenous expression of OCT1 and OCT2 enhances the sensitivities of tumor cells to the cytotoxic effect of oxaliplatin for OCT1, and cisplatin and oxaliplatin for OCT2.

Drugs may modulate transporters for endogenous ligands and thereby exert adverse effects (Figure 5–3, bottom panel). For example, bile acids are taken up mainly by Na\(^+\)-taurocholate cotransporting polypeptide (NTCP) and excreted into the bile by the bile salt export pump (BSEP, ABCB11). Bilirubin is taken up by OATP1B1 and conjugated with glucuronic acid, and bilirubin glucuronide is excreted by the multidrug-resistance-associated protein (MRP2, ABCC2). Inhibition of these transporters by drugs may cause cholestasis or hyperbilirubinemia.

*Uptake and efflux transporters determine the plasma and tissue concentrations of endogenous compounds and xenobiotics, thereby influencing the systemic or site-specific toxicity of drugs.*

**BASIC MECHANISMS OF MEMBRANE TRANSPORT**

**TRANSPORTERS VERSUS CHANNELS.** Both channels and transporters facilitate the membrane permeation of inorganic ions and organic compounds. In general, channels have 2 primary states, open and closed, that are totally stochastic phenomena. Only in the open state do channels appear to act as pores for the selected ions. After opening, channels return to the closed state as a function of time. In contrast, a transporter forms an intermediate complex with the
substrate (solute), and subsequently a conformational change in the transporter induces translocation of the substrates to the other side of the membrane.

The turnover rate constants of typical channels are $10^6$ to $10^8$ s$^{-1}$; those of transporters are, at most, $10^1$ to $10^3$ s$^{-1}$. Because a particular transporter forms intermediate complexes with specific compounds (referred to as substrates), transporter-mediated membrane transport is characterized by saturability and inhibition by substrate analogs, as described in “Kinetics of Transport.”

The basic mechanisms involved in solute transport across biological membranes include passive diffusion, facilitated diffusion, and active transport. Active transport can be further subdivided into primary and secondary active transport. These mechanisms are depicted in Figure 5–4.

![Figure 5–4](image)

**Figure 5–4** Classification of membrane transport mechanisms. Red circles depict the substrate. Size of the circles is proportional to the concentration of the substrate. Arrows show the direction of flux. Black squares represent the ion that supplies the driving force for transport (size is proportional to the concentration of the ion). Blue ovals depict transport proteins.

**PASSIVE DIFFUSION.** Simple diffusion of a solute across the plasma
membrane consists of 3 processes: partition from the aqueous to the lipid phase, diffusion across the lipid bilayer, and repartition into the aqueous phase on the opposite side. Diffusion of any solute (including drugs) occurs down an electrochemical potential gradient of the solute.

**FACILITATED DIFFUSION.** Diffusion of ions and organic compounds across the plasma membrane may be facilitated by a membrane transporter. Facilitated diffusion is a form of transporter-mediated membrane transport that does not require energy input. Just as in passive diffusion, the transport of ionized and nonionized compounds across the plasma membrane occurs down their electrochemical potential gradient. Therefore, steady state will be achieved when the electrochemical potentials of the compound on both sides of the membrane become equal.

**ACTIVE TRANSPORT.** Active transport is the form of membrane transport that requires the input of energy. It is the transport of solutes against their electrochemical gradients, leading to the concentration of solutes on 1 side of the plasma membrane and the creation of potential energy in the electrochemical gradient formed. Active transport plays an important role in the uptake and efflux of drugs and other solutes. Depending on the driving force, active transport can be subdivided into primary and secondary active transport (see Figure 5–4).

*Primary Active Transport.* Membrane transport that directly couples with ATP hydrolysis is called primary active transport. ABC transporters are examples of primary active transporters. In mammalian cells, ABC transporters mediate the unidirectional efflux of solutes across biological membranes.

*Secondary Active Transport.* In secondary active transport, the transport across a biological membrane of 1 solute $S_1$ against its concentration gradient is energetically driven by the transport of another solute $S_2$ in accordance with its concentration gradient. For example, an inwardly directed $\text{Na}^+$ concentration gradient across the plasma membrane is created by $\text{Na}^+$, $\text{K}^+$-ATPase. Under these conditions, inward movement of $\text{Na}^+$ produces the energy to drive the movement of a substrate $S_1$ against its concentration gradient by a secondary active transporter, as in $\text{Na}^+$/Ca$^{2+}$ exchange. Depending on the transport direction of the solute, secondary active transporters are classified as either
symporters or antiporters. Symporters, also termed cotransporters, transport \( S_2 \) and \( S_1 \) in the same direction, whereas antiporters, also termed exchangers, move their substrates in opposite directions (see Figure 5–4).

**KINETICS OF TRANSPORT**

The flux of a substrate (rate of transport) across a biological membrane via transporter-mediated processes is characterized by saturability. The relationship between the flux \( v \) and substrate concentration \( C \) in a transporter-mediated process is given by the Michaelis-Menten equation:

\[
v = \frac{V_{\text{max}} C}{K_m + C}
\]  
(Equation 5–1)

where \( V_{\text{max}} \) is the maximum transport rate and is proportional to the density of transporters on the plasma membrane, and \( K_m \) is the Michaelis constant, which represents the substrate concentration at which the flux is half the \( V_{\text{max}} \) value. \( K_m \) is an approximation of the dissociation constant of the substrate from the intermediate complex.

The \( K_m \) and \( V_{\text{max}} \) values can be determined by examining the flux at different substrate concentrations. The Eadie-Hofstee plot provides a graphical method for determining the \( V_{\text{max}} \) and \( K_m \) values (Figure 5–5).

\[
\frac{v}{C} = \frac{V_{\text{max}}}{K_m} - \frac{C}{K_m}
\]  
(Equation 5–2)
Figure 5–5 *Eadie-Hofstee plot of transport data.* The black lines show the hyperbolic concentration-dependence curve ($v$ vs $C$, left panel) and the Eadie-Hofstee transformation of the transport data ($v/C$ vs $v$, right panel) for a simple transport system. The blue lines depict transport in the presence of a competitive inhibitor (surmountable inhibition; achieves same $V_{\text{max}}$). The red lines depict the system in the presence of a noncompetitive inhibitor that reduces the number of transporting sites by half but leaves the $K_m$ of the functional sites unchanged.

Involvement of multiple transporters with different $K_m$ values gives an Eadie-Hofstee plot that is curved. Algebraically, the Eadie-Hofstee plot of kinetic data is equivalent to the Scatchard plot of equilibrium binding data.

Transporter-mediated membrane transport of a substrate is also characterized by inhibition by other compounds. The manner of inhibition can be categorized as 1 of 3 types: *competitive, noncompetitive,* and *uncompetitive.* *Competitive* inhibition occurs when substrates and inhibitors share a common binding site on the transporter, resulting in an increase in the apparent $K_m$ value in the presence of inhibitor. The flux of a substrate in the presence of a competitive inhibitor is

$$v = \frac{V_{\text{max}} C}{K_m(1 + I/K_i) + C}$$

(Equation 5–3)

where $I$ is the concentration of inhibitor, and $K_i$ is the inhibition constant.
Noncompetitive inhibition assumes that the inhibitor has an allosteric effect on the transporter, does not inhibit the formation of an intermediate complex of substrate and transporter, but does inhibit the subsequent translocation process.

\[
v = \frac{V_{\text{max}}}{K_m + C} \cdot \frac{1}{1 + I/K_i} \cdot C \quad \text{(Equation 5–4)}
\]

Uncompetitive inhibition assumes that inhibitors can form a complex only with an intermediate complex of the substrate and transporter and inhibit subsequent translocation.

\[
v = \frac{V_{\text{max}}}{K_m/1 + I/K_i + C} \cdot \frac{1}{1 + I/K_i} \cdot C \quad \text{(Equation 5–5)}
\]

VECTORIAL TRANSPORT

Asymmetrical transport across a monolayer of polarized cells, such as the epithelial and endothelial cells of brain capillaries, is called vectorial transport (Figure 5–6). Vectorial transport is important for the absorption of nutrients and bile acids in the intestine. Vectorial transport plays a major role in hepatobiliary and urinary excretion of drugs from the blood to the lumen and in the intestinal absorption of drugs. In addition, efflux of drugs from the brain via brain endothelial cells and brain choroid plexus epithelial cells involves vectorial transport. The ABC transporters mediate only unidirectional efflux, whereas SLC transporters mediate either drug uptake or efflux. For lipophilic compounds that have sufficient membrane permeability, ABC transporters alone are able to achieve vectorial transport without the help of influx transporters. For relatively hydrophilic organic anions and cations, coordinated uptake and efflux transporters in the polarized plasma membranes are necessary to achieve the vectorial movement of solutes across an epithelium. Common substrates of coordinated transporters are transferred efficiently across the epithelial barrier.
Transepithelial or transendothelial flux of drugs requires distinct transporters at the 2 surfaces of the epithelial or endothelial barriers. These are depicted diagrammatically for transport across the small intestine (absorption), the kidney and liver (elimination), and the brain capillaries that comprise the blood-brain barrier.

In the liver, a number of transporters with different substrate specificities are localized on the sinusoidal membrane (facing blood). These transporters are involved in the uptake of bile acids, amphipathic organic anions, and hydrophilic organic cations into the hepatocytes. Similarly, ABC transporters on the canalicular membrane (facing bile) export such compounds into the bile. Multiple combinations of uptake (OATP1B1, OATP1B3, OATP2B1) and efflux transporters (MDR1, MRP2, and BCRP) are involved in the efficient transcellular transport of a wide variety of compounds in the liver by using a model cell system called “doubly transfected cells,” which express both uptake and efflux transporter on each side. In many cases, overlapping substrate specificities between the uptake transporters (OATP family) and efflux transporters (MRP family) make the vectorial transport of organic anions highly efficient. Similar transport systems also are present in the intestine, renal tubules, and endothelial cells of the brain capillaries (see Figure 5–6).

REGULATION OF TRANSPORTER EXPRESSION. Transporter expression can be regulated transcriptionally in response to drug treatment and pathophysiological conditions, resulting in induction or down-regulation of transporter mRNAs. Recent studies have described important roles of type II nuclear receptors, which form heterodimers with the 9-cis-retinoic acid receptor.
(RXR), in regulating drug-metabolizing enzymes and transporters (see Table 6–4 and Figure 6–8). Table 5–1 summarizes the effects of drug activation of type II nuclear receptors on expression of transporters.

DNA methylation is one mechanism underlying the epigenetic control of gene expression. Reportedly, the tissue-selective expression of transporters is achieved by DNA methylation (silencing in the transporter-negative tissues) as well as by transactivation in the transporter-positive tissues. Transporters subjected to epigenetic control include OAT3, URAT1, OCT2, Oatp1b2, Ntcp, and PEPT2 in the SLC families; and MDR1, BCRP, BSEP, and ABCG5/ABCG8.

TRANSPORTER STRUCTURE AND MECHANISM
Predictions of secondary structure of membrane transport proteins based on hydropathy analysis indicate that membrane transporters in the SLC and ABC superfamilies are multi-membrane-spanning proteins. ABC transporters have nucleotide-binding domains (NBDs) on the cytoplasmic side that may be thought of as the motor domains with conserved motifs (e.g., Walker-A motif, ABC signature motif) that participate in binding and hydrolysis of ATP. Crystal structures of ABC transporters show 2 NBDs in contact with each other. The ABC transport mechanism appears to involve binding of ATP to the NBDs, which triggers one conformation of the transporter; dissociation of the hydrolysis products of ATP results in a conformation open toward the opposite side of the membrane. In the case of drug extrusion, when ATP binds, the transporters open to the outside, releasing their substrates to the extracellular media; when the hydrolysis products dissociate, the transporter returns to the inward-facing conformation, permitting the binding of ATP and transportable substrate. Chapter 5 of the 12th edition of the parent text provides additional details.

TRANSPORTER SUPERFAMILIES IN THE HUMAN GENOME

SLC TRANSPORTERS. The solute carrier (SLC) superfamily includes 48 families and represents ~315 genes in the human genome, some of which are associated with certain genetic diseases (Table 5–2). Transporters in the SLC superfamily transport diverse ionic and nonionic endogenous compounds and xenobiotics. SLC superfamily transporters may be facilitated transporters or secondary active symporters or antiporters.

Table 5–2

The Human Solute Carrier Superfamily
ABC SUPERFAMILY. The 7 groups of ABC transporters are essential for many cellular processes, and mutations in at least 13 of the genes for ABC transporters cause or contribute to human genetic disorders (Table 5–3). In addition to conferring multidrug resistance, an important pharmacological aspect of these transporters is xenobiotic export from healthy tissues. In particular, MDR1/ABCB1, MRP2/ABCC2, and BCRP/ABCG2 have been shown to be involved in overall drug disposition.

The ABC superfamily includes 49 genes, each containing 1 or 2 conserved ABC regions. The ABC region is a core catalytic domain of ATP hydrolysis and contains Walker A and B sequences and an intervening ABC transporter-specific signature C sequence. The ABC regions of these proteins bind and hydrolyze ATP, and the proteins use the energy for uphill transport of their substrates across the membrane. Although some ABC superfamily transporters contain only a single ABC motif, they form homodimers (BCRP/ABCG2) or heterodimers (ABCG5 and ABCG8) that exhibit a transport function. ABC transporters (e.g., MsbA) in prokaryotes are involved in the import of essential compounds that cannot be obtained by passive diffusion (sugars, vitamins, metals, etc.). Most ABC genes in eukaryotes transport compounds from the cytoplasm to the outside or into an intracellular compartment (endoplasmic reticulum, mitochondria, peroxisomes).

PROPERTIES OF ABC TRANSPORTERS RELATED TO
DRUG ACTION

The tissue distribution of drug-related ABC transporters in humans is summarized in Table 5–4 together with information about typical substrates.

*indicates substrates and cytotoxic drugs with increased resistance (cytotoxicity with increased resistance is usually caused by the decreased accumulation of the drug). Although MDR3 (ABCB4), BSEP (ABCB11), ABCG5 and ABCG8 are not directly involved in drug disposition, their inhibition will lead to unfavorable side effects.
TRANSPORTERS. MDR1 (ABCB1), MRP2 (ABCC2), and BCRP (ABCG2) are all expressed in the apical side of the intestinal epithelia, where they serve to pump out xenobiotics, including many orally administered drugs. MRP3 (ABCC3) is expressed in the basal side of the epithelial cells.

Key to the vectorial excretion of drugs into urine or bile, ABC transporters are expressed in the polarized tissues of kidney and liver: MDR1, MRP2, and MRP4 (ABCC4) on the brush-border membrane of renal epithelia; MDR1, MRP2, and BCRP on the bile canalicular membrane of hepatocytes; and MRP3 and MRP4 on the sinusoidal membrane of hepatocytes. Some ABC transporters are expressed specifically on the blood side of the endothelial or epithelial cells that form barriers to the free entrance of toxic compounds into tissues: the BBB (MDR1 and MRP4 on the luminal side of brain capillary endothelial cells), the blood-cerebrospinal fluid (CSF) barrier (MRP1 and MRP4 on the basolateral blood side of choroid plexus epithelia), the blood-testis barrier (MRP1 on the basolateral membrane of mouse Sertoli cells and MDR1 in several types of human testicular cells), and the blood-placenta barrier (MDR1, MRP2, and BCRP on the luminal maternal side and MRP1 on the antiluminal fetal side of placental trophoblasts).

MRP/ABCC FAMILY. The substrates of transporters in the MRP/ABCC family are mostly organic anions. Both MRP1 and MRP2 accept glutathione and glucuronide conjugates, sulfated conjugates of bile salts, and nonconjugated organic anions of an amphipathic nature (at least 1 negative charge and some degree of hydrophobicity). They also transport neutral or cationic anticancer drugs, such as vinca alkaloids and anthracyclines, possibly by means of a cotransport or symport mechanism with reduced glutathione. MRP3 also has a substrate specificity that is similar to that of MRP2 but with a lower transport affinity for glutathione conjugates compared with MRP1 and MRP2. MRP3 is expressed on the sinusoidal side of hepatocytes and is induced under cholestatic conditions. MRP3 functions to return toxic bile salts and bilirubin glucuronides into the blood circulation. MRP4 accepts negatively charged molecules, including cytotoxic compounds (e.g., 6-mercaptopurine and methotrexate), cyclic nucleotides, antiviral drugs (e.g., adefovir and tenofovir), diuretics (e.g., furosemide and trichlormethiazide), and cephalosporins (e.g., ceftizoxime and cefazolin). Glutathione enables MRP4 to accept taurocholate and leukotriene B4.
MRP5 has a narrower substrate specificity and accepts nucleotide analog and clinically important anti–human immunodeficiency virus (HIV) drugs. No substrates have been identified that explain the mechanism of the MRP6-associated disease, pseudoxanthoma.

BCRP/ABCG2. BCRP accepts both neutral and negatively charged molecules, including cytotoxic compounds (e.g., topotecan, flavopiridol, and methotrexate), sulfated conjugates of therapeutic drugs and hormones (e.g., estrogen sulfate), antibiotics (e.g., nitrofurantoin and fluoroquinolones), statins (e.g., pitavastatin and rosvastatin), and toxic compounds found in normal food [phytoestrogens, 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) and pheophorbide A, a chlorophyll catabolite].

ABC TRANSPORTERS IN DRUG ABSORPTION AND ELIMINATION. With respect to clinical medicine, MDR1 is the most important ABC transporter yet identified. The systemic exposure to orally administered digoxin is decreased by coadministration of rifampin (an MDR1 inducer) and is negatively correlated with the MDR1 protein expression in the human intestine. MDR1 is also expressed on the brush-border membrane of renal epithelia, and its function can be monitored using digoxin (>70% excreted in the urine). MDR1 inhibitors (e.g., quinidine, verapamil, valspodar, spironolactone, clarithromycin, and ritonavir) all markedly reduce renal excretion of digoxin. Drugs with narrow therapeutic windows (e.g., digoxin, cyclosporine, tacrolimus) should be used with great care if MDR1-based drug-drug interactions are likely.

In the intestine, MRP3 can mediate the intestinal absorption in conjunction with uptake transporters. MRP3 mediates sinusoidal efflux in the liver, decreasing the efficacy of the biliary excretion from the blood, and excretion of intracellularly formed metabolites, particularly, glucuronide conjugates. Thus, dysfunction of MRP3 results in a shortening of the elimination $t_{1/2}$. MRP4 substrates also can be transported by OAT1 and OAT3 on the basolateral membrane of the epithelial cells in the kidney. The rate-limiting process in renal tubular secretion is likely the uptake process at the basolateral surface. Dysfunction of MRP4 enhances the renal concentration, but has limited impact on the blood concentration.

GENETIC VARIATION IN MEMBRANE TRANSPORTERS: IMPLICATIONS FOR CLINICAL DRUG RESPONSE
There are inherited defects in SLC transporters (see Table 5–2) and ABC transporters (see Table 5–3). Polymorphisms in membrane transporters play a role in drug response and are yielding new insights in pharmacogenetics (see Chapter 7).

Clinical studies have focused on a limited number of transporters, relating genetic variation in membrane transporters to drug disposition and response. For example, 2 common single-nucleotide polymorphisms (SNPs) in \textit{SLCO1B1} (OATP1B1) have been associated with elevated plasma levels of pravastatin, a widely used drug for the treatment of hypercholesterolemia. Recent studies using genome-wide association methods have determined that genetic variants in \textit{SLCO1B1} (OATP1B1) predispose patients to risk for muscle toxicity associated with use of simvastatin. Other studies indicate that genetic variants in transporters in the SLC22A family associate with variation in renal clearance and response to various drugs including the antidiabetic drug, metformin.

**TRANSPORTERS INVOLVED IN PHARMACOKINETICS**

Drug transporters play a prominent role in pharmacokinetics (see Figure 5–1 and Table 5–4). Transporters in the liver and kidney have important roles in removal of drugs from the blood and hence in metabolism and excretion.

**HEPATIC TRANSPORTERS**

Hepatic uptake of organic anions (e.g., drugs, leukotrienes, and bilirubin), cations, and bile salts is mediated by SLC-type transporters in the basolateral (sinusoidal) membrane of hepatocytes: OATPs (SLCO) and OATs (SLC22), OCTs (SLC22), and NTCP (SLC10A1), respectively. These transporters mediate uptake by either facilitated or secondary active mechanisms.

ABC transporters such as MRP2, MDR1, BCRP, BSEP, and MDR2 in the bile canalicular membrane of hepatocytes mediate the efflux (excretion) of drugs and their metabolites, bile salts, and phospholipids against a steep concentration gradient from liver to bile.
This primary active transport is driven by ATP hydrolysis.

Vectorial transport of drugs from the circulating blood to the bile using an uptake transporter (OATP family) and an efflux transporter (MRP2) is important for determining drug exposure in the circulating blood and liver. Moreover, there are many other uptake and efflux transporters in the liver (Figures 5–7 and 5–8).

![Diagram](image)

**Figure 5–7** Hepatic uptake, backflux into blood, metabolism, and efflux into bile. The red circles represent parent drugs; the green triangles represent drug metabolites. PS, permeability surface product; CL_{met}, metabolic clearance; CL_{int}, intrinsic clearance.
Figure 5–8 *Transporters in the hepatocyte that function in the uptake and efflux of drugs across the sinusoidal membrane and efflux of drugs into the bile across the canalicular membrane.* See text for details of the transporters pictured.

The following examples illustrate the importance of vectorial transport in determining drug exposure in the circulating blood and liver and the role of transporters in drug-drug interactions.

**HMG-CoA REDUCTASE INHIBITORS.** Statins are cholesterol-lowering agents that reversibly inhibit HMG-CoA reductase, which catalyzes a rate-limiting step in cholesterol biosynthesis (see Chapter 31). Most of the statins in the acid form are substrates of uptake transporters, so they are taken up efficiently by the liver and undergo enterohepatic circulation (see Figures 5–5 and 5–8). In this process, hepatic uptake transporters such as OATP1B1 and efflux transporters such as MRP2 act cooperatively to produce vectorial trans-cellular transport of bisubstrates in the liver. The efficient first-pass hepatic uptake of these statins by OATP1B1 helps them to exert their pharmacological effect and also minimizes the systemic drug distribution, thereby minimizing adverse effects in smooth muscle. Recent studies indicate that the genetic polymorphism of OATP1B1 also affects the function of this transporter.
**GEMFIBROZIL.** The cholesterol-lowering agent gemfibrozil, a PPARα activator, can enhance toxicity (myopathy) to several statins by a mechanism that involves transport. Gemfibrozil inhibits the uptake of the active hydroxy forms of statins into hepatocytes by OATP1B1, resulting in an increase in the plasma concentration of the statin.

**IRINOTECAN (CPT-11).** Irinotecan hydrochloride (CPT-11) is a potent anticancer drug, but late-onset gastrointestinal toxic effects, such as severe diarrhea, make it difficult to use CPT-11 safely. After intravenous administration, CPT-11 is converted to SN-38, an active metabolite, by carboxylesterase. SN-38 is subsequently conjugated with glucuronic acid in the liver. SN-38 and SN-38 glucuronide are then excreted into the bile by MRP2. The inhibition of MRP2-mediated biliary excretion of SN-38 and its glucuronide by coadministration of probenecid reduces the drug-induced diarrhea, at least in rats. For additional details, see Figures 6–5 and 6–6; see also Figure 6–7 in the 12th edition of the parent text.

**BOSENTAN.** Bosentan is an endothelin antagonist used to treat pulmonary arterial hypertension. It is taken up in the liver by OATP1B1 and OATP1B3, and subsequently metabolized by CYP2C9 and CYP3A4. Transporter-mediated hepatic uptake can be a determinant of elimination of bosentan, and the inhibition of hepatic uptake by cyclosporin A, rifampicin, and sildenafil can affect its pharmacokinetics.

The parent text contains additional examples of the contribution to clinical drug use of vectorial transport and its genetic variability.

**RENAL TRANSPORTERS**

**ORGANIC CATION TRANSPORT.** Structurally diverse organic cations are secreted in the proximal tubule. A primary function of organic cation secretion is ridding the body of xenobiotics, including many positively charged drugs and their metabolites (e.g., cimetidine, ranitidine, metformin, procainamide, and N-acetylprocainamide) and toxins from the environment (e.g., nicotine). Organic cations that are secreted by the kidney may be either hydrophobic or hydrophilic. Hydrophilic organic drug cations generally have molecular weights <
400 daltons; a current model for their secretion in the proximal tubule of the nephron is shown in Figure 5–9, involving the transporters described below.

![Organic cation secretory transporters in the proximal tubule](image)

**Figure 5–9 Organic cation secretory transporters in the proximal tubule.** OC⁺, organic cation. See text for details of the transporters pictured.

For the transepithelial flux of a compound (e.g., secretion), the compound must traverse 2 membranes sequentially, the basolateral membrane facing the blood side and the apical membrane facing the tubular lumen. Organic cations appear to cross the basolateral membrane in human proximal tubule by 2 distinct transporters in the SLC family 22 (SCL22): OCT2 (SLC22A2) and OCT3 (SLC22A3). Organic cations are transported across this membrane down an electrochemical gradient.

Transport of organic cations from cell to tubular lumen across the apical membrane occurs through an electroneutral proton–organic cation exchange. The recent discovery of a new transporter family, SLC47A, *multidrug and toxin extrusion* family (MATEs), has provided the molecular identities of the previously characterized electroneutral proton–organic cation antiport mechanism. Transporters in the MATE family, assigned to the apical membrane
of the proximal tubule, appear to play a key role in moving hydrophilic organic cations from tubule cell to lumen. In addition, novel organic cation transporters (OCTNs), located on the apical membrane, appear to contribute to organic cation flux across the proximal tubule. In humans, these include OCTN1 (SLC22A4) and OCTN2 (SLC22A5). These bifunctional transporters are involved not only in organic cation secretion but also in carnitine reabsorption. In the reuptake mode, the transporters function as Na\(^{+}\) cotransporters, relying on the inwardly driven Na\(^{+}\) gradient created by Na\(^{+}\), K\(^{+}\)-ATPase to move carnitine from tubular lumen to cell. In the secretory mode, the transporters appear to function as proton–organic cation exchangers. That is, protons move from tubular lumen to cell interior in exchange for organic cations, which move from cytosol to tubular lumen. The inwardly directed proton gradient (from tubular lumen to cytosol) is maintained by transporters in the SLC9 family, which are Na\(^{+}/H^{+}\) exchangers (NHEs, antiporters). Of the 2 steps involved in secretory transport, transport across the luminal membrane appears to be rate-limiting.

**OCT2 (SLC22A2).** Human, mouse, and rat orthologs of OCT2 are expressed in abundance in human kidney and to some extent in neuronal tissue such as choroid plexus. In the kidney, OCT2 is localized to the proximal tubule and to distal tubules and collecting ducts. In the proximal tubule, OCT2 is restricted to the basolateral membrane. OCT2-mediated transport of model organic cations MPP\(^{+}\) and TEA is electrogenic, and both OCT2 and OCT1 can support organic cation–organic cation exchange. OCT2 generally accepts a wide array of monovalent organic cations with molecular weights < 400 daltons. OCT2 is also present in neuronal tissues; however, monoamine neurotransmitters have low affinities for OCT2.

**OCT3 (SLC22A3).** OCT3 is located in tandem with OCT1 and OCT2 on chromosome 6. Tissue distribution studies suggest that human OCT3 is expressed in liver, kidney, intestine, and placenta, although it appears to be expressed in considerably less abundance than OCT2 in the kidney. Like OCT1 and OCT2, OCT3 appears to support electrogenic potential-sensitive organic cation transport. OCT3 may play only a limited role in renal drug elimination.

**OCTN1 (SLC22A4).** OCTN1 seems to operate as an organic cation–proton exchanger. OCTN1-mediated influx of model organic cations is enhanced at alkaline pH, whereas efflux is increased by an inwardly directed proton gradient. OCTN1 contains a nucleotide-binding sequence motif, and transport of its
substrates appears to be stimulated by cellular ATP. OCTN1 also can function as an organic cation–organic cation exchanger. OCTN1 functions as a bidirectional pH- and ATP-dependent transporter at the apical membrane in renal tubular epithelial cells.

**OCTN2 (SLC22A5).** OCTN2 is a bifunctional transporter, it functions as both a Na\(^+\)-dependent carnitine transporter and a Na\(^+\)-independent organic cation transporter. OCTN2 transport of organic cations is sensitive to pH, suggesting that OCTN2 may function as an organic cation exchanger. The transport of L-carnitine by OCTN2 is a Na\(^+\)-dependent electrogenic process, and mutations in OCTN2 appear to be the cause of primary systemic carnitine deficiency.

**MATE1 AND MATE2-K (SLC47A1 AND SLC47A2).** Multidrug and toxin extrusion family members MATE1 and MATE2-K interact with structurally diverse hydrophilic organic cations including the antidiabetic drug metformin, the H\(_2\) antagonist cimetidine, and the anticancer drug, topotecan. In addition to cationic compounds, the transporters also recognize some anions, including the antiviral agents acyclovir and ganciclovir. The zwitterions cephalexin and cephradine are specific substrates of MATE1. The herbicide paraquat, a bis-quaternary ammonium compound, which is nephrotoxic in humans, is a potent substrate of MATE1. Both MATE1 and MATE2-K have been localized to the apical membrane of the proximal tubule. MATE1, but not MATE2-K, is also expressed on the canalicular membrane of the hepatocyte. These transporters appear to be the long-searched-for organic cation–proton antiporters on the apical membrane of the proximal tubule, that is, an oppositely directed proton gradient can drive the movement of organic cations via MATE1 or MATE2-K. The antibiotics, levofloxacin and ciprofloxacin, though potent inhibitors, are not translocated by either MATE1 or MATE2-K.

**Polymorphisms of OCTs.** OCT1 exhibits the greatest number of amino acid polymorphisms, followed by OCT2 and then OCT3. Recent studies suggest that genetic variants of OCT1 and OCT2 are associated with alterations in the renal elimination and response to the anti-diabetic drug, metformin.

**ORGANIC ANION TRANSPORT.** The primary function of organic anion secretion appears to be the removal from the body of xenobiotics, including many weakly acidic drugs (e.g., pravastatin,
captopril, p-aminohippurate [PAH], and penicillins) and toxins (e.g., ochratoxin). Organic anion transporters move both hydrophobic and hydrophilic anions but also may interact with cations and neutral compounds. A current model for the transepithelial flux of organic anions in the proximal tubule is shown in Figure 5–10.

**Figure 5–10 Organic anion secretory transporters in the proximal tubule.** Two primary transporters on the basolateral membrane mediate the flux of organic anions from interstitial fluid to tubule cell: OAT1 (SLC22A6) and OAT3 (SLC22A8). Hydrophilic organic anions are transported across the basolateral membrane against an electrochemical gradient in exchange with intracellular α-ketoglutarate, which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α-ketoglutarate is maintained at least in part by a basolateral Na\(^+\)-dicarboxylate uptake transporter (NaDC3). The Na\(^+\) gradient that drives NaDC3 is maintained by Na\(^+\), K\(^+\)-ATPase. OA, organic anion; α-KG, α-ketoglutarate.

**OAT1 (SLC22A6).** Mammalian isoforms of OAT1 are expressed primarily in the kidney, with some expression in brain and skeletal muscle. OAT1 generally transports small-molecular-weight organic anions that may be endogenous (e.g.,
PGE$_2$ and urate) or ingested drugs and toxins.

**OAT2 (SLC22A7).** OAT2 is present in both kidney and liver. In the kidney, the transporter is localized to the basolateral membrane of the proximal tubule, and appears to function as a transporter for nucleotides, particularly guanine nucleotides such as cyclic GMP.

**OAT3 (SLC22A8).** OAT3 transports a wide variety of organic anions, including model compounds, PAH and estrone sulfate, as well as many drug products (e.g., pravastatin, cimetidine, 6-mercaptopurine, and methotrexate).

**OAT4 (SLC22A9).** In humans, OAT4 is expressed in placenta and kidney (on the luminal membrane of the proximal tubule). Organic anion transport by OAT4 can be stimulated by transgradients of $\alpha$-ketoglutarate, suggesting that OAT4 may be involved in the reabsorption of organic anions from tubular lumen into cell.

**OTHER ANION TRANSPORTERS.** URAT1 (SLC22A12) is a kidney-specific transporter confined to the apical membrane of the proximal tubule. URAT1 is primarily responsible for urate reabsorption, mediating electroneutral urate transport that can be trans-stimulated by Cl$^-$ gradients. NPT1 (SLC17A1) is expressed on the luminal membrane of the proximal tubule as well as in the brain. NPT1 transports PAH, probenecid, and penicillin G. It appears to be part of the system involved in organic anion efflux from tubule cell to lumen.

MRP2 (ABCC2) is considered to be the primary transporter involved in efflux of many drug conjugates such as glutathione conjugates across the canalicular membrane of the hepatocyte. However, MRP2 is also found on the apical membrane of the proximal tubule, where it is thought to play a role in the efflux of organic anions into the tubular lumen. In general, MRP2 transports larger, bulkier compounds than do most of the organic anion transporters in the SLC22 family. MRP4 (ABCC4), localized on the apical membrane of the proximal tubule, transports a wide array of conjugated anions, including glucuronide and glutathione conjugates. MRP4 appears to interact with drugs, including methotrexate, cyclic nucleotide analogs, and antiviral nucleoside analogs.

**Polymorphisms of OATs.** Polymorphisms in OAT1 and OAT3 have been identified in ethnically diverse human populations.
TRANSPORTERS AND PHARMACODYNAMICS: DRUG ACTION IN THE BRAIN

Neurotransmitters are packaged in vesicles in presynaptic neurons, released in the synapse by fusion of the vesicles with the plasma membrane, and, excepting acetylcholine, are then taken back into the presynaptic neurons or postsynaptic cells (see Chapter 8). Transporters involved in the neuronal reuptake of the neurotransmitters and the regulation of their levels in the synaptic cleft belong to 2 major superfamilies, SLC1 and SLC6. Transporters in both families play roles in reuptake of γ-aminobutyric acid (GABA), glutamate, and the monoamine neurotransmitters norepinephrine (NE), serotonin (5HT), and dopamine (DA). These transporters may serve as pharmacologic targets for neuropsychiatric drugs. SLC6 family members localized in the brain and involved in the reuptake of neurotransmitters into presynaptic neurons include the NE transporter (NET, SLC6A2), the DA transporter (DAT, SLC6A3), the serotonin transporter (SERT, SLC6A4), and several GABA reuptake transporters (GAT1, GAT2, and GAT3).

SLC6 family members depend on the Na\(^+\) gradient to actively transport their substrates into cells. Cl\(^-\) is also required, although to a variable extent depending on the family member. Through reuptake mechanisms, the neurotransmitter transporters in the SLC6A family regulate the concentrations and dwell times of neurotransmitters in the synaptic cleft; the extent of transmitter uptake also influences subsequent vesicular storage of transmitters. Many of these transporters are present in other tissues (e.g., kidney and platelets) and may serve other roles. Further, the transporters can function in the reverse direction. That is, the transporters can export neurotransmitters in a Na\(^+\)-independent fashion.

SLC6A1 (GAT1), SLC6A11 (GAT3), AND SLC6A13 (GAT2). GAT1 is the most important GABA transporter in the brain, expressed in GABAergic neurons and found largely on presynaptic neurons. GAT1 is found in abundance in the neocortex, cerebellum, basal ganglia, brainstem, spinal cord, retina, and olfactory bulb. GAT3 is found only in the brain, largely in glial cells. GAT2 is found in peripheral tissues, including the kidney and liver, and within the CNS in
the choroid plexus and meninges. Physiologically, GAT1 appears to be responsible for regulating the interaction of GABA at receptors. The presence of GAT2 in the choroid plexus and its absence in presynaptic neurons suggest that this transporter may play a primary role in maintaining the homeostasis of GABA in the CSF. GAT1 is the target of the antiepileptic drug tiagabine, which presumably acts to increase GABA levels in the synaptic cleft of GABAergic neurons by inhibiting the reuptake of GABA. GAT3 is the target for the nipecotic acid derivatives that are anticonvulsants.

**SLC6A2 (NET).** NET is found in central and peripheral nervous tissues as well as in adrenal chromaffin tissue. NET colocalizes with neuronal markers, consistent with a role in reuptake of monoamine neurotransmitters. The transporter functions in the Na+-dependent reuptake of NE and DA. NET limits the synaptic dwell time of NE and terminate its actions, salvaging NE for subsequent repackaging. NET participates in the regulation of many neurological functions, including memory and mood. NET serves as a drug target for the antidepressant desipramine, other tricyclic antidepressants, and cocaine. Orthostatic intolerance, a rare familial disorder characterized by an abnormal blood pressure and heart rate response to changes in posture, has been associated with a mutation in NET.

**SLC6A3 (DAT).** DAT is located primarily in the brain in dopaminergic neurons. The primary function of DAT is the reuptake of DA, terminating its actions. Although present on presynaptic neurons at the neurosynaptic junction, DAT is also present in abundance along the neurons, away from the synaptic cleft, suggesting that DAT may play a role in clearance of excess DA in the vicinity of neurons. Physiologically, DAT is involved in functions attributed to the dopaminergic system, including mood, behavior, reward, and cognition. Drugs that interact with DAT include cocaine and its analogs, amphetamines, and the neurotoxin MPTP.

**SLC6A4 (SERT).** SERT plays a role in the reuptake and clearance of serotonin in the brain. Like the other SLC6A family members, SERT transports its substrates in a Na+-dependent fashion and is dependent on Cl− and possibly on the countertransport of K+. Substrates of SERT include 5HT, various tryptamine derivatives, and neurotoxins such as 3,4-methylenedioxyamphetamine (MDMA; ecstasy) and fenfluramine. SERT is the specific target of the selective serotonin reuptake inhibitor antidepressants (e.g., fluoxetine and paroxetine) and
1 of several targets of tricyclic antidepressants (e.g., amitriptyline). Genetic variants of SERT have been associated with an array of behavioral and neurological disorders. The precise mechanism by which a reduced activity of SERT, caused by either a genetic variant or an antidepressant, ultimately affects behavior, including depression, is not known.

**BLOOD-BRAIN BARRIER AND BLOOD-CEREBROSPINAL FLUID BARRIER**

Drugs acting in the CNS have to cross the BBB or blood-CSF barrier, which are formed by brain capillary endothelial cells and epithelial cells of the choroid plexus, respectively. These are not static anatomical barriers but dynamic ones in which efflux transporters play a role. P-glycoprotein extrudes its substrate drugs on the luminal membrane of the brain capillary endothelial cells into the blood, thereby, limiting the brain penetration. Thus, recognition by P-glycoprotein as a substrate is a major disadvantage for drugs used to treat CNS diseases. Other transporters involved in the efflux of organic anions from the CNS are being identified in the BBB and the blood-CSF barrier and include the members of OATP1A4 and OATP1A5 and OAT3 families. They mediate the uptake of organic compounds such as β-lactam antibiotics, statins, p-aminohippurate, H2 receptor antagonists, and bile acids on the plasma membrane facing the brain-CSF. Further clarification of influx and efflux transporters in the barriers will enable delivery of CNS drugs efficiently into the brain while avoiding undesirable CNS side effects.
COPING WITH EXPOSURE TO XENOBIOTICS

Substances foreign to the body, or xenobiotics, are metabolized by the same enzymatic pathways and transport systems that are used for normal metabolism of dietary constituents. Drugs are considered xenobiotics and most are extensively metabolized in humans. The capacity to metabolize xenobiotics has made development of drugs very time consuming and costly due in large part to:

- Interindividual variations in the capacity of humans to metabolize drugs
- Drug-drug interactions
- Metabolic activation of chemicals to toxic and carcinogenic derivatives
- Species differences in expression of enzymes that metabolize drugs, thereby limiting the use of animal models to predict effects in humans

Most xenobiotics are subjected to 1 or multiple enzymatic pathways that constitute phase 1 oxidation and phase 2 conjugation. Metabolism serves to convert these hydrophobic chemicals into more hydrophilic derivatives that can easily be eliminated from the body through the urine or the bile.

Many drugs are hydrophobic, a property that allows entry through the lipid bilayers into cells where the agents can interact with their target receptors or proteins. This property of hydrophobicity renders drugs difficult to eliminate, because in the absence of metabolism, they accumulate in fat and cellular phospholipid bilayers in cells. The xenobiotic-metabolizing enzymes convert drugs and other xenobiotics into derivatives that are more hydrophilic and thus easily eliminated through excretion into the aqueous compartments of the tissues.

Drug metabolism that leads to elimination also plays a major role in diminishing the biological activity of a drug. For example, (S)-phenytoin, an anticonvulsant
used in the treatment of epilepsy, is virtually insoluble in water. Metabolism by the phase 1 cytochromes P450 (CYPs) followed by phase 2 uridine diphosphate-glucuronosyltransferases (UGTs) produces a metabolite that is highly water soluble and readily eliminated from the body (Figure 6–1). Metabolism also terminates the biological activity of the drug.

Figure 6–1 Metabolism of phenytoin by phase 1 cytochrome P450 (CYP) and phase 2 uridine diphosphate-glucuronosyltransferase (UGT). CYP facilitates 4-hydroxylation of phenytoin. The hydroxy group serves as a substrate for UGT that conjugates a molecule of glucuronic acid (in green) using UDP-glucuronic acid (UDP-GA) as a cofactor. This converts a very hydrophobic molecule to a larger hydrophilic derivative that is eliminated via the bile.
Paradoxically, these drug metabolizing enzymes can also convert certain chemicals to highly reactive, toxic, and carcinogenic metabolites or carcinogens. Depending on the structure of the chemical substrate, xenobiotic-metabolizing enzymes can produce electrophilic metabolites that react with nucleophilic cellular macromolecules such as DNA, RNA, and protein. Reaction of these electrophiles with DNA can sometimes result in cancer through the mutation of genes, such as oncogenes or tumor suppressor genes. This potential for carcinogenic activity makes testing the safety of drug candidates of vital importance, particularly for drugs that will be used chronically.

THE PHASES OF DRUG METABOLISM

Xenobiotic metabolizing enzymes are grouped into those that carry out: *phase 1 reactions*, which include oxidation, reduction, or hydrolytic reactions; and the *phase 2 reactions*, in which enzymes catalyze the conjugation of the substrate (the phase 1 product) with a second molecule (Table 6–1). *Oxidation by phase 1 enzymes adds or exposes a functional group, permitting the products of phase 1 metabolism to serve as substrates for the phase 2 conjugating or synthetic enzymes*. While many phase 1 reactions result in the biological inactivation of the drug, phase 2 reactions produce a metabolite with improved water solubility, thereby facilitating drug elimination. The example of phase 1 and phase 2 metabolism of phenytoin is shown in Figure 6–1.

Table 6–1

**Xenobiotic Metabolizing Enzymes**
The **phase 1 enzymes** lead to the introduction of functional groups such as –OH, –COOH, –SH, –O–, or NH₂. The **phase 1 oxidation reactions** are carried out by CYPs, flavin-containing monooxygenases (FMOs), and epoxide hydrolases (EHs).

CYPs and FMOs comprise superfamilies of enzymes containing multiple genes. The addition of functional groups does little to increase the water solubility of the drug, but can dramatically alter the biological properties of the drug. Reactions carried out by phase 1 enzymes usually lead to the inactivation of a drug. However, in certain instances, metabolism, usually the hydrolysis of an ester or amide linkage, results in bioactivation of a drug. Inactive drugs that undergo metabolism to an active drug are called *prodrugs*. For example, the antitumor drug cyclophosphamide, is bioactivated to a cell-killing electrophilic derivative (*see Chapter 61*); clofibrate, used to reduce triglyceride levels, is converted in the cell from an ester to an active acidic metabolite.

Phase 2 enzymes facilitate the elimination of drugs and the inactivation of electrophilic and potentially toxic metabolites produced by oxidation. **Phase 2 enzymes** include several superfamilies of conjugating enzymes, such as the glutathione-S-transferases (GSTs), UDP-glucuronosyltransferases (UGTs), sulfotransferases (SULTs), N-acetyltransferases (NATs), and methyltransferases (MTs).
These conjugation reactions usually require the substrate to have oxygen (hydroxyl or epoxide groups), nitrogen, or sulfur atoms that serve as acceptor sites for a hydrophilic moiety, such as glutathione, glucuronic acid, sulfate, or an acetyl group.

In the case of the UGTs, glucuronic acid is delivered to the functional group, forming a glucuronide metabolite that is more water soluble and is targeted for excretion either in the urine or bile. When the substrate is a drug, these reactions usually convert the original drug to a form that is not able to bind to its target receptor, thus attenuating the biological response to the drug.

SITES OF DRUG METABOLISM

Xenobiotic metabolizing enzymes are found in most tissues in the body, with the highest levels located in the GI tract (liver, small and large intestines). The liver is the major “metabolic clearing house” for both endogenous chemicals (e.g., cholesterol, steroid hormones, fatty acids, and proteins) and xenobiotics. The small intestine plays a crucial role in drug metabolism because drugs that are orally administered are absorbed by the gut and taken to the liver through the portal vein. The xenobiotic-metabolizing enzymes located in the epithelial cells of the GI tract are responsible for the initial metabolic processing of most oral medications. The absorbed drug then enters the portal circulation for its first pass through the liver, where it can undergo significant metabolism. A portion of active drug escapes metabolism in the GI tract and liver and enters the systemic circulation; subsequent passes through the liver result in more metabolism of the parent drug until the agent is eliminated. Thus, drugs that are poorly metabolized remain in the body for longer periods of time (have longer elimination half-lives). Other organs that contain significant xenobiotic-metabolizing enzymes include tissues of the nasal mucosa and lung, which play important roles in the metabolism of drugs that are administered as aerosols.

At the cellular level, the phase 1 CYPs, FMOs, and EHs, and some phase 2
conjugating enzymes, notably the UGTs, are all located in the endoplasmic reticulum of the cell (Figure 6–2). Once subjected to oxidation, drugs can be directly conjugated by the UGTs (in the lumen of the endoplasmic reticulum) or by the cytosolic transferases such as GST and SULT. The metabolites can then be transported out of the cell into the bloodstream. Hepatocytes, which constitute >90% of the cells in the liver, carry out most drug metabolism and produce conjugated substrates that can also be transported through the bile canalicular membrane into the bile, from which they are eliminated into the gut (see Chapter 5).

**Figure 6–2** Location of CYPs in the cell. The figure shows increasingly microscopic levels of detail, sequentially expanding the areas within the black boxes. CYPs are embedded in the phospholipid bilayer of the endoplasmic reticulum (ER). Most of the enzyme is located on the cytosolic surface of the ER. A second enzyme, NADPH-cytochrome P<sub>450</sub> oxidoreductase, transfers electrons to the CYP where it can, in the presence of O<sub>2</sub>, oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single NADPH-CYP oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains a molecule of iron-protoporphyrin IX that functions to bind and activate O<sub>2</sub>. Substituents on the porphyrin ring are methyl (M),
propionyl (P), and vinyl (V) groups.

PHASE 1 REACTIONS

CYPs: THE CYTOCHROME P450 SUPERFAMILY

The CYPs are a superfamily of enzymes, all of which contain a molecule of heme that is noncovalently bound to the polypeptide chain (see Figure 6–2). The heme iron binds oxygen in the CYP active site, where oxidation of the substrates occurs. The H⁺ is supplied through the enzyme NADPH-cytochrome P450 oxidoreductase and its cofactor NADPH. Metabolism of a substrate by a CYP consumes 1 molecule of O₂ and produces an oxidized substrate and a molecule of water. Depending on the nature of the substrate, the reaction is “uncoupled,” consuming more O₂ than substrate metabolized and producing what is called activated oxygen or O₂⁻. The O₂⁻ is usually converted to water by the enzyme superoxide dismutase. Elevated O₂⁻, a reactive oxygen species (ROS), can give rise to oxidative stress that is detrimental to cells and associated with diseases.

Among the diverse reactions carried out by mammalian CYPs are N-dealkylation, O-dealkylation, aromatic hydroxylation, N-oxidation, S-oxidation, deamination, and dehalogenation (Table 6–2). CYPs are involved in the metabolism of dietary and xenobiotic chemicals, in the synthesis of endogenous compounds (e.g., steroids; fatty acid-derived signaling molecules, such as epoxyeicosatrienoic acids), and in the production of bile acids from cholesterol. In contrast to the drug-metabolizing CYPs, the CYPs that catalyze steroid and bile acid synthesis have very specific substrate preferences. For example, the CYP that produces estrogen from testosterone, CYP19 or aromatase, can metabolize only testosterone or androstenedione and does not metabolize xenobiotics. Specific inhibitors for aromatase, such as anastrozole, have been developed for use in the treatment of estrogen-dependent tumors (see Chapters 40 and 60-63). CYPs involved in bile acid production have strict substrate requirements and do not participate in xenobiotic or drug metabolism.
The CYPs that carry out xenobiotic metabolism can metabolize structurally diverse chemicals. This is due both to multiple forms of CYPs, to the capacity of a single CYP to metabolize many structurally distinct chemicals, to significant overlapping substrate specificity amongst CYPs, and to the capacity of CYPs to metabolize a single compound at different positions on the molecule. Indeed, CYPs are promiscuous in their capacity to bind and metabolize multiple substrates (see Table 6–2). This property sacrifices metabolic turnover
rates; CYPs metabolize substrates at a fraction of the rate of more typical enzymes involved in intermediary metabolism and mitochondrial electron transfer. As a result, drugs have, in general, half-lives in the range of 2-30 h, while endogenous compounds have half-lives of the order of seconds or minutes (e.g., dopamine and insulin).

The extensive overlapping substrate specificities by the CYPs is one of the underlying reasons for the predominance of drug-drug interactions. When 2 coadministered drugs are both metabolized by a single CYP, they compete for binding to the enzyme’s active site. This can result in the inhibition of metabolism of 1 or both of the drugs, leading to elevated plasma levels. If there is a narrow therapeutic index for the drugs, the elevated serum levels may elicit unwanted toxicities. Drug-drug interactions are among the leading causes of adverse drug reactions (ADRs).

**THE NAMING OF CYPs.** Genome sequencing has revealed the existence of 57 putatively functional genes and 58 pseudogenes in humans. These genes are grouped, based on amino acid sequence similarity, into a superfamily composed of families and subfamilies with increasing sequence similarity. CYPs are named with the root CYP followed by a number designating the family, a letter denoting the subfamily, and another number designating the CYP form. Thus, CYP3A4 is family 3, subfamily A, and gene number 4.

**A DOZEN CYPs SUFFICE FOR METABOLISM OF MOST DRUGS.** In humans, 12 CYPs (CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5) are known to be important for metabolism of xenobiotics. The liver contains the greatest abundance of xenobioc-metabolizing CYPs, thus ensuring efficient first-pass metabolism of drugs. CYPs are also expressed throughout the GI tract, and in lower amounts in lung, kidney, and even in the CNS. The most active CYPs for drug metabolism are those in the CYP2C, 2D, and 3A subfamilies. CYP3A4, the most abundantly expressed in liver, is involved in the metabolism of over 50% of clinically used drugs (Figure 6–3A). The CYP1A, 1B, 2A, 2B, and 2E subfamilies are not significantly involved in the metabolism of therapeutic drugs, but they do catalyze the metabolic activation of many prototoxins and procarcinogens.
Figure 6–3 The fraction of clinically used drugs metabolized by the major phase 1 and phase 2 enzymes. The relative size of each pie section represents the estimated percentage of drugs metabolized by the major phase 1 (panel A) and phase 2 (panel B) enzymes, based on studies in the literature. In some cases, more than a single enzyme is responsible for metabolism of a single drug. CYP, cytochrome P450; DPYD, dihydropyrimidine dehydrogenase; GST, glutathione-S-transferase; NAT, N-acetyltransferase; SULT, sulfotransferase, TPMT, thiopurine methyltransferase; UGT, UDP-glucuronosyltransferase.

CYPs AND DRUG-DRUG INTERACTIONS. Differences in the rate of metabolism of a drug can be caused by drug interactions. Most commonly, an interaction occurs when 2 drugs (e.g., a statin and a
macrolide antibiotic or antifungal agent) are metabolized by the same enzyme and affect each other’s metabolism. Thus, it is important to determine the identity of the CYP that metabolizes a particular drug and to avoid coadministering drugs that are metabolized by the same enzyme. Some drugs can also inhibit CYPs independently of being substrates for a CYP.

For example, the common antifungal agent, ketoconazole (NIZORAL), is a potent inhibitor of CYP3A4 and other CYPs, and coadministration of ketoconazole with an anti-HIV viral protease inhibitor reduces the clearance of the protease inhibitor and increases its plasma concentration and the risk of toxicity. For most drugs, information found on the package insert lists the CYP that metabolizes the drug and determines the potential for drug interactions.

Some drugs are CYP inducers that can increase not only their own rates of metabolism, but also induce metabolism of other coadministered drugs (see below and Figure 6–8).

![Figure 6–8](image)

*Figure 6–8 Induction of drug metabolism by nuclear receptor–mediated signal transduction.* When a drug such as atorvastatin (the Ligand) enters the cell, it can bind to a nuclear receptor such as the pregnane X receptor (PXR). PXR then forms a complex with the retinoid X receptor (RXR), binds to DNA upstream of
target genes, recruits coactivator (which binds to the TATA box binding protein, TBP), and activates transcription by RNA polymerase II (RNAP II). Among PXR target genes are CYP3A4, which can metabolize the atorvastatin and decrease its cellular concentration. Thus, atorvastatin induces its own metabolism. Atorvastatin undergoes both ortho and para hydroxylation.

For example, steroid hormones and herbal products such as St. John’s wort can increase hepatic levels of CYP3A4, thereby increasing the metabolism of many orally administered drugs. Indeed, St. John’s wort can induce hepatic metabolism of the steroid components of birth control pills, rendering the standard dose ineffective in preventing pregnancy.

Drug metabolism can also be influenced by diet.

Components found in grapefruit juice (e.g., naringin, furanocoumarins) are potent inhibitors of CYP3A4, and thus grapefruit juice can increase the bioavailability of certain drugs that are substrates for CYP3A4. Terfenadine, a once popular antihistamine, was removed from the market because its metabolism was inhibited by CYP3A4 substrates such as erythromycin and grapefruit juice. Terfenadine was actually a prodrug that required oxidation by CYP3A4 to its active metabolite, and at high doses the parent compound caused the potentially fatal arrhythmia, torsades de pointes. Thus, as a result of CYP3A4 inhibition by a coadministered agent, plasma levels of the parent drug could become dangerously elevated, causing ventricular tachycardia in some individuals; this led to terfenadine’s withdrawal from the market. Subsequently, the metabolite was developed as a drug, fexofenadine, which retains the therapeutic properties of the parent compound but avoids the step involving CYP3A4.

In addition, interindividual differences in drug metabolism are significantly influenced by heritable polymorphisms in CYPs.

Several human CYP genes exhibit polymorphisms, including CYP2A6, CYP2C9, CYP2C19, and CYP2D6. The CYP2D6 polymorphism has led to the withdrawal of several clinically used drugs (e.g., debrisoquine and perhexiline) and the cautious use of others that are known CYP2D6 substrates (e.g., encainide and flecainide [anti-arrhythmics], desipramine and nortriptyline [antidepressants],
and codeine).

**HYDROLYTIC ENZYMES**

Epoxides are highly reactive electrophiles that can bind to cellular nucleophiles found in protein, RNA, and DNA, resulting in cell toxicity and transformation. Two forms of epoxide hydrolase carry out hydrolysis of epoxides, most of which are produced by CYPs. The soluble epoxide hydrolase (EH) is expressed in the cytosol while the microsomal epoxide hydrolase (mEH) is localized to the membrane of the endoplasmic reticulum. Thus, epoxide hydrolases participate in the deactivation of potentially toxic metabolites generated by CYPs.

The antiepileptic drug *carbamazepine* is a prodrug that is converted to its pharmacologically active derivative, carbamazepine-10, 11-epoxide by a CYP. This metabolite is efficiently hydrolyzed to a dihydrodiol by mEH, resulting in inactivation of the drug (*Figure 6–4*). The tranquilizer *valnoctamide* and anticonvulsant *valproic acid* inhibit mEH, resulting in clinically significant drug interactions with carbamazepine by causing elevation of the active derivative.

![Figure 6–4](image.png)

**Figure 6–4** *Metabolism of carbamazepine by CYP and microsomal epoxide hydrolase (mEH).* Carbamazepine is oxidized to the pharmacologically active metabolite carbamazepine-10, 11-epoxide by CYP. The epoxide is converted to a transdihydrodiol by mEH. This metabolite is biologically inactive and can be conjugated by phase 2 enzymes.

The carboxylesterases superfamily catalyze the hydrolysis of ester- and amide-containing chemicals. These enzymes are found in both the endoplasmic reticulum and the cytosol of many cell types and are involved in detoxification or metabolic activation of various drugs, environmental toxicants, and carcinogens. Carboxylesterases also catalyze the activation of prodrugs to their respective free acids. For example, the prodrug and cancer chemotherapeutic agent irinotecan is a camptothecin analog that is bioactivated by plasma and
intracellular carboxylesterases to SN-38 (Figure 6–5), a potent inhibitor of topoisomerase 1.

Figure 6–5 Metabolism of irinotecan (CPT-11). The prodrug CPT-11 is initially metabolized by a serum esterase (CES2) to the topoisomerase inhibitor SN-38, which is the active camptothecin analog that slows tumor growth. SN-38 is then subject to glucuronidation, which results in loss of biological activity and facilitates elimination of the SN-38 in the bile.

FLAVIN-CONTAINING MONOOXYGENASE

The FMOs are another superfamily of phase 1 enzymes involved in drug metabolism. Similar to CYPs, the FMOs are expressed at high
levels in the liver and are bound to the endoplasmic reticulum. There are 6 families of FMOs, with FMO3 being the most abundant in liver. A genetic deficiency in this enzyme causes the fish-odor syndrome due to a lack of metabolism of trimethylamine N-oxide (TMAO) to trimethylamine (TMA). FMOs are considered minor contributors to drug metabolism and they almost always produce benign metabolites. FMOs are not induced by any of the xenobiotic receptors (see below) or easily inhibited; thus, in contrast to CYPs, FMOs are less involved in drug-drug interactions. In fact, this has been demonstrated by comparing the pathways of metabolism of 2 drugs used in the control of gastric motility, itopride, and cisapride. Itopride is metabolized by FMO3 while cisapride is metabolized by CYP3A4; thus, itopride is less likely to be involved in drug-drug interactions than is cisapride. CYP3A4 participates in drug-drug interactions through induction and inhibition of metabolism, whereas FMO3 is not induced or inhibited by any clinically used drugs. FMOs could be of importance in the development of new drugs. A candidate drug could be designed by introducing a site for FMO oxidation with the knowledge that favorable metabolism and pharmacokinetic properties could be accurately predicted.

CONJUGATING ENZYMES (PHASE 2 REACTIONS)

The phase 2 conjugating enzymes, synthetic in nature, catalyze reactions that normally terminate the biological activity of drugs, although for drugs like morphine and minoxidil, glucuronide and sulfate conjugates, respectively, are more pharmacologically active than the parent. The contributions of different phase 2 reactions to drug metabolism are shown in Figure 6–3B. Two of the phase 2 reactions, glucuronidation and sulfation, result in the formation of metabolites with a significantly increased hydrophilicity. Characteristic of the phase 2 reactions is the dependency on the catalytic reactions for cofactors, such as UDP-glucuronic acid (UDP-
GA) for UDP-glucuronosyltransferases (UGTs) and 3’-phosphoadenosine-5’-phosphosulfate (PAPS) for sulfotransferases (SULTs); these cofactors react with available functional groups on the substrates, reactive functional groups that are often generated by the phase 1 CYPs. All of the phase 2 reactions are carried out in the cytosol of the cell, with the exception of glucuronidation, which occurs on the luminal side of the endoplasmic reticulum.

*The catalytic rates of phase 2 reactions are significantly faster than the rates of the CYPs.* Thus, if a drug is targeted for phase 1 oxidation through the CYPs, followed by a phase 2 conjugation reaction, usually the rate of elimination will depend on the initial (phase 1) oxidation reaction.

**GLUCURONIDATION.** UGTs catalyze the transfer of glucuronic acid from the cofactor UDP-glucuronic acid to a substrate to form β-D-glucopyranosiduronic acids (*glucuronides*), metabolites that are sensitive to cleavage by β-glucuronidase. The generation of glucuronides can be formed through alcoholic and phenolic hydroxyl groups, carboxyl, sulfuryl, and carbonyl moieties, as well as through primary, secondary, and tertiary amine linkages. Examples of glucuronidation reactions are shown in Table 6–2 and Figure 6–5. The structural diversity in the many different types of drugs and xenobiotics that are processed through glucuronidation assures that most clinically efficacious therapeutic agents will be excreted as glucuronides.

The UGTs are expressed in a tissue-specific and often inducible fashion in most human tissues, with the highest concentration found in the GI tract and liver. Glucuronides are excreted into the urine or through active transport processes through the apical surface of the liver hepatocytes into the bile ducts where they are transported to the duodenum for excretion with components of the bile. Most of the bile acids that are conjugated are reabsorbed from the gut back to the liver via *enterohepatic recirculation*; many drugs that are glucuronidated and excreted in the bile can reenter the circulation by this process.

The expression of UGT1A1 assumes an important role in drug metabolism, because the glucuronidation of bilirubin by UGT1A1 is the rate-limiting step in
assuring efficient bilirubin clearance, and this rate can be affected by both genetic variation and competing substrates (drugs). Bilirubin is the breakdown product of heme, 80% of which originates from circulating hemoglobin and 20% from other heme-containing proteins such as the CYPs. Bilirubin is hydrophobic, associates with serum albumin, and must be metabolized further by glucuronidation to assure its elimination. The failure to efficiently metabolize bilirubin by glucuronidation leads to elevated serum levels and a clinical symptom called hyperbilirubinemia or jaundice. There are >50 genetic lesions in the \textit{UGT1A1} gene that can lead to inheritable unconjugated hyperbilirubinemia. Crigler-Najjar syndrome type I is diagnosed as a complete lack of bilirubin glucuronidation; Crigler-Najjar syndrome type II is differentiated by the detection of low amounts of bilirubin glucuronides in duodenal secretions. These rare syndromes result from genetic polymorphisms in the \textit{UGT1A1} gene, resulting in abolished or highly diminished levels of functional protein.

Gilbert syndrome is a generally benign condition present in up to 10% of the population; it is diagnosed clinically because circulating bilirubin levels are 60-70% higher than those seen in normal subjects. The most common genetic polymorphism associated with Gilbert syndrome is a mutation in the \textit{UGT1A1} gene promoter, which leads to reduced expression levels of UGT1A1. Subjects diagnosed with Gilbert syndrome may be predisposed to adverse drug reactions (ADRs) (see \textit{Table 6–3}) that result from a reduced capacity of UGT1A1 to metabolize drugs. If a drug undergoes selective metabolism by UGT1A1, competition for drug metabolism with bilirubin glucuronidation will exist, resulting in pronounced hyperbilirubinemia as well as reduced clearance of the metabolized drug. Gilbert syndrome also alters patient responses to irinotecan (CPT-11). Irinotecan, a prodrug used in chemotherapy of solid tumors (see Chapter 61), is metabolized to its active form, SN-38, by serum carboxylesterases (see Figure 6–5). SN-38, a potent topoisomerase inhibitor, is inactivated by UGT1A1 and excreted in the bile (Figure 6–6). Once in the lumen of the intestine, the SN-38 glucuronide undergoes cleavage by bacterial β-glucuronidase and reenters the circulation through intestinal absorption. Elevated levels of SN-38 in the blood lead to bone marrow toxicities characterized by leukopenia and neutropenia, as well as damage to the intestinal epithelial cells (see Figure 6–6), resulting in acute and life-threatening diarrhea. Patients with Gilbert syndrome who are receiving irinotecan therapy are predisposed to the hematological and GI toxicities resulting from elevated serum levels of SN-38.

**SULFATION.** The sulfotransferases (SULTs) are cytosolic and conjugate sulfate derived from 3’-phosphoadenosine-5’-phosphosulfate (PAPS) to the hydroxyl
and, less frequently, amine groups of aromatic and aliphatic compounds. In humans, significant fractions of circulating catecholamines, estrogens, iodothyronines, and DHEA exist in the sulfated form. In humans, 13 SULT isoforms have been identified and classified into 4 families [SULT1 (8 members), SULT2 (3 members), SULT4 (1 member), and SULT6 (1 member) families]. SULTs play an important role in normal human homeostasis. For example, SULT2B1b is a predominant form expressed in skin, carrying out the catalysis of cholesterol. Cholesterol sulfate is an essential metabolite in regulating keratinocyte differentiation and skin development. SULT2A1 is very highly expressed in the fetal adrenal gland, where it produces the large quantities of dehydroepiandrosterone sulfate that are required for placental estrogen biosynthesis during the second half of pregnancy. SULT1A3 is highly selective for catecholamines; SULT1E1 sulfates estrogens.

Members SULT1 family are the major forms involved in xenobiotic metabolism, with SULT1A1 being the most important in the liver. It displays extensive diversity in its capacity to catalyze the sulfation of a wide variety of structurally heterogeneous xenobiotics with high affinity. SULT1B1 is similar to SULT1A1, but it is much more abundant in the intestine than the liver. Three SULT1C isoforms exist in humans, but little is known about their substrate specificity. SULT1C enzymes are expressed abundantly in human fetal tissues and decline in abundance in adults. SULT1E catalyzes the sulfation of steroids, and is localized in liver, as well as in hormone-responsive tissues such as the testis, breast, adrenal gland, and placenta. In the upper GI tract, SULT1A3 and SULT1B1 are particularly abundant. Drug metabolism through sulfation often leads to the generation of chemically reactive metabolites, where the sulfate is electron withdrawing and may be heterolytically cleaved, leading to the formation of an electrophilic cation. Examples of the generation by sulfation of a carcinogenic or toxic response in mutagenicity assays have been documented with chemicals derived from the environment or from food mutagens generated from well-cooked meat. Thus, it is important to understand whether genetic linkages can be made by associating known human SULT polymorphisms to cancers related to environmental sources.

**GLUTATHIONE CONJUGATION.** The glutathione-S-transferases (GSTs) catalyze the transfer of glutathione to reactive electrophiles, a function that protects cellular macromolecules from interacting with electrophiles that contain
electrophilic heteroatoms (-O, -N, and -S). The cosubstrate in the reaction is the tripeptide glutathione, which is synthesized from l-glutamic acid, cysteine, and glycine (Figure 6–7). Glutathione exists in the cell as oxidized (GSSG) or reduced (GSH) forms, and the ratio of GSH:GSSG is critical in maintaining a cellular environment in the reduced state. In addition to affecting xenobiotic conjugation with GSH, a severe reduction in GSH content can predispose cells to oxidative damage, a state that has been linked to a number of human health issues.

![Glutathione conjugation](image)

**Figure 6–7** Glutathione (GSH) as a cosubstrate in the conjugation of a drug or xenobiotic (X) by glutathione-S-transferase (GST).

The formation of glutathione conjugates generates a thioether linkage with drug or xenobiotic to the cysteine moiety of the tripeptide. Because the concentration of glutathione in cells is usually very high, typically in the 10 mM range, many drugs and xenobiotics can react nonenzymatically with glutathione. However, the GSTs have been found to occupy up to 10% of the total cellular protein concentration, a property that assures efficient conjugation of glutathione to reactive electrophiles. More than 20 human GSTs have been identified and divided into 2 subfamilies: the cytosolic and the microsomal forms. The cytosolic forms have more importance in the metabolism of drugs and xenobiotics, whereas the microsomal GSTs are important in the endogenous metabolism of leukotrienes and prostaglandins. The high concentration of GSTs also provides the cells with a sink of cytosolic protein that sequesters compounds that are not substrates for glutathione conjugation. The cytosolic pool of GSTs
binds steroids, bile acids, bilirubin, cellular hormones, and environmental toxicants, in addition to complexing with other cellular proteins.

The high concentrations of GSH in the cell and the plenitude of GSTs mean that few reactive molecules escape detoxification. However, there is always concern that some reactive intermediates will escape detoxification, and by nature of their electrophilicity, will cause toxicity. The potential for such an occurrence is heightened if GSH is depleted or if a specific form of GST is polymorphic. Reactive therapeutic agents that require large doses for clinical efficacy have the greatest potential to lower cellular GSH levels. Acetaminophen, which is normally metabolized by glucuronidation and sulfation, is also a substrate for oxidative metabolism by CYP2E1 and CYP3A4, which generate the toxic metabolite N-acetyl-p-benzoquinone imine (NAPQI) that, under normal dosing, is readily neutralized through conjugation with GSH. An overdose of acetaminophen can deplete cellular GSH levels, thereby increasing the potential for NAPQI to interact with other cellular components resulting in toxicity and cell death (see Figure 4–4).

The GSTs are polymorphic, and several of the polymorphic forms express a null phenotype; thus, individuals polymorphic at these loci are predisposed to toxicities by agents that are selective substrates for these GSTs. For example, the mutant GSTM1*0 allele is observed in 50% of the Caucasian population and has been linked genetically to human malignancies of the lung, colon, and bladder. Null activity in the GSTT1 gene has been associated with adverse side effects and toxicity in cancer chemotherapy with cytostatic drugs; the toxicities result from insufficient clearance of the drugs by GSH conjugation. Expression of the null genotype can be as high as 60% in Chinese and Korean populations. GST polymorphisms may influence efficacies and severity of adverse side effects of drugs. GST activities in cancerous tissues have been linked to the development of drug resistance toward chemotherapeutic agents. See Figures 6–10 and 6–11 in the 12th edition of the parent text for more on this subject.

**N-ACETYLATION.** The cytosolic N-acetyltransferases (NATs) are responsible for the metabolism of drugs and environmental agents that contain an aromatic amine or hydrazine group. The addition of the acetyl group from the cofactor acetyl-coenzyme A often leads to a metabolite that is less water soluble because the potential ionizable amine is neutralized by the covalent addition of the acetyl group. There are 2 functional NAT genes in humans, \textit{NAT1} and \textit{NAT2}. NATs are
among the most polymorphic of all the human xenobiotic drug-metabolizing enzymes. More than 25 allelic variants of \( \text{NAT1} \) and \( \text{NAT2} \) have been characterized, and in individuals in whom acetylation of drugs is compromised, homozygous genotypes for at least 2 variant alleles are required to predispose a patient to lowered drug metabolism. The frequency of the slow acetylation patterns are attributed mostly to the polymorphism in the \( \text{NAT2} \) gene. The characterization of an acetylator phenotype in humans was one of the first hereditary traits identified, and was responsible for the development of the field of pharmacogenetics (see Chapter 7). Following the discovery that isonicotinic acid hydrazide (isoniazid, INH) could be used in the cure of tuberculosis, a significant proportion of the patients (5-15%) experienced toxicities. Individuals suffering from the toxic effects of the drug excreted the largest amount of unchanged drug and the least amount of acetylated isoniazid. Pharmacogenetic studies led to the classification of “rapid” and “slow” acetylators, with the “slow” phenotype being associated with toxicity. Characterization of \( N \)-acetyltransferase revealed polymorphisms that correspond to the “slow” acetylator phenotype. See Figures 56–3 and 56–4 for details of isoniazid metabolism and NAT2 polymorphisms.

Drug substrates of NATs and their toxicities are listed in Table 6–4. If a drug is known to be metabolized through acetylation, determining an individual’s phenotype can be important in maximizing outcome in subsequent therapy. Several drugs, such as the sulfonamides, that are targets for acetylation have been implicated in idiosyncratic hypersensitivity reactions; in such instances, an appreciation of a patient’s acetyling phenotype is particularly important. Sulfonamides are transformed into hydroxylamines that interact with cellular proteins, generating haptens that can elicit autoimmune responses. Individuals who are slow acetylators are predisposed to drug-induced autoimmune disorders.

**Table 6–4**

**Indications and Unwanted Side Effects of Drug Metabolized by \( N \)-Acetyltransferases**
Tissue-specific expression patterns of NAT1 and NAT2 have a significant impact on drug metabolism and the potential for toxicity. NAT1 is expressed in most tissues, whereas NAT2 is found predominantly in the liver and GI tract. Both NAT1 and NAT2 can form N-hydroxy–acetylated metabolites from bicyclic aromatic hydrocarbons, a reaction that leads to the nonenzymatic release of the acetyl group and the generation of highly reactive nitrenium ions. Thus, N-hydroxy acetylation is thought to activate certain environmental toxicants. In contrast, direct N-acetylation of bicyclic aromatic amines is stable and leads to detoxification. Individuals who are NAT2 fast acetylators are able to efficiently metabolize and detoxify bicyclic aromatic amines through liver-dependent acetylation. Slow acetylators (NAT2 deficient) accumulate bicyclic aromatic amines, which are metabolized by CYPs to N-OH metabolites that are eliminated in the urine. In bladder epithelium, NAT1 is highly expressed and can catalyze the N-hydroxy acetylation of bicyclic aromatic amines and the formation of the mutagenic nitrenium ion, especially in NAT2-deficient subjects. Slow acetylators are predisposed to bladder cancer if exposed environmentally to bicyclic aromatic amines.
**METHYLATION.** In humans, drugs and xenobiotics can undergo O-, N-, and S-methylation. Methyltransferases (MTs) are identified by substrate and methyl conjugate. Humans express 3 N-methyltransferases, 1 catechol-O-methyltransferase (COMT), 1 phenol-O-methyltransferase (POMT), 1 thiopurine S-methyltransferase (TPMT), and 1 thiol methyltransferase (TMT). These MTs use S-adenosyl-methionine (SAM; AdoMet) as the methyl donor. With the exception of a signature sequence that is conserved among the MTs, there is limited conservation in sequence, indicating that each MT has evolved to display a unique catalytic function. Although all MTs generate methylated products, the substrate specificity is high.

Nicotinamide N-methyltransferase (NNMT) methylates serotonin and tryptophan and pyridine-containing compounds (e.g., nicotinamide and nicotine). Phenylethanolamine N-methyltransferase (PNMT) methylates norepinephrine to epinephrine; the histamine N-methyltransferase (HNMT) metabolizes drugs containing an imidazole ring (e.g., histamine). COMT methylates neurotransmitters containing a catechol moiety (e.g., dopamine and norepinephrine, methyldopa and drugs of abuse such as ecstasy).

Clinically, the most important MT may be thiopurine S-methyltransferase (TPMT), which catalyzes the S-methylation of aromatic and heterocyclic sulfhydryl compounds, including azathioprine (AZA), 6-mercaptopurine (6-MP), and thioguanine. AZA and 6-MP are used for inflammatory bowel disease (see Chapter 47) and autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. Thioguanine is used in the treatment of acute myeloid leukemia, and 6-MP is used for the treatment of childhood acute lymphoblastic leukemia (see Chapters 61-63). Because TPMT is responsible for the detoxification of 6-MP, a genetic deficiency in TPMT can result in severe toxicities in patients taking these drugs. The toxic side effects arise when a lack of 6-MP methylation by TPMT causes a buildup of 6-MP, resulting in the generation of toxic levels of 6-thioguanine nucleotides (see Figure 47–5). Tests for TPMT activity have made it possible to identify individuals who may be predisposed to the toxic side effects of 6-MP therapy.

**XENOBIOTIC METABOLISM, EFFICACY, AND ADVERSE RESPONSES**

Metabolism of drugs normally results in the inactivation of their
therapeutic effectiveness and facilitates their elimination. The extent of metabolism can determine the efficacy and toxicity of a drug by controlling its biological $t_{1/2}$. Among the most serious considerations in the clinical use of drugs are adverse drug responses (ADRs). If a drug is metabolized too quickly, it rapidly loses its therapeutic efficacy. A drug that is metabolized too slowly can accumulate in the bloodstream; the plasma clearance of the drug is decreased and the pharmacokinetic parameter AUC (area under the plasma concentration-time curve; see Figure 2–6) is elevated. An increase in AUC often results when specific xenobiotic-metabolizing enzymes are inhibited by diet or drug interactions.

For example, the consumption of grapefruit juice (which contains CYP3A4 inhibitors naringin and furanocoumarins) can inhibit intestinal CYP3A4, blocking the metabolism and altering the oral bioavailability of many classes of drugs, including, immunosuppressants, antidepressants, antihistamines, statins, and certain antihypertensives. Phenotypic changes in drug metabolism are also observed in individuals that are genetically predisposed to adverse drug reactions because of pharmacogenetic differences in the expression of xenobiotic-metabolizing enzymes (see Chapter 7). See, for example, the discussion of Gilbert syndrome, above (see Figures 6–5 and 6–6).

Nearly every class of therapeutic agent has been reported to initiate an ADR. In the U.S., the annual costs of ADRs have been estimated at >100,000 deaths and $100 billion. About 56% of drugs that are associated with adverse responses are subjected to metabolism by CYPs and UGTs. Because many of the CYPs and UGTs are subject to induction as well as inhibition by drugs, dietary factors, and other environmental agents, these enzymes play an important role in most ADRs. Thus, before a new drug application (NDA) is filed with the FDA, the route of metabolism and the enzymes involved in the metabolism must be known.

Xenobiotics can influence the extent of drug metabolism by activating transcription and expression of genes encoding drug-metabolizing enzymes. Thus, a drug may induce its own metabolism. One potential consequence of this is a decrease in plasma drug concentration over
the course of treatment, resulting in loss of efficacy. Many ligands and receptors participate in this way to induce drug metabolism (Table 6–5). A particular receptor, when activated by a ligand, can induce the transcription of a battery of target genes, including CYPs and drug transporters, leading to drug interactions. The aryl hydrocarbon receptor (AHR) is a member of a superfamily of transcription factors. The AHR induces expression of genes encoding CYP1A1, CYP1A2, and CYP1B1, which metabolically activate chemical carcinogens, including environmental contaminants and carcinogens derived from food. Many of these substances are inert unless metabolized by CYPs. Induction of these CYPs by a drug could potentially result in an increase in the toxicity and carcinogenicity of procarcinogens.

For example, omeprazole, a proton pump inhibitor used to treat gastric and duodenal ulcers (see Chapter 45), is a ligand for the AHR and can induce CYP1A1 and CYP1A2, possibly activating toxins/carcinogens as well as drug-drug interactions in patients receiving agents that are substrates for either of these CYPs.

Another important induction mechanism is caused by type 2 nuclear receptors that are in the same superfamily as the steroid hormone receptors. Figure 6–8 shows the scheme by which a drug may interact with nuclear receptors to induce its own metabolism. Many of these
receptors were originally termed “orphan receptors,” because they had no known endogenous ligands. The type 2 nuclear receptors of most importance to drug metabolism and drug therapy include the pregnane X receptor (PXR), constitutive androstane receptor (CAR), and the peroxisome proliferator activated receptors (PPARs).

PXR is activated by a number of drugs including, antibiotics (rifampicin and troleandomycin), Ca\(^{2+}\) channel blockers (nifedipine), statins (mevastatin), antidiabetic drugs (troglitazone), HIV protease inhibitors (ritonavir), and anticancer drugs (paclitaxel). Hyperforin, a component of St. John’s wort, an over-the-counter herbal remedy used for depression, also activates PXR. This activation is thought to be the basis for the increase in failure of oral contraceptives in individuals taking St. John’s wort: Activated PXR induces CYP3A4, which can metabolize steroids found in oral contraceptives. PXR also induces the expression of genes encoding certain drug transporters and phase 2 enzymes including SULTs and UGTs. Thus, PXR facilitates the metabolism and elimination of xenobiotics, including drugs, with notable consequences.

The nuclear receptor CAR was discovered based on its ability to activate genes in the absence of ligand. Steroids such as androstenol, the antifungal agent clotrimazole, and the antiemetic meclizine are inverse agonists that inhibit gene activation by CAR, while the pesticide 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene, the steroid 5-β-pregnane-3,20-dione, are agonists that activate gene expression when bound to CAR. Genes induced by CAR include those encoding several CYPs (CYP2B6, CYP2C9, and CYP3A4), phase 2 enzymes (including GSTs, UGTs, and SULTs), and drug and endobiotic transporters. CYP3A4 is induced by both PXR and CAR and thus its level is highly influenced by a number of drugs and other xenobiotics. There are species differences in the ligand specificities of these receptors. For example, rifampin activates human PXR, but not mouse or rat PXR, while meclizine activates mouse CAR, but inhibits gene induction by human CAR. These findings further underscore that data from rodent model systems do not always reflect the response of humans to drugs.

Members of a receptor family do not always show similar activities toward xenobiotics. One peroxisome proliferator activated receptor, PPAR\(\alpha\), is the target for the fibrate class of hyperlipidemic drugs (e.g., gemfibrozil and fenofibrate).
Activation of PPARα) results in induction of genes encoding fatty acid metabolizing enzymes (result: ↓ serum triglycerides) and of CYP4 enzymes that oxidize fatty acids and compounds with fatty acid side chains, such as leukotriene and arachidonic acid analogs. Another family member, PPARγ, is the target for the thiazolidinedione class of agents for type 2 diabetes (e.g., rosiglitazone and pioglitazone); PPARγ does not induce xenobiotic metabolism.

The UGT genes, especially UGT1A1, are inducible via a host of transcriptional activation pathways, including AHR, Nrf2 (a transcriptional regulator of cytoprotective genes that is induced by an antioxidant response), PXR, CAR, and PPARα. Because the UGTs are abundant in the GI track and liver, regulation of the UGTs by drug-induced activation of these receptors could affect the pharmacokinetic parameters of many orally administered therapeutics.

ROLE OF DRUG METABOLISM IN THE DRUG DEVELOPMENT PROCESS. There are 2 key elements associated with successful drug development: efficacy and safety. Both depend on drug metabolism. It is necessary to determine which enzymes metabolize a potential new drug candidate in order to predict whether the compound may cause drug-drug interactions or be susceptible to marked interindividual variation in metabolism because of genetic polymorphisms. Computational chemical systems biology and metabolomic approaches can enhance these studies.

Historically, drug candidates have been administered to rodents at doses well above the human target dose to predict acute toxicity. For drug candidates to be used chronically in humans, long-term carcinogenicity studies are carried out in rodent models. For determination of metabolism, the compound is subjected to analysis by human liver cells or extracts from these cells that contain the drug-metabolizing enzymes. If a CYP is involved, a panel of recombinant CYPs can be used to determine which CYP predominates in the metabolism of the drug. If a single CYP, such as CYP3A4, is found to be the sole CYP that metabolizes a drug candidate, then a decision can be made about the likelihood of drug interactions. Interactions arise when multiple drugs are simultaneously administered, for example, in elderly patients, who on a daily basis may take prescribed anti-inflammatory drugs, 1 or 2 cholesterol-lowering drugs, several
classes of blood pressure medications, a gastric acid suppressant, an anticoagulant, and a number of over-the-counter medications. Ideally, the best drug candidate would be metabolized by several CYPs so that variability in expression levels of one CYP or drug-drug interactions would not alter its metabolism and pharmacokinetics.

Similar studies can be carried out with phase 2 enzymes and drug transporters. In addition to the use of recombinant human xenobiotic-metabolizing enzymes in predicting drug metabolism, human receptor-based (PXR and CAR) systems or cell lines expressing these receptors are used to determine whether a particular drug candidate could be a ligand or activator of PXR, CAR, or PPARα. For example, a drug that activates PXR may result in rapid clearance of other drugs that are CYP3A4 substrates, thus decreasing their bioavailability and efficacy.

Traditional toxicity studies in animals can be a bottleneck in the drug development process of lead compound optimization. A new technology of high-throughput screening for biomarkers of toxicity is being adopted for drug development using *metabolomics*, the systematic identification and quantification of all metabolites in a given organism or biological sample. Analytical platforms such as 1H-NMR and liquid or gas chromatography coupled to mass spectrometry, in conjunction with chemometric and multivariate data analysis, allow the simultaneous determination and comparison of thousands of chemicals in biological fluids such as serum and urine, as well as the chemical constituents of cells and tissues. Metabolomics can be used to find biomarkers for drug efficacy and toxicity that can be of value in clinical trials to identify responders and nonresponders.
Pharmacogenetics is the study of the genetic basis for variation in drug response. In this broadest sense, pharmacogenetics encompasses pharmacogenomics, which employs tools for surveying the entire genome to assess multigenic determinants of drug response. Individuals differ from each other approximately every 300-1000 nucleotides, with an estimated total of 10 million single nucleotide polymorphisms (SNPs; single base pair substitutions found at frequencies ≥1% in a population) and thousands of copy number variations in the genome. Identifying which of these variants or combinations of variants have functional consequence for drug effects is the task of modern pharmacogenetics.

IMPORTANCE OF PHARMACOGENETICS TO VARIABILITY IN DRUG RESPONSE

Drug response is considered to be a gene-by-environment phenotype. An individual’s response to a drug depends on the complex interplay between environmental factors (e.g., diet, age, infections, drugs, exercise level, occupation, exposure to toxins, tobacco, and alcohol use) and genetic factors (e.g., gender, variants of drug transporters, and drug metabolizing enzymes expressed). Variation in drug response therefore may be explained by variation in environmental and genetic factors, alone or in combination.

Drug metabolism is highly heritable, with genetic factors accounting for most of the variation in metabolic rates for many drugs. Comparison of intra-twin vs inter-pair variability suggests that ~75-85% of the variability in pharmacokinetic half-lives for drugs that are eliminated by metabolism is heritable. Extended kindreds may be used to estimate heritability.
Inter-vs. intra-family variability and relationships among members of a kindred are used to estimate heritability. Using this approach with lymphoblastoid cells, cytotoxicity from chemotherapeutic agents was shown to be heritable, with ~20-70% of the variability in sensitivity to 5-fluorouracil, cisplatin, docetaxel, and other anticancer agents estimated as inherited.

For “monogenic” phenotypic traits, it is often possible to predict phenotype based on genotype. Several genetic polymorphisms of drug metabolizing enzymes result in monogenic traits. Based on a retrospective study, 49% of adverse drug reactions were associated with drugs that are substrates for polymorphic drug metabolizing enzymes, a proportion larger than estimated for all drugs (22%) or for top-selling drugs (7%). Prospective genotype determinations may result in the ability to prevent adverse drug reactions. Defining multigenic contributors to drug response will be much more challenging. For some multigenic phenotypes, such as response to antihypertensives, the large numbers of candidate genes will necessitate a large patient sample size to produce the statistical power required to solve the “multigene” problem.

GENOMIC BASIS OF PHARMACOGENETICS

PHENOTYPE-DRIVEN TERMINOLOGY

A trait (e.g., CYP2D6 “poor metabolism”) is deemed *autosomal recessive* if the responsible gene is located on an autosome (i.e., it is not sex-linked) and a distinct phenotype is evident only with nonfunctional alleles on both the maternal and paternal chromosomes. An autosomal recessive trait does not appear in heterozygotes. A trait is deemed *codominant* if heterozygotes exhibit a phenotype that is intermediate to that of homozygotes for the common allele and homozygotes for the variant allele. With the advances in molecular characterization of polymorphisms and a genotype-to-phenotype approach, many polymorphic traits (e.g., CYP2C19 metabolism of drugs such as mephenytoin and omeprazole) are now recognized to exhibit some degree of codominance. Two major factors complicate the historical designation of recessive, codominant, and dominant
traits. First, even within a single gene, a vast array of polymorphisms (promoter, coding, non-coding, completely inactivating, or modestly modifying) are possible. Each polymorphism may produce a different effect on gene function and therefore differentially affect a measured trait. Second, most traits (pharmacogenetic and otherwise) are multigenic, not monogenic. Thus, even if the designations of recessive, codominant, and dominant are informative for a given gene, their utility in describing the genetic variability that underlies variability in drug response phenotype is diminished, because variability is likely to be multigenic.

**TYPES OF GENETIC VARIANTS**

*A polymorphism* is a variation in the DNA sequence that is present at an allele frequency of 1% or greater in a population. Two major types of sequence variation have been associated with variation in human phenotype: *single nucleotide polymorphisms* (SNPs) and *insertions/deletions* (indels). In comparison to base pair substitutions, indels are much less frequent in the genome and are of particularly low frequency in coding regions of genes. Single base pair substitutions that are present at frequencies $\geq 1\%$ in a population are termed SNPs and are present in the human genome at $\sim 1$ SNP every few hundred to a thousand base pairs.

SNPs in the coding region are termed cSNPs (coding SNPs), and are further classified as *nonsynonymous* (or *missense*) or *synonymous* (or *sense*). Coding nonsynonymous SNPs result in a nucleotide substitution that changes the amino acid codon (e.g., proline [CCG] to glutamine [CAG]), which could change protein structure, stability, substrate affinities, or introduce a stop codon. Coding synonymous SNPs do not change the amino acid codon, but may have functional consequences (transcript stability, splicing). Typically, substitutions of the third base pair, termed the *wobble position*, in a 3 base pair codon, such as the G to A substitution in proline (CCG $\rightarrow$ CCA), do not alter the encoded amino acid. Base pair substitutions that lead to a stop codon are termed *nonsense* mutations. In addition, $\sim 10\%$ of SNPs can have more than 2 possible alleles (e.g., a C can
be replaced by either an A or G), so that the same polymorphic site can be associated with amino acid substitutions in some alleles but not others.

**Synonymous polymorphisms** have sometimes been found to contribute directly to a phenotypic trait. One of the most notable examples is a polymorphism in **ABCB1**, which encodes P-glycoprotein, an efflux pump that interacts with many clinically used drugs. The synonymous polymorphism, C3435T, is associated with various phenotypes and results in a change from a preferred codon for isoleucine to a less preferred codon. Presumably, the less preferred codon is translated at a slower rate, which apparently changes the folding of the protein, its insertion into the membrane, and its interaction with drugs.

Noncoding SNPs may be in promoters, introns, or other regulatory regions that may affect transcription factor binding, enhancers, transcript stability, or splicing. Polymorphisms in noncoding regions of genes may occur in the 3’ and 5’ untranslated regions, in promoter or enhancer regions, in intronic regions, or in large regions between genes, intergenic regions (for nomenclature guide, see Figure 7–1). Noncoding SNPs in promoters or enhancers may alter **cis-** or **trans-**acting elements that regulate gene transcription or transcript stability. Noncoding SNPs in introns or exons may create alternative exon splicing sites, and the altered transcript may have fewer or more exons, or shorter or larger exons, than the wild-type transcript. Introduction or deletion of exonic sequence can cause a frame shift in the translated protein and thereby change protein structure or function, or result in an early stop codon, which makes an unstable or nonfunctional protein. Because 95% of the genome is intergenic, most polymorphisms are unlikely to directly affect the encoded transcript or protein. However, intergenic polymorphisms may have biological consequences by affecting DNA tertiary structure, interaction with chromatin and topoisomerases, or DNA replication. Thus, intergenic polymorphisms cannot be assumed to be without pharmacogenetic importance.
The second major type of polymorphism is indels. SNP indels can have any of the same effects as SNP substitutions: short repeats in the promoter (which can affect transcript amount), or insertions/deletions that add or subtract amino acids. A remarkable diversity of indels is tolerated as germline polymorphisms. A common glutathione-S-transferase M1 (GSTM1) polymorphism is caused by a 50-kilobase (kb) germline deletion, and the null allele has a population frequency of 0.3-0.5. Biochemical studies indicate that livers from homozygous null individuals have only ~50% of the glutathione conjugating capacity of those with at least 1 copy of the GSTM1 gene. The number of TA repeats in the UGT1A1 promoter affects the quantitative expression of this crucial glucuronosyltransferase in liver; 6 or 7 repeats constitute the most common alleles.

Some deletion and duplication polymorphisms can be seen as a special case of copy number variations (CNVs). Copy number variations involve large segments of genomic DNA that may involve gene duplications (stably transmitted inherited germline gene replication that causes increased protein expression and activity), gene deletions that result in the complete lack of protein production, or inversions of genes that may disrupt gene function. CNVs range in size from 1 kb to many megabases. CNVs appear to occur in ~10% of the human genome and in 1 study accounted for ~18% of the detected genetic variation in expression of around 15,000 genes in lymphoblastoid cell lines. There are notable examples of CNVs in pharmacogenetics; gene duplications of CYP2D6 are associated with an ultra-rapid metabolizer phenotype.

A haplotype, which is defined as a series of alleles found at a linked locus on a chromosome, specifies the DNA sequence variation in a gene or a gene region on 1 chromosome. For example, consider 2 SNPs in ABCB1, which encodes for the multidrug resistance protein, P-glycoprotein. One SNP is a T-to-A base pair substitution at position 3421 and the other is a C-to-T change at position 3435. Possible haplotypes would be T$_{3421}$C$_{3435}$, T$_{3421}$T$_{3435}$, A$_{3421}$C$_{3435}$, and A$_{3421}$T$_{3435}$. For any gene, individuals will have 2 haplotypes, 1 maternal and 1 paternal in origin. A haplotype represents the constellation of variants that occur together for the gene on each chromosome. In some cases, this constellation of variants, rather than the individual variant or allele, may be functionally
important. In others, however, a single mutation may be functionally important regardless of other linked variants within the haplotype(s).

Two terms describe the relationship of genotypes at 2 loci: linkage equilibrium and linkage disequilibrium. Linkage equilibrium occurs when the genotype present at 1 locus is independent of the genotype at the second locus. Linkage disequilibrium occurs when the genotypes at the 2 loci are not independent of one another. In complete linkage disequilibrium, genotypes at 2 loci always occur together. Patterns of linkage disequilibrium are population specific and as recombination occurs linkage disequilibrium between 2 alleles will decay and linkage equilibrium will result.

ETHNIC DIVERSITY. Polymorphisms differ in their frequencies within human populations and have been classified as either cosmopolitan or population (or race and ethnic) specific. Cosmopolitan polymorphisms are those polymorphisms present in all ethnic groups, although frequencies may differ among ethnic groups. Likely to have arisen before migrations of humans from Africa, cosmopolitan polymorphisms are generally older than population-specific polymorphisms. The presence of ethnic and race-specific polymorphisms is consistent with geographical isolation of human populations. These polymorphisms probably arose in isolated populations and then reached a certain frequency because they are advantageous (positive selection) or, more likely, neutral to a population. African Americans have the highest number of population-specific polymorphisms in comparison to European Americans, Mexican Americans, and Asian Americans.

PHARMACOGENETIC STUDY DESIGN CONSIDERATIONS

PHARMACOGENETIC TRAITS

A pharmacogenetic trait is any measurable or discernible trait associated with a drug. Thus, enzyme activity, drug or metabolite levels in plasma or urine, blood pressure or lipid lowering produced by a drug, and drug-induced gene expression patterns are examples of pharmacogenetic traits. Directly measuring a trait (e.g., enzyme activity) has the advantage that the net effect of the contributions of
all genes that influence the trait is reflected in the phenotypic measure. However, it has the disadvantage that it is also reflective of nongenetic influences (e.g., diet, drug interactions, diurnal, or hormonal fluctuation) and thus, may be “unstable.”

For CYP2D6, if a patient is given an oral dose of dextromethorphan, and the urinary ratio of parent drug to metabolite is assessed, the phenotype is reflective of the genotype for CYP2D6. However, if dextromethorphan is given with quinidine, a potent inhibitor of CYP2D6, the phenotype may be consistent with a poor metabolizer genotype, even though the subject carries wild-type CYP2D6 alleles. In this case, quinidine administration results in a *drug-induced haploinsufficiency*, and the assignment of a CYP2D6 poor metabolizer phenotype would not be accurate for that subject in the absence of quinidine. If a phenotypic measure, such as the erythromycin breath test (for CYP3A), is not stable within a subject, this is an indication that the phenotype is highly influenced by nongenetic factors, and may indicate a multigenic or weakly penetrant effect of a monogenic trait. *Most pharmacogenetic traits are multigenic rather than monogenic* (Figure 7–2), and considerable effort is being made to identify the important polymorphisms that influence variability in drug response.

**Figure 7–2 Monogenic versus multigenic pharmacogenetic traits.** Possible
alleles for a monogenic trait (*upper left*), in which a single gene has a low-
activity (1a) and a high-activity (1b) allele. The population frequency
distribution of a monogenic trait (*bottom left*), here depicted as enzyme activity,
may exhibit a trimodal frequency distribution among low activity (homozygosity
for 1a), intermediate activity (heterozygote for 1a and 1b), and high activity
(homozygosity for 1b). This is contrasted with multigenic traits (e.g., an activity
influenced by up to 4 different genes, genes 2 through 5), each of which has 2, 3,
or 4 alleles (a through d). The population histogram for activity is unimodal-
skewed, with no distinct differences among the genotypic groups. Multiple
combinations of alleles coding for low activity and high activity at several of the
genes can translate into low-, medium-, and high-activity phenotypes.

**GENETIC TESTING.** Most genotyping methods use constitutional or germline
DNA, that is, DNA extracted from any somatic, diploid cells, usually white
blood cells or buccal cells. DNA is extremely stable if appropriately extracted
and stored and DNA sequence is generally invariant throughout an individual’s
lifetime. Because genotyping tests are directed at specific known polymorphic
sites, and because not all known functional polymorphisms are likely to be
known for any particular gene, it is critical to understand the methodology for
interrogating the polymorphic sites. One method to assess the reliability of any
specific genotype determination in a group of individuals is to assess whether the
relative number of homozygotes to heterozygotes is consistent with the overall
allele frequency at each polymorphic site. *Hardy-Weinberg* equilibrium is
maintained when mating within a population is random and there is no natural
selection effect on the variant. Such assumptions are described mathematically
when the proportions of the population that are observed to be homozygous for
the variant genotype ($q^2$), homozygous for the wild-type genotype ($p^2$), and
heterozygous ($2*p*q$) are not significantly different from that predicted from the
overall allele frequencies ($p = \text{frequency of wild-type allele}; q = \text{frequency of
variant allele}$) in the population. Proportions of the observed 3 genotypes must
add up to 1.

**CANDIDATE GENE VERSUS GENOME-WIDE
APPROACHES**

After genes in drug response pathways are identified, the next step in
the design of a candidate gene association pharmacogenetic study is to
identify the genetic polymorphisms that are likely to contribute to the therapeutic and/or adverse responses to the drug. There are several databases that contain information on polymorphisms and mutations in human genes (Table 7–1); these databases allow the investigator to search by gene for reported polymorphisms. Some of the databases, such as the Pharmacogenetics and Pharmacogenomics Knowledge Base (PharmGKB), include phenotypic as well as genotypic data.

In candidate gene association studies, specific genes are prioritized as playing a role in response or adverse response to a drug, it is important to select polymorphisms in those genes for association studies. For this purpose, there are 2 categories of polymorphisms. The first are polymorphisms that do not, in and of themselves, cause altered function or expression level of the encoded protein (e.g., an enzyme that metabolizes the drug or the drug receptor). Rather, these polymorphisms are linked to the variant allele(s) that produces the altered function. The second type of polymorphism is the causative polymorphism, which directly precipitates the phenotype. For example, a causative SNP may change an amino acid residue at a site that is highly conserved throughout evolution. This substitution may result in a protein that is nonfunctional or has reduced function. If biological information indicates that a particular
polymorphism alters function, e.g., in cellular assays of nonsynonymous variants, this polymorphism is an excellent candidate to use in an association study. When causative SNPs are unknown, tag SNPs can be typed to represent important, relatively common blocks of variation within a gene. Once a tag SNP is found to associate with a drug response phenotype, the causative variant or variants, which may be in linkage with the tag SNP, should be identified. Because the causative variant may be an unknown variant, sequencing the gene may be necessary to identify potential causative variants. These additional causative variants may be uncovered by further deep resequencing of the gene.

GENOME-WIDE AND ALTERNATIVE LARGE-SCALE APPROACHES. A potential drawback of the candidate gene approach is that the wrong genes may be studied. Genome-wide approaches, using gene expression arrays, genome-wide scans, or proteomics, can complement and feed into the candidate gene approach by providing a relatively unbiased survey of the genome to identify previously unrecognized candidate genes. For example, RNA, DNA, or protein from patients who have unacceptable toxicity from a drug can be compared with identical material from identically treated patients who did not have such toxicity. Differences in gene expression, DNA polymorphisms, or relative amounts of proteins can be ascertained using computational tools, to identify genes, genomic regions, or proteins that can be further assessed for germline polymorphisms differentiating the phenotype. Gene expression and proteomic approaches have the advantage that the abundance of signal may itself directly reflect some of the relevant genetic variation; however, both types of expression are highly influenced by choice of tissue type, which may not be available from the relevant tissue; for example, it may not be feasible to obtain biopsies of brain tissue for studies on CNS toxicity. DNA has the advantage that it is readily available and independent of tissue type, but the vast majority of genomic variation is not in genes, and the large number of polymorphisms presents the danger of type I error (finding differences in genome-wide surveys that are false positives). Current research challenges include prioritizing among the many possible differentiating variations in genome-wide surveys of RNA, DNA, and protein to focus on those that hold the most promise for future pharmacogenomic utility.

FUNCTIONAL STUDIES OF POLYMORPHISMS
For most polymorphisms, functional information is not available. Therefore, to select polymorphisms that are likely to be causative, it is important to predict whether a polymorphism may result in a change in expression level of a protein or a change in protein function, stability, or subcellular localization. One way to gain an understanding of the functional effects of various types of genomic variations is to survey the mutations that have been associated with human Mendelian disease. The greatest numbers of DNA variations associated with Mendelian diseases or traits are missense and nonsense mutations, followed by deletions.

Functional genomics studies of numerous variants in membrane transporters suggest that the variants that alter function are likely to change an evolutionarily conserved amino acid residue and to be at low allele frequencies. These data indicate that SNPs that alter evolutionarily conserved residues are most deleterious. For example, substitution of a charged amino acid (Arg) for a nonpolar, uncharged amino acid (Cys) is more likely to affect function than substitution of residues that are more chemically similar (e.g., Arg to Lys). The data also suggest that rare SNPs, at least in the coding region, are likely to alter function.

Among the first pharmacogenetic examples to be discovered was glucose-6-phosphate dehydrogenase (G6PD) deficiency, an X-linked monogenic trait that results in severe hemolytic anemia in individuals after ingestion of fava beans or various drugs, including many antimalarial agents. G6PD is normally present in red blood cells and helps to regulate levels of glutathione (GSH), an antioxidant. Antimalarials such as primaquine increase red blood cell fragility in individuals with G6PD deficiency, leading to profound hemolytic anemia. The severity of the deficiency syndrome varies among individuals and is related to the amino acid variant in G6PD. The severe form of G6PD deficiency is associated with changes at residues that are highly conserved across evolutionary history. Collectively, studies of Mendelian traits and polymorphisms suggest that non-synonymous SNPs that alter residues that are highly conserved among species and those that result in more radical changes in the nature of the amino acid are likely to be the best candidates for causing functional changes. The information in Table 7–2 can be used as a guide for prioritizing polymorphisms in candidate
gene association studies.

AA, amino acid.

With the increasing number of SNPs that have been identified, it is clear that computational methods are needed to predict the functional consequences of SNPs. To this end, predictive algorithms have been developed to identify potentially deleterious amino acid substitutions. These methods can be classified into 2 groups. The first group relies on sequence comparisons alone to identify and score substitutions according to their degree of conservation across multiple
species; different scoring matrices have been used (e.g., BLOSUM62, SIFT, and PolyPhen). The second group of methods relies on mapping of SNPs onto protein structures, in addition to sequence comparisons. For example, rules have been developed that classify SNPs in terms of their impact on folding and stability of the native protein structure as well as shapes of its binding sites.

Functional activity of amino acid variants for many proteins can be studied in cellular assays. An initial step in characterizing the function of a non-synonymous variant is to isolate the variant gene or construct the variant by site-directed mutagenesis, express it in cells, and compare its functional activity to that of the reference or most common form of the protein. For many proteins, including enzymes, transporters, and receptors, the mechanisms by which amino acid substitutions alter function have been characterized in kinetic studies. Figure 7–3 shows simulated curves depicting the rate of metabolism of a substrate by 2 amino acid variants of an enzyme and the most common genetic form of the enzyme.

![Figure 7–3 Concentration-dependence curves showing the rate of metabolism of a hypothetical substrate by the common genetic form of an enzyme and 2 nonsynonymous variants. Variant A exhibits an increased $K_m$ and likely reflects a change in the substrate binding site of the protein by the substituted amino acid. Variant B exhibits a change in the maximum rate of metabolism ($V_{max}$) of the substrate. This may be due to reduced expression level of the enzyme.](image)
In contrast to the studies with SNPs in coding regions, we know much less about noncoding region SNPs. SNPs identified in genome-wide association studies as being associated with clinical phenotypes including drug response phenotypes have largely been in noncoding regions, either intergenic or intronic regions, of the genome. An example of profound functional effect of a noncoding SNP is provided by CYP3A5; a common noncoding intronic SNP in CYP3A5 accounts for its polymorphic expression in humans. The SNP accounting for variation in CYP3A5 protein creates an alternative splice site, resulting in a transcript with a larger exon 3 but also the introduction of an early stop codon (Figure 7–4).

Figure 7–4 An intronic SNP can affect splicing and account for polymorphic
expression of CYP3A5. A common polymorphism (A > G) in intron 3 of CYP3A5 defines the genotypes associated with the wild-type CYP3A5*1 allele, or the variant nonfunctional CYP3A5*3 allele. This intronic SNP creates an alternative splice site that results in the production of an alternative CYP3A5 transcript carrying an additional intron 3B (panel B), with an early stop codon and truncated CYP3A5 protein. The wild-type gene (more common in African than Caucasian or Asian populations) results in production of active CYP3A5 protein (panel A); the *3 variant results in a truncated and inactive protein. Thus, metabolism of CYP3A5 substrates is diminished in vitro (panel C) and blood concentrations of such medications are higher in vivo (panel D) for those with the *3 than the *1 allele.

**PHARMACOGENETIC PHENOTYPES**

Candidate genes for therapeutic and adverse response can be divided into 3 categories: pharmacokinetic, receptor/target, and disease modifying.

**PHARMACOKINETIC ALTERATIONS.** Germline variability in genes that encode determinants of the pharmacokinetics of a drug, in particular metabolizing enzymes and transporters, affect drug concentrations, and are therefore major determinants of therapeutic and adverse drug response (Table 7–3). Multiple enzymes and transporters may be involved in the pharmacokinetics of a single drug. Several polymorphisms in drug metabolizing enzymes were discovered as monogenic phenotypic trait variations.

For example, a very large number of medications (estimated at 15-25% of all medicines in use) have been shown to be substrates for CYP2D6 (see Table 7–3 and Figure 6–3A). Phenotypic consequences of the deficient CYP2D6 phenotype include increased risk of toxicity of antidepressants or antipsychotics (catabolized by the enzyme), lack of analgesic effects of codeine (anabolized by the enzyme), and lack of activation of tamoxifen, leading to a greater risk of relapse or recurrence in breast cancer. Conversely, the ultrarapid phenotype is associated with extremely rapid clearance and thus inefficacy of antidepressants.

A promoter region variant in the enzyme UGT1A1, UGT1A1*28, which has an additional TA in comparison to the more common form of the gene, has been associated with a reduced transcription rate of UGT1A1 and lower glucuronidation activity of the enzyme. This reduced activity has been associated with higher levels of the active metabolite SN38 of the cancer chemotherapeutic agent irinotecan (see Chapter 6), which is associated with the increased risk of toxicity (see Figures 6–5 and 6–6). CYP2C19, historically termed mephenytoin hydroxylase, displays penetrant pharmacogenetic variability, with just a few SNPs accounting for the majority of the deficient, poor metabolizer phenotype. The deficient phenotype is much more common in Chinese and Japanese populations. Several proton pump inhibitors, including omeprazole and lansoprazole, are inactivated by CYP2C19. Thus, the deficient patients have higher exposure to active parent drug, a greater pharmacodynamic

effect (higher gastric pH), and a higher probability of ulcer cure than heterozygotes or homozygous wild-type individuals.

Both pharmacokinetic and pharmacodynamic polymorphisms affect warfarin dosing. The anticoagulant warfarin is catabolized by CYP2C9, and its action is partly dependent upon the baseline level of reduced vitamin K (catalyzed by vitamin K epoxide reductase; Figure 7–5 and see Figure 30–6). Inactivating polymorphisms in CYP2C9 are common, with 2-10% of most populations being homozygous for low-activity variants, and are associated with lower warfarin clearance, a higher risk of bleeding complications, and lower dose requirements (see Table 30–2). Combined with genotyping for a common polymorphism in VKORC1, inherited variation in these 2 genes account for 20-60% of the variability in warfarin doses needed to achieve the desired coagulation level.

Figure 7–5 Pharmacogenetics of warfarin dosing. Warfarin is metabolized by CYP2C9 to inactive metabolites and exerts its anticoagulant effect partly via inhibition of VKORC1 (vitamin K epoxide hydrolase), an enzyme necessary for reduction of inactive to active vitamin K. Common polymorphisms in both genes, CYP2C9 and VKORC1, impact on warfarin pharmacokinetics and pharmacodynamics, respectively, to affect the population mean therapeutic doses of warfarin necessary to maintain the desired degree of anticoagulation (often measured by the international normalized ratio [INR] blood test) and minimize the risk of too little anticoagulation (thrombosis) or too much anticoagulation (bleeding). See also Figure 30–6 and Table 30–2.
**DRUG RECEPTOR/TARGET ALTERATIONS.** Gene products that are direct targets for drugs have an important role in pharmacogenetics. Highly penetrant variants with profound functional consequences in some genes may cause disease phenotypes that confer negative selective pressure; more subtle variations in the same genes can be maintained in the population without causing disease, but nonetheless causing variation in drug response.

For example, complete inactivation by means of rare point mutations in methylenetetrahydrofolate reductase (MTHFR) causes severe mental retardation, cardiovascular disease, and a shortened lifespan. Conversely, the 677C → T SNP causes an amino acid substitution that is maintained in the population at a high frequency (frequency in most white populations = 0.4) and is associated with modestly lower MTHFR activity (~30% less than the 677C allele) and modest but significantly elevated plasma homocysteine concentrations (~25% higher). This polymorphism does not alter drug pharmacokinetics, but does appear to modulate pharmacodynamics by predisposing to GI toxicity to the antifolate drug methotrexate in stem cell transplant recipients.

**FACTORS MODIFYING METHOTREXATE ACTION.** The methotrexate pathway involves metabolism, transport, drug modifier, and drug target polymorphisms. Methotrexate is a substrate for transporters and anabolizing enzymes that affect its intracellular pharmacokinetics and that are subject to common polymorphisms. Several of the direct targets (dihydrofolate reductase, purine transformylases, and thymidylate synthase [TYMS]) are also subject to common polymorphisms. A polymorphic indel in TYMS (2 vs. 3 repeats of a 28-base pair repeat in the enhancer) affects the amount of enzyme expression in both normal and tumor cells. The TYMS polymorphism can affect both toxicity and efficacy of anticancer agents (e.g., fluorouracil and methotrexate) that target TYMS. Thus, the genetic contribution to variability in the pharmacokinetics and pharmacodynamics of methotrexate cannot be understood without assessing genotypes at a number of different loci.

**OTHER EXAMPLES OF DRUG TARGET POLYMORPHISMS.** Many drug target polymorphisms have been shown to predict responsiveness to drugs (Table 7–3). Serotonin receptor polymorphisms predict not only the responsiveness to antidepressants, but also the overall risk of depression. β Adrenergic receptor
Polymorphisms have been linked to asthma responsiveness, renal function following angiotensin-converting enzyme (ACE) inhibitors, and heart rate following β blockers. Polymorphisms in HMG-CoA reductase have been linked to the degree of lipid lowering following statins (see Chapter 31), and to the degree of positive effects on high-density lipoproteins among women on estrogen replacement therapy. Ion channel polymorphisms have been linked to a risk of cardiac arrhythmias in the presence and absence of drug triggers.

**POLYMORPHISM-MODIFYING DISEASES.** Some genes may be involved in an underlying disease being treated, but do not directly interact with the drug. Modifier polymorphisms are important for the de novo risk of some events and for the risk of drug-induced events.

For example, the *MTHFR* polymorphism is linked to homocysteinemia, which in turn affects thrombosis risk. The risk of a drug-induced thrombosis is dependent not only on the use of prothrombotic drugs, but on environmental and genetic predisposition to thrombosis, which may be affected by germline polymorphisms in *MTHFR*, factor V, and prothrombin. These polymorphisms do not directly act on the pharmacokinetics or pharmacodynamics of prothrombotic drugs, such as glucocorticoids, estrogens, and asparaginase, but may modify the risk of the phenotypic event (thrombosis) in the presence of the drug. Likewise, polymorphisms in ion channels (e.g., *HERG*, KvLQT1, Mink, and *MiRP1*) may affect the overall risk of cardiac dysrhythmias, risk that may be accentuated by a drug that can prolong the QT interval in some circumstances (e.g., macrolide antibiotics, antihistamines).

**CANCER AS A SPECIAL CASE.** Cancer pharmacogenetics have an unusual aspect in that tumors exhibit somatically acquired mutations in addition to the underlying germline variation of the host. Thus, the efficacy of some anticancer drugs depends on the genetics of both the host and the tumor.

For example, non-small-cell lung cancer is treated with an inhibitor of epidermal growth factor receptor (EGFR), gefitinib. Patients whose tumors have activating mutations in the tyrosine kinase domain of *EGFR* appear to respond better to gefitinib than those without the mutations. Breast cancer patients with expression of the Her2 antigen (as an acquired genetic changes) are more likely
to benefit from the antibody trastuzumab than are those who are negative for Her2 expression, and this results in a common tailoring of anticancer therapy in patients with breast cancer based on tumor genetics. Some genetic alterations affects both tumor and host: the presence of 2 instead of 3 copies of a TYMS enhancer repeat polymorphism increases the risk of host toxicity but also increases the chance of tumor susceptibility to thymidylate synthase inhibitors.

**PHARMACOGENETICS IN CLINICAL PRACTICE**

Three major types of evidence should accumulate to implicate a polymorphism in clinical care:

1. *Screens of tissues from multiple humans linking the polymorphism to a trait*
2. *Complementary preclinical functional studies indicating that the polymorphism is plausibly linked with the phenotype*
3. *Multiple supportive clinical phenotype/genotype association studies*

Most drug dosing relies on a population “average” dose of drug. Adjusting dosages for variables such as renal or liver dysfunction is often accepted in drug dosing. Even though there are many examples of significant effects of polymorphisms on drug disposition (e.g., see Table 7–3), there is much more hesitation from clinicians to adjust doses based on genetic testing than on indirect clinical measures of renal and liver function. The frequency of functionally important polymorphisms means that complexity of dosing will be likely to increase substantially in the postgenomic era. Even if every drug has only 1 important polymorphism to consider when dosing, the scale of complexity could be large. The potential utility of pharmacogenetics to optimize drug therapy is great. With continued incorporation of pharmacogenetics into clinical trials, the important genes and polymorphisms will be identified, and data will demonstrate whether dosage individualization can improve outcomes and decrease short- and long-term adverse effects.

There are useful resources that permit clinicians to access information
on pharmacogenetics, (see Table 7–1). Passage of laws to prevent genetic discrimination may assuage concerns that genetic data placed in medical records could penalize those with “unfavorable” genotypes.
Section II
Neuropharmacology
ANATOMY AND GENERAL FUNCTIONS

The autonomic nervous system (ANS; a.k.a. the visceral, vegetative, or involuntary nervous system) regulates autonomic functions that occur without conscious control. In the periphery, it consists of nerves, ganglia, and plexuses that innervate the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues.

DIFFERENCES BETWEEN AUTONOMIC AND SOMATIC NERVES

- The efferent nerves of the ANS supply all innervated structures of the body except skeletal muscle, which is served by somatic nerves.
- The most distal synaptic junctions in the autonomic reflex arc occur in ganglia that are entirely outside the cerebrospinal axis. Somatic nerves contain no peripheral ganglia, and the synapses are located entirely within the cerebrospinal axis.
- Many autonomic nerves form extensive peripheral plexuses; such networks are absent from the somatic system.
- Postganglionic autonomic nerves generally are nonmyelinated; motor nerves to skeletal muscles are myelinated.
- When the spinal efferent nerves are interrupted, smooth muscles and glands generally retain some level of spontaneous activity, whereas the denervated skeletal muscles are paralyzed.

VISCERAL AFFERENT FIBERS. The afferent fibers from visceral structures are the first link in the reflex arcs of the autonomic system. With certain exceptions, such as local axon reflexes, most visceral reflexes are mediated through the central nervous system (CNS).
Information on the status of the visceral organs is transmitted to the CNS through 2 main sensory systems: the cranial nerve (parasympathetic) visceral sensory system and the spinal (sympathetic) visceral afferent system. The cranial visceral sensory system carries mainly mechanoreceptor and chemosensory information, whereas the afferents of the spinal visceral system principally convey sensations related to temperature and tissue injury of mechanical, chemical, or thermal origin.

Cranial visceral sensory information enters the CNS by 4 cranial nerves: the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X) nerves. These 4 cranial nerves transmit visceral sensory information from the internal face and head (V); tongue (taste, VII); hard palate and upper part of the oropharynx (IX); and carotid body, lower part of the oropharynx, larynx, trachea, esophagus, and thoracic and abdominal organs (X), with the exception of the pelvic viscera. The pelvic viscera are innervated by nerves from the second through fourth sacral spinal segments. The visceral afferents from these 4 cranial nerves terminate topographically in the solitary tract nucleus.

Sensory afferents from visceral organs also enter the CNS from the spinal nerves and convey information concerned with temperature as well as nociceptive visceral inputs related to mechanical, chemical, and thermal stimulation. Those concerned with muscle chemosensation may arise at all spinal levels, whereas sympathetic visceral sensory afferents generally arise at the thoracic levels where sympathetic preganglionic neurons are found. The neurotransmitters that mediate transmission from sensory fibers have not been characterized unequivocally. Substance P and calcitonin gene-related peptide (CGRP), are leading candidates for neurotransmitters that communicate nociceptive stimuli from the periphery. Somatostatin (SST), vasoactive intestinal polypeptide (VIP), and cholecystokinin (CCK), also occur in sensory neurons. ATP appears to be a neurotransmitter in certain sensory neurons. Enkephalins, present in interneurons in the dorsal spinal cord, have antinociceptive effects both pre- and postsynaptically to inhibit the release of substance P. The excitatory amino acids glutamate and aspartate also play major roles in transmission of sensory responses to the spinal cord. These transmitters and their signaling pathways are reviewed in Chapter 14.
DIVISIONS OF THE PERIPHERAL AUTONOMIC SYSTEM. The ANS consists of 2 large divisions: the sympathetic and the parasympathetic (Figure 8–1).

Figure 8–1 The autonomic nervous system. Yellow, cholinergic; red, adrenergic; dotted blue, visceral afferent; solid lines, preganglionic; broken lines, postganglionic. The rectangle at right shows the finer details of the ramifications of adrenergic fibers at any 1 segment of the spinal cord, the path of the visceral afferent nerves, the cholinergic nature of somatic motor nerves to skeletal muscle, and the presumed cholinergic nature of the vasodilator fibers in the dorsal roots of the spinal nerves. The asterisk (*) indicates that it is not known
whether these vasodilator fibers are motor or sensory or where their cell bodies are situated.

The neurotransmitter of all preganglionic autonomic fibers, most postganglionic parasympathetic fibers, and a few postganglionic sympathetic fibers is \textit{acetylcholine} (ACh). Some postganglionic parasympathetic nerves use \textit{nitric oxide} (NO) and are referred to as \textit{nitrergic}. The majority of the postganglionic sympathetic fibers are \textit{adrenergic}, in which the transmitter is \textit{norepinephrine} (NE, noradrenaline). The terms \textit{cholinergic} and \textit{adrenergic} describe neurons that liberate ACh or NE, respectively. Substance P and glutamate may also mediate many afferent impulses.

\textbf{SYMPATHETIC NERVOUS SYSTEM.} The cells that give rise to the preganglionic fibers of this division lie mainly in the intermediolateral columns of the spinal cord and extend from the first thoracic to the second or third lumbar segment. The axons from these cells are carried in the anterior (ventral) nerve roots and synapse, with neurons lying in sympathetic ganglia outside the cerebrospinal axis. Sympathetic ganglia are found in 3 locations: paravertebral, prevertebral, and terminal.

The 22 pairs of paravertebral sympathetic ganglia form the lateral chains on either side of the vertebral column. The ganglia are connected to each other by nerve trunks and to the spinal nerves by \textit{rami communicantes}. The white rami carry the preganglionic myelinated fibers that exit the spinal cord by the anterior spinal roots. The gray rami carry postganglionic fibers back to the spinal nerves for distribution to sweat glands and pilomotor muscles and to blood vessels of skeletal muscle and skin. The prevertebral ganglia lie in the abdomen and the pelvis near the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The terminal ganglia are few in number, lie near the organs they innervate, and include ganglia connected with the urinary bladder and rectum and the cervical ganglia in the region of the neck. In addition, small intermediate ganglia lie outside the conventional vertebral chain, especially in the
thoracolumbar region. They are variable in number and location but usually are in close proximity to the communicating rami and the anterior spinal nerve roots.

Preganglionic fibers from the spinal cord may synapse with the neurons of more than 1 sympathetic ganglion. Their principal ganglia of termination need not correspond to the original level from which the preganglionic fiber exits the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the paravertebral ganglia to form the splanchnic nerves. Most of the splanchnic nerve fibers do not synapse until they reach the celiac ganglion; others directly innervate the adrenal medulla (see below).

Postganglionic fibers arising from sympathetic ganglia innervate visceral structures of the thorax, abdomen, head, and neck. The trunk and the limbs are supplied by the sympathetic fibers in spinal nerves. The prevertebral ganglia contain cell bodies whose axons innervate the glands and smooth muscles of the abdominal and the pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses, such as the cardiac, esophageal, and pulmonary plexuses. The sympathetic distribution to the head and the neck (vasomotor, pupillodilator, secretory, and pilomotor) is by means of the cervical sympathetic fibers and its 3 ganglia. All postganglionic fibers in this chain arise from cell bodies located in these 3 ganglia; all preganglionic fibers arise from the upper thoracic segments of the spinal cord, there being no sympathetic fibers that leave the CNS above the first thoracic level.

Pharmacologically, the chromaffin cells of the adrenal medulla resemble a collection of postganglionic sympathetic nerve cells. Typical preganglionic fibers that release ACh innervate these chromaffin cells, stimulating the release of epinephrine (EPI, adrenaline), in distinction to the NE released by postganglionic sympathetic fibers.

PARASYMPATHETIC NERVOUS SYSTEM. The parasympathetic nervous system consists of preganglionic fibers that originate in the CNS and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata, and the sacral part of the spinal cord. The midbrain, or tectal, outflow consists of fibers arising from the Edinger-Westphal nucleus of the third cranial nerve and going to the ciliary ganglion in the orbit. The medullary outflow
consists of the parasympathetic components of the VII, IX, and X cranial nerves.

The fibers in the VII (facial) cranial nerve form the chorda tympani, which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the greater superficial petrosal nerve, which innervates the sphenopalatine ganglion. The autonomic components of the IX (glossopharyngeal) cranial nerve innervate the otic ganglia. Postganglionic parasympathetic fibers from these ganglia supply the sphincter of the iris (pupillary constrictor muscle), the ciliary muscle, the salivary and lacrimal glands, and the mucous glands of the nose, mouth, and pharynx. These fibers also include vasodilator nerves to these same organs. The X (vagus) cranial nerve arises in the medulla and contains preganglionic fibers, most of which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. In the intestinal wall, the vagal fibers terminate around ganglion cells in the myenteric and submucosal plexuses. Thus, in the parasympathetic branch of the autonomic nervous system, preganglionic fibers are very long, whereas postganglionic fibers are very short. The vagus nerve also carries a far greater number of afferent fibers (but apparently no pain fibers) from the viscera into the medulla. The parasympathetic sacral outflow consists of axons that arise from cells in the second, third, and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves (nervi erigentes). They synapse in terminal ganglia lying near or within the bladder, rectum, and sexual organs. The vagal and sacral outflows provide motor and secretory fibers to thoracic, abdominal, and pelvic organs (see Figure 8–1).

**ENTERIC NERVOUS SYSTEM.** The processes of mixing, propulsion, and absorption of nutrients in the GI tract are controlled through the enteric nervous system (ENS). The ENS consists of both afferent sensory neurons and a number of motor nerves and interneurons that are organized principally into 2 nerve plexuses: the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus.

The myenteric plexus, located between the longitudinal and circular muscle layers, plays an important role in the contraction and relaxation of GI smooth muscle. The submucosal plexus is involved with secretory and absorptive
functions of the GI epithelium, local blood flow, and neuroimmune activities. The ENS incorporates components of the sympathetic and parasympathetic nervous systems and has sensory nerve connections through the spinal and nodose ganglia (see Figure 46–1). Parasympathetic preganglionic inputs are provided to the GI tract via the vagus and pelvic nerves. ACh released from preganglionic neurons activates nicotinic ACh receptors (nAChRs) on postganglionic neurons within the enteric ganglia. Excitatory preganglionic input activates both excitatory and inhibitory motor neurons that control processes such as muscle contraction and secretion/absorption. Postganglionic sympathetic nerves also synapse with intrinsic neurons and generally induce relaxation. Sympathetic input is excitatory (contractile) at some sphincters. Information from afferent and preganglionic neural inputs to the enteric ganglia is integrated and distributed by a network of interneurons. ACh is the primary neurotransmitter providing excitatory inputs between interneurons, but other substances such as ATP (via postjunctional P2X receptors), substance P (by NK3 receptors), and serotonin (via 5HT3 receptors) are also important in mediating integrative processing via interneurons.

The muscle layers of the GI tract are dually innervated by excitatory and inhibitory motor neurons with cell bodies primarily in the myenteric ganglia. ACh is a primary excitatory motor neurotransmitter released from postganglionic neurons. ACh activates M2 and M3 receptors in postjunctional cells to elicit motor responses. Pharmacological blockade of muscarinic cholinergic (mAChRs) receptors does not block all excitatory neurotransmission, however, because neurokinins (neurokinin A and Substance P) are also coreleased by excitatory motor neurons and contribute to postjunctional excitation. Inhibitory motor neurons in the GI tract regulate motility events such as accommodation, sphincter relaxation, and descending receptive relaxation. Inhibitory responses are elicited by a purine derivative (either ATP or β-nicotinamide adenine dinucleotide (β-NAD) acting at postjunctional P2Y1 receptors) and NO. Inhibitory neuropeptides, such as VIP and pituitary adenylyl cyclase-activating peptide (PACAP), may also be released from inhibitory motor neurons under conditions of strong stimulation.

COMPARISON OF SYMPATHETIC, PARASYMPATHETIC, AND MOTOR NERVES (FIGURE 8–2)
• The sympathetic system is distributed to effectors throughout the body, whereas parasympathetic distribution is much more limited.

• A preganglionic sympathetic fiber may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it finally synapses with a postganglionic neuron; also, its terminals make contact with a large number of postganglionic neurons. The parasympathetic system has terminal ganglia very near or within the organs innervated and is generally more circumscribed in its influences.

• The cell bodies of somatic motor neurons reside in the ventral horn of the spinal cord; the axon divides into many branches, each of which innervates a single muscle fiber, so more than 100 muscle fibers may be supplied by 1 motor neuron to form a motor unit. At each neuromuscular junction, the axonal terminal loses its myelin sheath and forms a terminal arborization that lies in apposition to a specialized surface of the muscle membrane, termed the motor end plate (see Figure 11–3).
Figure 8–2 Wiring diagram for somatic motor nerves and the efferent nerves of the autonomic nervous system. The principal neurotransmitters, acetylcholine (ACh) and norepinephrine (NE), are shown in red. The receptors for these transmitters, nicotinic (N) and muscarinic (M) cholinergic receptors, and adrenergic receptors, are shown in green.

- Somatic nerves innervate skeletal muscle directly at a specialized synaptic junction, the motor end plate, where ACh activates $N_m$ receptors.
- Autonomic nerves innervate smooth muscles, cardiac tissue and glands. Both parasympathetic and sympathetic systems have ganglia, where ACh is released by the preganglionic fibers; ACh acts on $N_n$ receptors on the postganglionic nerves. ACh is also the neurotransmitter at cells of the
adrenal medulla, where it acts on $N_n$ receptors to cause release of EPI and NE into the circulation.

- ACh is the dominant neurotransmitter released by postganglionic parasympathetic nerves and acts on muscarinic receptors. The ganglia in the parasympathetic system are near or within the organ being innervated with generally a one-to-one relationship between pre- and post-ganglionic fibers.
- NE is the principal neurotransmitter of postganglionic sympathetic nerves, acting on $\alpha$- or $\beta$-adrenergic receptors. Autonomic nerves form a diffuse pattern with multiple synaptic sites. In the sympathetic system the ganglia are generally far from the effector cells (e.g., within the sympathetic chain ganglia). Preganglionic sympathetic fibers may make contact with a large number of postganglionic fibers.

**RESPONSES OF EFFECTOR ORGANS TO AUTONOMIC NERVE IMPULSES.** In most instances, the sympathetic and parasympathetic neurotransmitters can be viewed as physiological or functional antagonists (Table 8–1).

Most viscera are innervated by both divisions of the autonomic nervous system, and their activities on specific structures may be either discrete and independent or integrated and interdependent. For example, the effects of sympathetic and parasympathetic stimulation of the heart and the iris show a pattern of functional antagonism in controlling heart rate and pupillary aperture, respectively, whereas their actions on male sexual organs are complementary and are integrated to promote sexual function.

**GENERAL FUNCTIONS OF THE AUTONOMIC NERVOUS SYSTEM.** The ANS is the primary regulator of the constancy of the internal environment of the organism.
The sympathetic system and its associated adrenal medulla are not essential to life in a controlled environment, but the lack of sympathoadrenal functions becomes evident under circumstances of stress. In the absence of the sympathetic system: body temperature cannot be regulated when environmental temperature varies; the concentration of glucose in blood does not rise in response to urgent need; compensatory vascular responses to hemorrhage, oxygen deprivation, excitement, and exercise are lacking; and resistance to fatigue is lessened. Sympathetic components of instinctive reactions to the external environment are lost; and other serious deficiencies in the protective forces of the body are discernible. The sympathetic system normally is continuously active, the degree of activity varying from moment to moment and from organ to organ, adjusting to a constantly changing environment. The sympathoadrenal system can discharge as a unit. Heart rate is accelerated; blood pressure rises; blood flow is shifted from the skin and splanchnic region to the skeletal muscles; blood glucose rises; the bronchioles and pupils dilate; and the organism is better prepared for “fight or flight.” Many of these effects result primarily from or are reinforced by the actions of epinephrine secreted by the adrenal medulla.

The parasympathetic system is organized mainly for discrete and localized discharge. Although it is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal activity, its elimination is not compatible with life. The parasympathetic system slows the heart rate, lowers the blood pressure, stimulates GI movements and secretions, aids absorption of nutrients, protects the retina from excessive light, and empties the urinary bladder and rectum.

**NEUROTRANSMISSION**

Nerve impulses elicit responses in smooth, cardiac, and skeletal muscles, exocrine glands, and postsynaptic neurons by liberating specific chemical neurotransmitters. Neurohumoral transmission relates to the transmission of impulses from postganglionic autonomic fibers to effector cells. Evidence supporting this concept includes:

- Demonstration of the presence of a physiologically active transmitter and its biosynthetic enzymes at appropriate sites
- Recovery of the transmitter from the perfusate of an innervated structure
during periods of nerve stimulation but not (or in greatly reduced amounts) in the absence of stimulation

- Demonstration that the putative transmitter is capable of producing responses identical to responses to nerve stimulation
- Demonstration that the responses to nerve stimulation and to the administered transmitter candidate are modified in the same manner by various drugs, usually competitive antagonists

While these criteria are applicable for most neurotransmitters, including NE and ACh, there are now exceptions to these general rules. For example, NO has been found to be a neurotransmitter; however, NO is not stored in neurons and released by exocytosis. Rather, it is synthesized when needed and readily diffuses across membranes. Synaptic transmission in many instances may be mediated by the release of more than 1 neurotransmitter.

**STEPS INVOLVED IN NEUROTRANSMISSION**

The sequence of events involved in neurotransmission is of particular importance because pharmacologically active agents modulate the individual steps.

**AXONAL CONDUCTION.** At rest, the interior of the typical mammalian axon is ~70 mV negative to the exterior. In response to depolarization to a threshold level, an action potential is initiated at a local region of the membrane. The action potential consists of 2 phases. Following depolarization that induces an open conformation of the channel, *the initial phase* is caused by a rapid increase in the permeability and inward movement of Na⁺ through voltage-sensitive Na⁺ channels, and a rapid depolarization from the resting potential continues to a positive overshoot. *The second phase* results from the rapid inactivation of the Na⁺ channel and the delayed opening of a K⁺ channel, which permits outward movement of K⁺ to terminate the depolarization.

The transmembrane ionic currents produce local circuit currents such that
adjacent resting channels in the axon are activated, and excitation of an adjacent portion of the axonal membrane occurs, leading to propagation of the action potential without decrement along the axon. The region that has undergone depolarization remains momentarily in a refractory state.

The puffer fish poison, tetrodotoxin, and a close congener found in some shellfish, saxitoxin, selectively block axonal conduction by blocking the voltage-sensitive Na+ channel and preventing the increase in Na+ permeability associated with the rising phase of the action potential. In contrast, batrachotoxin, an extremely potent steroidal alkaloid secreted by a South American frog, produces paralysis through a selective increase in permeability of the Na+ channel, which induces a persistent depolarization. Scorpion toxins are peptides that also cause persistent depolarization by inhibiting the inactivation process. Na+ and Ca2+ channels are discussed in more detail in Chapters 11, 14, and 20.

JUNCTIONAL TRANSMISSION. The arrival of the action potential at the axonal terminals initiates events that trigger transmission of an excitatory or inhibitory impulse across the synapse or neuroeffector junction. These events, summarized by Figure 8–3, are:

![Figure 8–3](image-url)

Figure 8–3 Excitatory and inhibitory neurotransmission.
1. The nerve action potential (AP) consists of a transient self-propagated reversal of charge on the axonal membrane. The internal potential $E_i$ goes from a negative value, through zero potential, to a slightly positive value primarily through increases in $Na^+$ permeability and then returns to resting values by an increase in $K^+$ permeability. When the AP arrives at the presynaptic terminal, it initiates release of the excitatory or inhibitory transmitter. Depolarization at the nerve ending and entry of $Ca^{2+}$ initiate docking and then fusion of the synaptic vesicle with the membrane of the nerve ending.

2. Combination of the excitatory transmitter with postsynaptic receptors produces a localized depolarization, the excitatory postsynaptic potential (EPSP), through an increase in permeability to cations, most notably $Na^+$. An inhibitory transmitter causes a selective increase in permeability to $K^+$ or $Cl^-$, resulting in a localized hyperpolarization, the inhibitory postsynaptic potential (IPSP).

3. The EPSP initiates a conducted AP in the postsynaptic neuron; this can be prevented, however, by the hyperpolarization induced by a concurrent IPSP. The transmitter is dissipated by enzymatic destruction, by reuptake into the presynaptic terminal or adjacent glial cells, or by diffusion. Depolarization of the postsynaptic membrane can permit $Ca^{2+}$ entry if voltage-gated $Ca^{2+}$ channels are present.

1. **Release of the transmitter.** The nonpeptide (small molecule) neurotransmitters are largely synthesized in the region of the axonal terminals and stored there in synaptic vesicles. An action potential causes the synchronous release of several hundred quanta of neurotransmitter. The influx of $Ca^{2+}$, is a critical step; $Ca^{2+}$ enters the axonal cytoplasm and promotes fusion between the axoplasmic membrane and those vesicles in proximity to it. The contents of the vesicles, are discharged to the exterior by a process termed *exocytosis*.

Receptors on soma, dendrites, and axons of neurons, respond to neurotransmitters or modulators released. *Soma–dendritic receptors*; when activated, they primarily modify functions of the soma–dendritic region such as protein synthesis and generation of action potentials. *Presynaptic receptors*; when activated, they modify functions of the terminal region such
as synthesis and release of transmitters. Two main classes of presynaptic receptors have been identified on most neurons: *Heteroreceptors* are presynaptic receptors that respond to neurotransmitters, neuromodulators, or neuro-hormones released from adjacent neurons or cells. *Autoreceptors* are receptors located on or close to axon terminals of a neuron through which the neuron’s own transmitter can modify transmitter synthesis and release (see Figures 8–3, 8–4, and 8–6).

2. *Combination of the transmitter with postjunctional receptors and production of the postjunctional potential.* The transmitter diffuses across the synaptic or junctional cleft and combines with specialized receptors on the postjunctional membrane; this often results in a localized increase in the ionic permeability, or conductance, of the membrane. With certain exceptions, 1 of 3 types of permeability change can occur:

- A generalized increase in the permeability to cations (notably Na\(^+\) but occasionally Ca\(^{2+}\)), resulting in a localized depolarization of the membrane, that is, an excitatory postsynaptic potential (EPSP)
- A selective increase in permeability to anions, usually Cl\(^-\), resulting in stabilization or actual hyperpolarization of the membrane, which constitutes an inhibitory postsynaptic potential (IPSP)
- An increased permeability to K\(^+\). Because the K\(^+\) gradient is directed out of the cell, hyperpolarization and stabilization of the membrane potential occur (an IPSP)

Electric potential changes associated with the EPSP and IPSP at most sites are the results of passive fluxes of ions down their concentration gradients. The changes in channel permeability that cause these potential changes are specifically regulated by the specialized postjunctional receptors for the neurotransmitter that initiates the response (see Figures 8–4, 8–6, and 11–4; and Chapter 14). *High-conductance ligand-gated ion channels* usually permit passage of Na\(^+\) or Cl\(^-\); K\(^+\) and Ca\(^{2+}\) are involved less frequently. The ligand-gated channels belong to a superfamily of ionotropic receptor proteins that includes the nicotinic, glutamate, and certain serotonin (5HT\(_3\)) and purine receptors, which conduct primarily Na\(^+\), cause depolarization, and are excitatory; and GABA acid and glycine receptors, which conduct Cl\(^-\), cause hyperpolarization, and are inhibitory. Neurotransmitters also can modulate the permeability of K\(^+\) and Ca\(^{2+}\) channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed
between them by G proteins (see Chapter 3).

3. *Initiation of postjunctional activity.* If an EPSP exceeds a certain threshold value, it initiates a propagated action potential in a postsynaptic neuron or a muscle action potential in skeletal or cardiac muscle by activating voltage-sensitive channels in the immediate vicinity. In certain smooth muscle types in which propagated impulses are minimal, an EPSP may increase the rate of spontaneous depolarization, cause Ca\(^{2+}\) release, and enhance muscle tone; in gland cells, the EPSP initiates secretion through Ca\(^{2+}\) mobilization. An IPSP, which is found in neurons and smooth muscle will tend to oppose excitatory potentials simultaneously initiated by other neuronal sources. Whether a propagated impulse or other response ensues depends on the summation of all the potentials.

4. *Destruction or dissipation of the transmitter.* At cholinergic synapses, which are involved in rapid neurotransmission, high and localized concentrations of acetylcholinesterase (AChE) rapidly hydrolyze the ACh. When AChE activity is inhibited, removal of the transmitter is accomplished principally by diffusion. Under these circumstances, the effects of released ACh are potentiated and prolonged (see Chapter 10).

Rapid termination of NE occurs by a combination of simple diffusion and reuptake by the axonal terminals of the released NE. Termination of the action of amino acid transmitters is by active transport into neurons and surrounding glia. Peptide neurotransmitters are hydrolyzed by various peptidases and dissipated by diffusion.

5. *Nonelectrogenic functions.* The activity and turnover of enzymes involved in the synthesis and inactivation of neurotransmitters, the density of presynaptic and postsynaptic receptors, and other characteristics of synapses are controlled by trophic actions of neurotransmitters or other trophic factors released by the neuron or target cells.

**CHOLINERGIC TRANSMISSION**

The neurochemical events that underlie cholinergic neurotransmission are summarized in Figure 8–4.
Figure 8–4 A cholinergic neuroeffectector junction. The synthesis of ACh in the
depends on the uptake of choline via a sodium-dependent carrier that can be
blocked by hemicholinium. Choline and the acetyl moiety of acetyl coenzyme A,
derived from mitochondria, form ACh, a process catalyzed by the enzyme
choline acetyl transferase (ChAT). ACh is transported into the storage vesicle by
another carrier that can be inhibited by vesamicol. ACh is stored in vesicles
along with other potential cotransmitters (Co-T) such as ATP and VIP at certain
neuroeffectector junctions. Release of ACh and the Co-T occurs on depolarization
of the varicosity, which allows the entry of Ca^{2+} through voltage-dependent Ca^{2+}
channels. Elevated [Ca^{2+}]_in promotes fusion of the vesicular membrane with the
cell membrane, and exocytosis of the transmitters occurs. This fusion process
involves the interaction of specialized proteins associated with the vesicular
membrane (vesicle-associated membrane proteins [VAMPs]) and the membrane
of the varicosity (synaptosome-associated proteins [SNAPs]). The exocytotic
release of ACh can be blocked by botulinum toxin. Once released, ACh can
interact with the muscarinic receptors (M), which are GPCRs, or nicotinic
receptors (N), which are ligand-gated ion channels, to produce the characteristic response of the effector. ACh also can act on presynaptic mAChRs or nAChRs to modify its own release. The action of ACh is terminated by metabolism to choline and acetate by acetylcholinesterase (AChE), which is associated with synaptic membranes.

**SYNTHESIS AND STORAGE OF ACH.** Two enzymes, choline acetyltransferase and AChE, are involved in ACh synthesis and degradation, respectively.

**Choline Acetyltransferase.** *Choline acetyltransferase* catalyzes the final step in the synthesis of ACh—the acetylation of choline with acetyl coenzyme A (CoA). Choline acetyltransferase is synthesized within the perikaryon and then is transported along the length of the axon to its terminal. Axonal terminals contain a large number of mitochondria, where acetyl CoA is synthesized. Choline is taken up from the extracellular fluid into the axoplasm by active transport. The final step in the synthesis occurs within the cytoplasm, following which most of the ACh is sequestered within synaptic vesicles.

**Choline and Choline Transport.** Choline availability is rate limiting to the synthesis of ACh and is provided from the diet as there is little *de novo* synthesis. Choline is taken up from the extracellular space by 2 transport systems: a ubiquitous low affinity, *Na*+-independent transport system that is inhibited by *hemicholinium*-3 with a *K*_i* 50 µM, and high affinity *Na*+ - and *Cl*–dependent choline transport system that is also sensitive to inhibition by *hemicholinium*-3 (*K*_i 10-100 nM). This second transport system is found predominantly in cholinergic neurons. ACh is released from cholinergic neurons is hydrolyzed by *acetylcholine esterase (AChE)* to acetate and choline. Choline is recycled after reuptake into the nerve terminal and reused for ACh synthesis.

**Storage of ACh.** ACh is transported into synaptic vesicles by vesicular ACh transporter (VAcHt) using the potential energy of a proton electrochemical gradient. The process is inhibited by the noncompetitive and reversible inhibitor *vesamicol*, which does not affect the vesicular ATPase.

**RELEASE OF ACh.** Exocytotic release of ACh and cotransmitters (e.g., ATP, VIP, NO) occurs upon depolarization of the nerve
terminals. Depolarization of the terminals allows the entry of Ca$^{2+}$ through voltage-gated Ca$^{2+}$ channels and promotes fusion of the vesicular membrane with the plasma membrane, allowing exocytosis to occur.

ACh is stored in vesicles located close to presynaptic membranes. A multiprotein complex appears to attach the vesicle to the plasma membrane close to other signaling elements. Various synaptic proteins, including the plasma membrane protein syntaxin and synaptosomal protein 25 kDa (SNAP-25), and the vesicular membrane protein, synaptobrevin, form a complex designated as SNAP regulators (SNARES). SNARE proteins are involved in transmitter release which is blocked by botulinum neurotoxins.

**ACETYLCHOLINESTERASE.** At the neuromuscular junction, immediate removal is required to prevent lateral diffusion and activation of adjacent receptors. The time required for hydrolysis of ACh at the neuromuscular junction is less than a millisecond.

AChE is found in cholinergic neurons and is highly concentrated at the postsynaptic end plate of the neuromuscular junction. Butyrylcholinesterase (BuChE) is virtually absent in neuronal elements of the central and peripheral nervous systems. BuChE is synthesized primarily in the liver and is found in liver and plasma; its likely physiological function is the hydrolysis of ingested esters from plant sources. AChE and BuChE typically are distinguished by the relative rates of ACh and butyrylcholine hydrolysis and by effects of selective inhibitors (see Chapter 10).

**CHARACTERISTICS OF CHOLINERGIC TRANSMISSION AT VARIOUS SITES**

*Skeletal Muscle.* At the neuromuscular junction (see Figure 8–2), ACh stimulates the nicotinic receptor’s intrinsic channel, which opens for ~1 ms, admitting ~50,000 Na$^+$ ions. The channel-opening process is the basis for the localized depolarizing end-plate potential (EPP) within the end plate, which triggers the muscle AP and leads to contraction.
**Autonomic Effector Cells.** Stimulation or inhibition of autonomic effector cells occurs on activation of mAChRs. In contrast to skeletal muscle and neurons, smooth muscle and the cardiac conduction system exhibit intrinsic activity (both electrical and mechanical) that is modulated but not initiated by nerve impulses.

In the heart, spontaneous depolarizations normally arise from the SA node. In the cardiac conduction system, particularly in the SA and AV nodes, stimulation of the cholinergic innervation or the direct application of ACh causes inhibition, associated with hyperpolarization of the membrane and a marked decrease in the rate of depolarization. These effects are due, at least in part, to a selective increase in permeability to K+.

**Autonomic Ganglia.** The primary pathway of cholinergic transmission in autonomic ganglia is similar to that at the neuromuscular junction of skeletal muscle. The initial depolarization is the result of activation of nAChRs, which are ligand-gated cation channels with properties similar to those found at the neuromuscular junction. Several secondary transmitters or modulators either enhance or diminish the sensitivity of the postganglionic cell to ACh (see Chapter 11).

**Prejunctional Sites.** ACh release is subject to complex regulation by mediators, including ACh itself acting on M₂ and M₄ autoreceptors, and activation of heteroreceptors (e.g., NE acting on α₂A and α₂C adrenergic receptors) or substances produced locally in tissues (e.g., NO). ACh-mediated inhibition of ACh release following activation of M₂ and M₄ autoreceptors is a physiological negative-feedback control mechanism. At some neuroeffector junctions (e.g., the myenteric plexus in the GI tract or the cardiac SA node), sympathetic and parasympathetic nerve terminals often lie juxtaposed to each other. There, opposing effects of NE and ACh result not only from the opposite effects of the 2 transmitters on the smooth muscle or cardiac cells but also from the inhibition of ACh release by NE or inhibition of NE release by ACh acting on heteroreceptors on parasympathetic or sympathetic terminals.

**Extraneuronal Sites.** All elements of the cholinergic system are functionally expressed independently of cholinergic innervation in numerous non-neuronal cells. These non-neuronal cholinergic systems can both modify and control phenotypic cell functions such as proliferation, differentiation, formation of
physical barriers, migration, and ion and water movements.

**CHOLINERGIC RECEPTORS AND SIGNAL TRANSDUCTION**

Acetylcholine elicits responses similar to those of either nicotine or muscarine depending on the pharmacological preparation. The physiological receptors for ACh are classified as having a “nicotine action” (*nicotinic*) or a “muscarine action” (*muscarinic*). *Tubocurarine* and *atropine* block nicotinic and muscarinic effects of ACh, respectively.

*Nicotinic receptors* are ligand-gated ion channels whose activation always causes a rapid (millisecond) increase in cellular permeability to Na$^+$ and Ca$^{2+}$, depolarization, and excitation. *Muscarinic receptors* are G protein-coupled receptors (GPCRs). Responses to muscarinic agonists are slower; they may be either excitatory or inhibitory, and they are not necessarily linked to changes in ion permeability.

**SUBTYPES OF NICOTINIC ACETYLCHOLINE RECEPTORS (TABLE 8–2).** The *nicotinic ACh receptors* (nAChRs) exist at the skeletal neuromuscular junction, autonomic ganglia, adrenal medulla, the CNS and in nonneuronal tissues. The nAChRs are composed of 5 homologous subunits organized around a central pore (see Chapter 11). In general the nAChRs are further divided into 2 groups:

1. **Muscle type** (N$_m$), found in vertebrate skeletal muscle, where they mediate transmission at the neuromuscular junction (NMJ)
2. **Neuronal type** (N$_n$), found mainly throughout the peripheral nervous system, central nervous system, and also nonneuronal tissues

| Table 8–2 |

**Characteristics of Subtypes of Nicotinic Acetylcholine Receptors (nAChRs)**
Neuronal nAChRs are widely distributed in the CNS and are found at presynaptic, perisynaptic, and postsynaptic sites. At pre- and perisynaptic sites, nAChRs appear to act as autoreceptors or heteroreceptors to regulate the release of several neurotransmitters (ACh, DA, NE, glutamate, and 5HT) at several diverse sites throughout the brain.

**SUBTYPES OF MUSCARINIC RECEPTORS (TABLE 8–3).** Five distinct subtypes of muscarinic ACh receptors (mAChRs) have been identified, each produced by a different gene. Like the different forms of nicotinic receptors, these variants have distinct anatomic locations in the periphery and CNS and differing chemical specificities (see Table 8–3 and Chapter 9).

<td><strong>Characteristics of Muscarinic Acetylcholine Receptor Subtypes (mAChRs)</strong></td>
</tr>
</tbody>
</table>
The functions of mAChRs are mediated by interactions with G proteins. The M₁, M₃, and M₅ subtypes couple through Gq/11 to stimulate the PLC-IP₃/DAG-Ca²⁺ pathway, leading to activation of PKC and Ca²⁺-sensitive enzymes. Activation of M₁, M₃, and M₅ receptors can also cause the activation of phospholipase A₂, leading to the release of arachidonic acid and consequent eicosanoid synthesis; these effects of M₁, M₃, and M₅ mAChRs are generally secondary to elevation of intracellular Ca²⁺. Stimulated M₂ and M₄ cholinergic receptors couple to Gi and Go, with a resulting inhibition of adenyl cyclase, leading to a decrease in cellular cyclic AMP, activation of inwardly rectifying K⁺ channels, and inhibition of voltage-gated Ca²⁺ channels. The functional consequences of these effects are hyperpolarization and inhibition of excitable membranes. In the myocardium, inhibition of adenyl cyclase and activation of K⁺ conductances account for the negative inotropic and chronotropic effects of ACh.
ADRENERGIC TRANSMISSION

Norepinephrine (NE) is the principal transmitter of most sympathetic postganglionic fibers and of certain tracts in the CNS; dopamine (DA) is the predominant transmitter of the mammalian extrapyramidal system and of several mesocortical and mesolimbic neuronal pathways; and epinephrine (EPI) is the major hormone of the adrenal medulla. Collectively, these 3 amines are called catecholamines.

SYNTHESIS OF CATECHOLAMINES. The steps in the synthesis of catecholamines and the characteristics of the enzymes involved are shown in Figure 8–5 and Table 8–4.
Figure 8–5 Biosynthesis of catecholamines. The enzymes involved are shown in red; essential cofactors in italics. The final step occurs only in the adrenal medulla and in a few epinephrine-containing neuronal pathways in the brainstem.

Table 8–4

Enzymes for Synthesis of Catecholamines
Table 8–4 summarizes the characteristics of these synthetic enzymes. These enzymes are not completely specific; consequently, other endogenous substances, as well as certain drugs, are also substrates. For example, 5-hydroxytryptamine (5HT, serotonin) can be produced from 5-hydroxy-L-tryptophan by aromatic L-amino acid decarboxylase (or dopa decarboxylase). Dopa decarboxylase also converts dopa into DA (see Chapter 13) and methyldopa to α-methyldopamine, which in turn is converted by dopamine β-hydroxylase (DβH) to methylnorepinephrine.

The hydroxylation of tyrosine by tyrosine hydroxylase (TH) is the rate-limiting step in the biosynthesis of catecholamines.

This enzyme is activated following stimulation of sympathetic nerves or the adrenal medulla. The enzyme is a substrate for PKA, PKC, and CaM kinase; phosphorylation is associated with increased hydroxylase activity. In addition, there is a delayed increase in TH gene expression after nerve stimulation. These mechanisms serve to maintain the content of catecholamines in response to increased transmitter release. TH also is subject to feedback inhibition by catechol compounds. TH deficiency has been reported in humans and is characterized by generalized rigidity, hypokinesia, and low cerebrospinal fluid (CSF) levels of NE and DA metabolites homovanillic acid (HVA) and 3-
methoxy-4-hydroxyphenylethylene glycol.

The main features of the mechanisms of synthesis, storage, and release of catecholamines and their modifications by drugs are summarized in Figure 8–6.

![Figure 8–6 An adrenergic neuroeffector junction.](image)

Tyrosine is transported into the varicosity and converted to dopa by tyrosine hydroxylase (TH); aromatic l-amino acid decarboxylase (AAADC) converts dopa to dopamine (DA). Dopamine is taken up into the vesicles of the varicosity by a transporter, VMAT2, that can be blocked by reserpine. Cytoplasmic NE also can be taken up by this transporter. DA is converted to NE within the vesicle by dopamine-p-hydroxylase (DβH). NE is stored in vesicles along with other cotransmitters, NPY and ATP, depending on the particular neuroeffector junction. Release of the transmitters occurs upon depolarization of the varicosity, which allows entry of
Ca\(^{2+}\) through voltage-dependent Ca\(^{2+}\) channels. Elevated levels of Ca\(^{2+}\) promote the fusion of the vesicular membrane with the membrane of the varicosity, with subsequent exocytosis of transmitters, as described in the legend to Figure 8–4. NE, NPY, and ATP may be stored in the same or different vesicles and co-released. Once in the synapse, NE can interact with \(\alpha\) and \(\beta\) adrenergic receptors to produce the characteristic response of the effector. The adrenergic receptors are GPCRs. \(\alpha\) and \(\beta\) Receptors also can be located presynaptically where NE can either diminish (\(\alpha_2\)), or facilitate (\(\beta_2\)) its own release and that of the cotransmitters. The principal mechanism by which NE is cleared from the synapse is via a cocaine-sensitive neuronal uptake transporter, NET. Once transported into the cytosol, NE can be re-stored in the vesicle or metabolized by monoamine oxidase (MAO). NPY produces its effects by activating NPY receptors, of which there are at least 5 types (Y\(_1\) through Y\(_5\)), all GPCRs. NPY can modify its own release and that of the other transmitters via presynaptic receptors of the Y\(_2\) type; NPY is removed from the synapse by metabolic breakdown by peptidases. ATP produces its effects by activating P2X receptors or P2Y receptors (see Table 14–8). ATP can act prejunctionally to modify its own release via receptors for ATP or via its metabolic breakdown to adenosine that acts on P1 (adenosine) receptors. ATP is cleared from the synapse primarily by releasable nucleotidases (rNTPase) and by cell-fixed ectonucleotidases.

In the case of adrenergic neurons, the enzymes that participate in the formation of NE are synthesized in the cell bodies of the neurons and then are transported along the axons to their terminals. In the course of synthesis, the hydroxylation of tyrosine to dopa and the decarboxylation of dopa to DA take place in the cytoplasm. DA then is actively transported into the D\(\beta\)H-containing storage vesicles, where it is converted to NE by D\(\beta\)H in sympathetic nerves (about 90%); the remainder is metabolized. DA is converted by MAO to an aldehyde intermediate DOPAL, and then mainly converted to 3,4-dihydroxyphenyl acetic acid (DOPAC) by aldehyde dehydrogenase and to a minor extent 3,4-dihydroxyphenylethanol (DOPET) by aldehyde reductase. DOPAC is further converted to HVA by O-methylation in nonneuronal sites.

The adrenal medulla has 2 distinct catecholamine-containing cell types: those with NE and those with primarily EPI. The latter cell population contains the enzyme phenylethanolamine-N-methyltransferase (PNMT). In these cells, the NE formed in the granules leaves these structures and is methylated in the
cytoplasm to EPI. Epinephrine then reenters the chromaffin granules, where it is stored until released. EPI accounts for ~80% of the catecholamines of the adrenal medulla and NE ~20%. The level of glucocorticoids, secreted by the adrenal cortex, is a major factor that controls the rate of synthesis of EPI and the amount available for release from the adrenal medulla. The intra-adrenal portal vascular system carries the corticosteroids directly to the adrenal medullary chromaffin cells, where they induce the synthesis of PNMT. The activities of both TH and D H also are increased in the adrenal medulla when the secretion of glucocorticoids is stimulated.

In addition to de novo synthesis, NE stores in the terminal portions of the adrenergic fibers are also replenished by reuptake and re-storage of NE following its release. At least 2 distinct carrier-mediated transport systems are involved:

1. One across the axonal membrane from the extracellular fluid to the cytosol (the NE transporter [NET], previously called uptake 1)
2. The other from the cytosol into the storage vesicles (the vesicular monoamine transporter [VMAT2]) Sympathetic nerves as a whole remove ~87% of released NE by NET. More than 70% of recaptured NE is sequestered by VMAT2 into storage vesicles. In contrast, clearance of circulating catecholamines is primarily by nonneuronal mechanisms, with liver and kidney accounting for more than 60% of the clearance.

**STORAGE OF CATECHOLAMINES.** Catecholamines are stored in vesicles, ensuring their regulated release. VMAT2 is driven by pH and potential gradients that are established by an *ATP-dependent proton translocase*. For every molecule of amine taken up, 2 H⁺ ions are extruded. Monoamine transporters transport DA, NE, EPI, and 5HT. Reserpine inhibits monoamine transport into storage vesicles and ultimately leads to depletion of catecholamine from sympathetic nerve endings and in the brain.

There are 2 neuronal membrane transporters for catecholamines, the NE transporter (NET) and the DA transporter (DAT) (Table 8–5). NET is Na⁺-dependent and is blocked selectively by cocaine and
tricyclic antidepressants (e.g. imipramine). This transporter has a higher affinity for NE than for EPI.

Indirectly acting sympathomimetic drugs (e.g., ephedrine and tyramine) produce some of their effects by displacing and releasing NE from the nerve terminals to the effector cells. These agents are substrates for NET. As a result of their transport across the neuronal
membrane and release into the axoplasm, they make NET available at the inner surface of the membrane for the outward transport of NE (“facilitated exchange diffusion”). These amines also mobilize NE stored in the vesicles by competing for the vesicular uptake process (VMAT2).

Three extraneuronal transporters (ENTs) handle a range of endogenous and exogenous substrates (see Table 8–5). The ENT (or uptake-2 and OCT3), is an organic cation transporter that exhibits lower affinity for catecholamines, compared to NET, and favors EPI over NE and DA. Other members of this family are the organic cation transporters OCT1 and OCT2 (see Chapter 5).

RELEASE OF CATECHOLAMINES. Details of excitation-secretion coupling in sympathetic neurons and adrenal medulla are not completely known, The triggering event is the entry of Ca^{2+}, which results in the exocytosis of the granular contents, including EPI, ATP, some neuroactive peptides or their precursors, chromogranins, and D, H.

PREJUNCTIONAL REGULATION OF NOREPINEPHRINE RELEASE. Following their release from sympathetic terminals, the 3 sympathetic cotransmitters—NE, neuropeptide Y (NPY), and ATP—can feed back on prejunctional receptors to inhibit the release of each other. The α_{2A} and α_{2C} adrenergic receptors are the principal prejunctival receptors that inhibit sympathetic neurotransmitter release, whereas the α_{2B} adrenergic receptors also may inhibit transmitter release at selected sites. NPY, acting on Y_{2} receptors, and ATP-derived adenosine, acting on P1 receptors, also can inhibit sympathetic neurotransmitter release. Numerous heteroreceptors on sympathetic nerve varicosities also inhibit the release of sympathetic neurotransmitters; these include: M_{2} and M_{4} muscarinic, 5HT, PG E_{2}, histamine, enkephalin, and DA receptors. Enhancement of
sympathetic neurotransmitter release can be produced by activation of β2 adrenergic receptors, angiotensin AT2 receptors, and nAChRs.

**TERMINATION OF THE ACTIONS OF CATECHOLAMINES.** The actions of NE and EPI are terminated by:

- Reuptake into nerve terminals by NET
- Dilution by diffusion out of junctional cleft and extraneuronal uptake by ENT, OCT1, and OCT2

**METABOLISM OF CATECHOLAMINES.** Following uptake, catecholamines are either metabolized by *monoamine oxidase* (MAO) and *catechol-O-methyltransferase* (COMT). MAO metabolizes transmitter that is released within the nerve terminal. COMT, particularly in the liver, plays a major role in the metabolism of endogenous circulating and administered catecholamines. MAO and COMT can act sequentially in conjunction with aldehyde reductase, aldehyde dehydrogenase, and alcohol dehydrogenase to produce a variety of intermediates en route to vanillylmandelic acid, which is secreted into the urine (Figure 8–7).
Figure 8–7 Metabolism of catecholamines. NE and EPI are first oxidatively deaminated to a short-lived intermediate (DOPGAL) by monoamine oxidase (MAO). DOPGAL then undergoes further metabolism to more stable alcohol or acid deaminated metabolites. Aldehyde dehydrogenase (AD) metabolizes DOPGAL to 3,4-dihydroxymandelic acid (DOMA) while aldehyde reductase (AR) metabolizes DOPGAL to 3,4-dihydroxyphenyl glycol (DOPEG). Under normal circumstances DOMA is a minor metabolite with DOPEG being the major metabolite produced from NE and EPI. Once DOPEG leaves the major sites of its formation (sympathetic nerves; adrenal medulla), it is converted to 3-methoxy, 4-hydroxyphenylglycol (MOPEG) by catechol-0-methyl transferase (COMT). MOPEG is then converted to the unstable aldehyde (MOPGAL) by
alcohol dehydrogenase (ADH) and finally to vanillylmandelic acid (VMA) by aldehyde dehydrogenase. VMA is the major end product. Another route for the formation of VMA is conversion of NE or EPI into normetanephrine or metanephrine by COMT either in the adrenal medulla or extraneuronal sites, with subsequent metabolism to MOPGAL and thence to VMA. Catecholamines are also metabolized by sulfotransferases.

The 2 enzymes have different subcellular localizations: MAO is associated chiefly with the outer surface of mitochondria; COMT is largely cytoplasmic. Both MAO and COMT are distributed widely throughout the body, however, little or no COMT is found in sympathetic neurons. The physiological substrates for COMT include l-dopa, all 3 endogenous catecholamines (DA, NE, and EPI), their hydroxylated metabolites, catecholestrogens, ascorbic acid, and dihydroxyindolic intermediates of melanin. Two different isozymes of MAO (MAO-A and MAO-B) occur in widely varying proportions in different cells in the CNS and in peripheral tissues. In the brain, MAO-A is located in all regions containing catecholamines. MAO-B, on the other hand, is found primarily in regions that are known to synthesize and store 5HT. MAO inhibitors are useful in the treatment of Parkinson disease and mental depression (see Chapters 15 and 22). Inhibitors of MAO (e.g., pargyline and nialamide) can cause an increase in the concentration of NE, DA, and 5HT in the brain and other tissues.

Adrenal medullary chromaffin cells contain both MAO and COMT; the COMT is mainly present as the membrane-bound form of the enzyme in contrast to the form found in the cytoplasm of extra-neuronal tissue.

CLASSIFICATION OF ADRENERGIC RECEPTORS. Adrenergic receptors are broadly classified as either α or β, with subtypes within each group (Table 8–6). The original subclassification was based on the rank order of potency of agonists:

- Epinephrine ≥ norepinephrine >> isoproterenol for α adrenergic receptors
- Isoproterenol > epinephrine ≥ norepinephrine for β adrenergic receptors

MOLECULAR BASIS OF ADRENERGIC RECEPTOR FUNCTION. All adrenergic receptors are GPCRs that link to heterotrimeric G proteins. Each major type shows preference for a particular class of G proteins, that is, $\alpha_1$ to $G_q$, $\alpha_2$ to $G_i$, and $\beta$ to $G_s$ (see Table 8–6). The responses that follow activation result from G protein–mediated effects on the generation of second messengers and on the activity of ion channels, as discussed in Chapter 3. The pathways overlap broadly with those discussed for muscarinic ACh receptors.

$\alpha$ ADRENERGIC RECEPTORS. The $\alpha_1$ receptors ($\alpha_{1A}$, $\alpha_{1B}$, and $\alpha_{1D}$) and the $\alpha_2$ receptors ($\alpha_{2A}$, $\alpha_{2B}$, and $\alpha_{2C}$) are heptahelical proteins that couple differentially to a variety of G proteins to regulate smooth muscle contraction, secretory pathways, and cell growth (see Table 8–6).
\(\alpha_1\) ADRENERGIC RECEPTORS. Stimulation of \(\alpha_1\) receptors activates the G\(_q\)-PLC\(\beta\)-IP\(_3\)/DAG-Ca\(^{2+}\) pathway and results in the activation of PKC and other Ca\(^{2+}\) and calmodulin sensitive pathways such as CaM kinases, with sequelae depending on cell differentiation (e.g., contraction of vascular smooth muscle, activation of eNOS in vascular endothelium) (see Chapter 3). Activation of C\(_1\) receptor subtypes also stimulates several phospholipases (PLA\(_2\), PLD).

PKC phosphorylates many substrates, including membrane proteins such as channels, pumps, and ionexchange proteins (e.g., Ca\(^{2+}\)-transport ATPase). \(\alpha_1\) Receptor stimulation of PLA\(_2\) leads to the release of free arachidonate, which is then metabolized by cyclooxygenase (yielding prostaglandins) and lipoxygenase (yielding leukotrienes) (see Chapter 33); PLD hydrolyzes phosphatidylcholine to yield phosphatidic acid. In most smooth muscles, the increased concentration of intracellular Ca\(^{2+}\) causes contraction (see Chapter 3 and Figure 3–14). In contrast, the increased concentration of intracellular Ca\(^{2+}\) that result from stimulation of \(\alpha_1\) receptors in GI smooth muscle causes hyperpolarization and relaxation by activation of Ca\(^{2+}\)-dependent K\(^{+}\) channels. \(\alpha_1\) Receptors activate MAPKs, PI3K, and others to affect cell growth and proliferation.

\(\alpha_2\) ADRENERGIC RECEPTORS. \(\alpha\) Adrenergic receptors (\(\alpha_{2A}\), \(\alpha_{2B}\), and \(\alpha_{2C}\)) couple to a variety of effectors, generally inhibiting adenylyl cyclase (reducing signaling via the cyclic AMP-PKA pathway) and activating G protein–gated K\(^{+}\) channels (resulting in membrane hyperpolarization).

Activation of \(\alpha_{2A}\) receptors inhibits NE release from sympathetic nerve endings and suppresses sympathetic outflow from the brain, leading to hypotension. In the CNS, \(\alpha_{2A}\) receptors, probably produce the antinociceptive effects, sedation, hypothermia, hypotension, and behavioral actions of \(\alpha_2\) agonists. The \(\alpha_{2B}\) receptor is the main receptor mediating \(\alpha_2\)-induced vasoconstriction, whereas the \(\alpha_{2C}\) receptor is the predominant receptor inhibiting the release of catecholamines from the adrenal medulla and modulating dopamine neurotransmission in the brain.
β ADRENERGIC RECEPTORS. β Receptors regulate numerous functions, including heart rate and contractility, smooth muscle relaxation, and multiple metabolic events in numerous tissues including adipose and hepatic cells and skeletal muscle (see Table 8–1). All 3 of the β receptor subtypes (β₁, β₂, and β₃) couple to Gₛ and activate adenylyl cyclase (see Table 8–6). However, recent data suggest possible differences in downstream signals and events activated by the 3 β receptors.

β₁, β₂, and β₃ receptors can differ in their intracellular signaling pathways and subcellular location. Stimulation of β₂ receptors cause a transient increase in heart rate that is followed by a prolonged decrease. Following pretreatment with pertussis toxin, which prevents activation of Gᵢ, the negative chronotropic effect of β₂ activation is abolished. It is thought that these specific signaling properties of β receptor subtypes are linked to subtype-selective association with intracellular scaffolding and signaling proteins. β₂ receptors normally are confined to caveolae in cardiac myocyte membranes; the importance of compartmentation of components of the cyclic AMP pathway are discussed in Chapter 3.

REFRACTORINESS TO CATECHOLAMINES. Exposure of catecholamine-sensitive cells and tissues to adrenergic agonists causes a progressive diminution in their capacity to respond to such agents. This phenomenon, variously termed refractoriness, desensitization, or tachyphylaxis (see Chapter 3). Multiple mechanisms are involved in desensitization, including receptor phosphorylation by both G-protein receptor kinases (GRKs) and by signaling kinases such as PKA and PKC, receptor sequestration and endocytosis, interaction with scaffold proteins, and activation of specific cyclic nucleotide phosphodiesterases. The β₂ receptor system is the best studied in this regard.

PHARMACOLOGICAL CONSIDERATIONS

Each step involved in neurotransmission (see Figures 8–3, 8–4, and 8–6) represents a potential point of therapeutic intervention. This is depicted in the diagrams of the cholinergic and adrenergic terminals and their postjunctional sites (see Figures 8–4 and 8–6). Drugs that
Affect processes involved in each step of transmission at cholinergic and adrenergic junctions are summarized in Table 8–7.

</table>
OTHER AUTONOMIC NEUROTRANSMITTERS

Most neurons in both the central and peripheral nervous systems contain more than 1 putative neurotransmitter (see Chapter 14). Although the parasympathetic and sympathetic components of the autonomic nervous system and the actions of ACh and NE still provide the essential framework for studying autonomic function, a host of other chemical messengers such as purines, eicosanoids, NO, and peptides modulate or mediate responses that follow stimulation of the ANS.
ATP. ATP is a cotransmitter with NE. The sympathetic nerves store ATP and NE in the same synaptic vesicles, and the 2 cotransmitters are released together. ATP and NE may also be released from separate subsets of vesicles and be subject to differential regulation. There is also evidence that ATP may be a cotransmitter with ACh in certain post-ganglionic parasympathetic nerves.

NPY. NPY peptides are distributed widely in the central and peripheral nervous systems. NPY is colocalized and coreleased with NE and ATP in most sympathetic nerves in the peripheral nervous system, especially those innervating blood vessels. Thus, NPY, together with NE and ATP, is likely a third sympathetic cotransmitter. The functions of NPY include (1) direct postjunctional contractile effects; (2) potentiation of the contractile effects of the other sympathetic cotransmitters; and (3) inhibitory modulation of the nerve stimulation–induced release of all 3 sympathetic cotransmitters.

VIP AND ACH. VIP and ACh coexist in peripheral autonomic neurons, possibly in separate populations of storage vesicles. There is evidence for their cotransmission in the regulation of salivation.

NONADRENERGIC, NONCHOLINERGIC (NANC) TRANSMISSION BY PURINES. There is evidence for the existence of NANC transmission in the ANS and of purinergic neurotransmission in the GI tract, genitourinary tract, and certain blood vessels. Indeed, ATP has fulfilled all the criteria for a neurotransmitter. Adenosine, generated from the released ATP by ectoenzymes and releasable nucleotidases acts as a modulator by causing feedback inhibition of release of the transmitter. Purinergic receptors are classified as adenosine (P1) receptors and ATP (P2X and P2Y) receptors. Adenosine receptors and P2Y receptors mediate their responses via G proteins, whereas the P2X receptors are a subfamily of ligand-gated ion channels (see Figure 14–8). Methylxanthines (e.g., caffeine and theophylline) preferentially block adenosine receptors (see Chapter 36).

MODULATION OF VASCULAR RESPONSES BY ENDOTHELium-DERIVED FACTORS; NO. An intact endothelium is necessary to achieve vascular relaxation in response to physiological ligands with Gq-linked receptors on endothelial cells and to exogenous ACh. In response to a variety of vasoactive agents and physical stimuli, endothelial cells produce and release a vasodilator called endothelium-derived relaxing factor (EDRF), now known to
be NO. Less commonly, an endothelium-derived hyperpolarizing factor (EDHF) and endothelium-derived contracting factor (EDCF) are released. NO production contributes to vascular tone and thus can modulate the influence of α- and β-agonists and antagonists thereon. See Figure 3–14 for more information on the multiple signaling systems that can influence vascular tone.
Muscarinic acetylcholine receptors in the peripheral nervous system occur primarily on autonomic effector cells innervated by postganglionic parasympathetic nerves. Muscarinic receptors are also present in autonomic ganglia and on some cells (e.g., vascular endothelial cells) that, paradoxically, receive little or no cholinergic innervation. Within the CNS, the hippocampus, cortex, and thalamus have high densities of muscarinic receptors. Acetylcholine (ACh), the naturally occurring neurotransmitter for these receptors, has virtually no systemic therapeutic applications because its actions are diffuse, and its hydrolysis, catalyzed by both acetylcholinesterase (AChE) and plasma butyrylcholinesterase, is rapid. Muscarinic agonists mimic the effects of ACh at these sites and are longer-acting congeners of ACh or natural alkaloids.

Cholinergic synapses are found at:

- Autonomic effector sites innervated by postganglionic parasympathetic nerves (or, in the sweat glands, by postganglionic sympathetic nerves)
- Sympathetic and parasympathetic ganglia and the adrenal medulla, innervated by preganglionic autonomic nerves
- Motor end plates on skeletal muscle, innervated by somatic motor nerves
- Certain synapses in the CNS, where ACh can have either pre- or postsynaptic actions

The actions of ACh and related drugs at autonomic effector sites are termed *muscarinic*, based on the observation that the alkaloid muscarine acts selectively at those sites and produces the same qualitative effects as ACh (see Table 8–1). Muscarinic receptors are
present in autonomic ganglia and the adrenal medulla but primarily function to modulate the nicotinic actions of ACh at these sites (see Chapter 11). In the CNS, muscarinic receptors are widely distributed and mediate many important responses. The actions of ACh and its congeners at muscarinic receptors can be blocked competitively by atropine.

**PROPERTIES AND SUBTYPES OF MUSCARINIC RECEPTORS**

Muscarinic receptors comprise 5 distinct gene products, designated as M₁ through M₅ (see Table 8–3). Muscarinic receptors are GPCRs that in turn couple to various cellular effectors. Selectivity is not absolute but, in general, stimulation of M₁, M₃, and M₅ receptors activates the G₉-PLC-IP₃/DAG-Ca²⁺ pathway, resulting in a variety of Ca²⁺-mediated responses. By contrast, M₂ and M₄ muscarinic receptors couple to the pertussis toxin–sensitive G proteins, Gᵢ and Gₒ, to inhibit adenylyl cyclase and regulate specific ion channels.

The 5 muscarinic receptor subtypes are widely distributed in both the CNS and peripheral tissues; most cells express at least 2 subtypes (see Table 8–3). The M₂ receptor is the predominant subtype in the cholinergic control of the heart, whereas the M₃ receptor is the predominant subtype in the cholinergic control of smooth muscle, secretory glands, and the eye. The M₁ receptor has an important role in the modulation of nicotinic cholinergic transmission in ganglia.

**PHARMACOLOGICAL EFFECTS OF ACETYLCHOLINE**

**CARDIOVASCULAR SYSTEM.** ACh has 4 primary effects on the cardiovascular system:

- Vasodilation
- Decrease heart rate (negative chronotropic effect)
- Decrease the conduction velocity in the atrioventricular (AV) node (negative dromotropic effect)
• Decrease in the force of cardiac contraction (negative inotropic effect)

The negative inotropic effect is less significant in the ventricles than in the atria. Some of these responses can be obscured by baroreceptor and other reflexes that dampen the direct responses to ACh. Although ACh rarely is given systemically, its cardiac actions are important because the cardiac effects of cardiac glycosides, anti-arrhythmic agents, and many other drugs are at least partly due to changes in parasympathetic (vagal) stimulation of the heart; in addition, afferent stimulation of the viscera during surgical interventions can reflexly increase the vagal stimulation of the heart.

The intravenous injection of a small dose of ACh produces a transient fall in blood pressure owing to generalized vasodilation (mediated by vascular endothelial NO), which is usually accompanied by reflex tachycardia. A considerably larger dose is required to see direct effects of ACh on the heart, such as eliciting bradycardia or AV nodal conduction block. The generalized vasodilation produced by exogenously administered ACh is due to the stimulation of muscarinic receptors, primarily of the M3 subtype, located on vascular endothelial cells despite the apparent lack of cholinergic innervation. Occupation of the receptors by agonist activates the Gq-PLC-IP3 pathway, leading to Ca2+-calmodulin–dependent activation of endothelial NO synthase and production of NO, which diffuses to adjacent vascular smooth muscle cells and causes them to relax (see Chapters 3 and 8). If the endothelium is damaged, as occurs under various pathophysiological conditions, ACh acts predominantly on M3 receptors located on vascular smooth muscle cells, causing vasoconstriction.

ACh affects cardiac function directly and also indirectly through inhibition of the adrenergic stimulation of the heart. Cardiac effects of ACh are mediated primarily by M2 muscarinic receptors, which couple to G\textsubscript{i}/G\textsubscript{o}. The direct effects include:

• Increase in the ACh-activated K\textsuperscript{+} current (I\textsubscript{K-ACh}) due to activation of K-ACh channels
• Decrease in the L-type Ca\textsuperscript{2+} current (I\textsubscript{Ca-L}) due to inhibition of L-type Ca\textsuperscript{2+} channels
• Decrease in the cardiac pacemaker current (I\textsubscript{f}) due to inhibition of HCN
(pacemaker) channels

The *indirect* effects include:

- $G_i$-mediated decrease in cyclic AMP, which opposes and counteracts the $\beta_1$ receptor/$G_s$–mediated increase in cyclic AMP
- Inhibition of the release of NE from sympathetic nerve terminals

The inhibition of NE release is mediated by presynaptic $M_2$ and $M_3$ receptors, which are stimulated by ACh released from adjacent parasympathetic postganglionic nerve terminals. Presynaptic $M_2$ receptors also inhibit ACh release from parasympathetic postganglionic nerve terminals in the human heart.

ACh slows the heart rate primarily by decreasing the rate of spontaneous depolarization of the SA node (*see Chapter 29*); attainment of the threshold potential and the succeeding events in the cardiac cycle are therefore delayed. In the *atria*, ACh causes hyperpolarization and a decreased action potential duration by increasing IK-ACh. ACh also inhibits cyclic AMP formation and NE release, decreasing atrial contractility. The rate of impulse conduction is either unaffected or may increase in response to ACh; the increase probably is due to the activation of additional Na$^+$ channels in response to ACh-induced hyperpolarization. In contrast, in the AV node (which has Ca$^{2+}$ channel-dependent action potentials; *see Chapter 29*), ACh slows conduction and increases the refractory period by inhibiting $I_{Ca-L}$; the decrement in AV conduction is responsible for the complete heart block that may be observed when large quantities of cholinergic agonists are administered systemically.

Cholinergic (vagal) innervation of the His-Purkinje system and ventricular myocardium is sparse and the effects of ACh are smaller than those observed in the atria and nodal tissues. In the ventricles, ACh, whether released by vagal stimulation or applied directly, has a small negative inotropic effect; this inhibition is most apparent when there is concomitant adrenergic stimulation or underlying sympathetic tone. Automaticity of Purkinje fibers is suppressed, and the threshold for ventricular fibrillation is increased.

**RESPIRATORY TRACT.** The parasympathetic nervous system plays a major role in regulating bronchomotor tone. The effects of ACh on
the respiratory system include not only bronchoconstriction but also increased tracheobronchial secretion and stimulation of the chemoreceptors of the carotid and aortic bodies. These effects are mediated primarily by M3 muscarinic receptors.

**URINARY TRACT.** Parasympathetic sacral innervation causes detrusor muscle contraction, increased voiding pressure, and ureteral peristalsis. M2 receptors appear most prevalent in the bladder; M3 receptor mediates detrusor muscle contraction.

**GI TRACT.** Stimulation of vagal input to the GI tract increases tone, amplitude of contractions, and secretory activity of the stomach and intestine. The muscarinic receptors of the M2 subtype are most prevalent, but M3 muscarinic receptors are primarily responsible for mediating the cholinergic control of GI motility.

**SECRETORY AND OCULAR EFFECTS.** ACh stimulates secretion from glands that receive parasympathetic or sympathetic cholinergic innervation, including the lacrimal, nasopharyngeal, salivary, and sweat glands. These effects are mediated primarily by M3 muscarinic receptors; M1 receptors also contribute significantly to the cholinergic stimulation of salivary secretion. When instilled into the eye, ACh produces miosis by contracting the pupillary sphincter muscle and accommodation for near vision by contracting the ciliary muscle (see Chapter 64); both effects are mediated primarily by M3 muscarinic receptors.

**CNS EFFECTS.** All 5 muscarinic receptor subtypes are found in the brain, and studies suggest that muscarinic receptor-regulated pathways may have an important role in cognitive function, motor control, appetite regulation, nociception, and other processes. Elevation of ACh with AChE inhibitors is used in treating some of the cognitive symptoms of Alzheimer disease (see Table 22–2).
MUSCARINIC RECEPTOR AGONISTS

Muscarinic cholinergic receptor agonists can be divided into 2 groups:

- Choline esters, including ACh and several synthetic esters
- Naturally occurring cholinomimetic alkaloids (particularly pilocarpine, muscarine, and arecoline) and their synthetic congeners

Of several hundred synthetic choline derivatives investigated, only methacholine, carbachol, and bethanechol have had clinical applications, along with a few natural alkaloids (Figure 9–1; Table 9–1).

Methacholine (acetyl-β-methylcholine), the β-methyl analog of ACh, is a synthetic choline ester that differs from ACh chiefly in its greater duration of action (the added methyl group increases its resistance to hydrolysis by cholinesterases) and its predominantly muscarinic selectivity. Carbachol and bethanechol are unsubstituted carbamoyl esters that are completely resistant to hydrolysis by cholinesterases; their $t_{1/2}$ are thus sufficiently long that they become distributed to areas of low blood flow. Carbachol retains substantial nicotinic activity, particularly on autonomic ganglia. Bethanechol has mainly muscarinic actions, with prominent effects on motility of the GI tract and urinary bladder. The major natural alkaloid muscarinic agonists are muscarine, pilocarpine, and arecoline. Muscarine acts almost exclusively at muscarinic receptor sites and is of toxicological significance (see below). Pilocarpine has a dominant muscarinic action but is a partial rather than a full agonist; the sweat glands are particularly sensitive to pilocarpine. Arecoline acts at nicotinic receptors. Although these naturally occurring alkaloids are of great value as pharmacological tools, present clinical use is restricted largely to the employment of pilocarpine as a sialogogue and miotic agent (see Chapter 64).

**ABSORPTION, DISTRIBUTION, AND ELIMINATION.** Muscarine and the choline esters are quaternary amines (see Figure 9–1), hence they are poorly absorbed following oral administration and have a limited ability to cross the blood-brain barrier. The choline esters are short-acting agents due to rapid elimination by the kidneys. Muscarine can still, however, be toxic when ingested and can even have CNS effects. Pilocarpine and arecoline, being tertiary amines, are readily absorbed and can cross the blood-brain barrier. Pilocarpine clearance is decreased in patients with hepatic impairment. The natural alkaloids are primarily eliminated by the kidneys; excretion of the tertiary amines can be accelerated by acidification of the urine.

**THERAPEUTIC USES OF MUSCARINIC RECEPTOR AGONISTS**

Muscarinic agonists are currently used in the treatment of urinary bladder disorders and xerostomia and in the diagnosis of bronchial hyper-reactivity. They are also used in ophthalmology as miotic agents and for the treatment of glaucoma. There is growing interest in the role of muscarinic receptors in cognition and the potential utility
of M₁ agonists in treating the cognitive impairment associated with Alzheimer disease.

**ACETYLCHOLINE.** ACh (Miochol-E) is used topically for the induction of miosis during ophthalmologic surgery; it is instilled into the eye as a 1% solution (see Chapter 64).

**METHACHOLINE.** Methacholine (Provocholine) is administered by inhalation for the diagnosis of bronchial airway hyperreactivity in patients who do not have clinically apparent asthma. Contraindications to methacholine testing include severe airflow limitation, recent myocardial infarction or stroke, uncontrolled hypertension, or pregnancy. The response to methacholine also may be exaggerated or prolonged in patients taking β adrenergic receptor antagonists. Methacholine is available as a powder that is diluted with 0.9% NaCl and administered via a nebulizer.

**BETHANECHOL.** Bethanechol (Urecholine, others) primarily affects the urinary and GI tracts. In the urinary tract, bethanechol has utility in treating urinary retention and inadequate emptying of the bladder as in postoperative urinary retention. When used chronically, 10-50 mg of the drug is given orally 3 to 4 times daily, administered on an empty stomach (i.e., 1 h before or 2 h after a meal) to minimize nausea and vomiting. In the GI tract, bethanechol stimulates peristalsis, increases motility, and increases resting lower esophageal sphincter pressure. Bethanechol formerly was used to treat postoperative abdominal distention, gastric atony, gastroparesis, adynamic ileus, and gastroesophageal reflux; more efficacious therapies for these disorders are now available (see Chapters 45 and 46).

**CARBACHOL.** Carbachol (Miostat, Isopto Carbachol, others) is used topically in ophthalmology for the treatment of glaucoma and the induction of miosis during surgery; it is instilled into the eye as a 0.01-3% solution (see Chapter 64).

**PILOCARPINE.** Pilocarpine hydrochloride (Salagen, others) is used for the treatment of xerostomia that follows head and neck radiation treatments or that is associated with Sjögren syndrome, an autoimmune disorder occurring primarily in women in whom
secretions, particularly salivary and lacrimal, are compromised. Side effects typify cholinergic stimulation. The usual dose is 5-10 mg 3 times daily; the dose should be lowered in patients with hepatic impairment. Pilocarpine (ISOPTO CARPINE, others) is used topically in ophthalmology for the treatment of glaucoma and as a miotic agent; it is instilled in the eye as a 0.5-6% solution and also can be delivered via an ocular insert (see Chapter 64).

CEVIMELINE. Cevimeline (EVOXAC), a quinuclidine derivative of ACh, is a muscarinic agonist with a high affinity for M₃ muscarinic receptors on lacrimal and salivary gland epithelia. Cevimeline has a long-lasting sialogogic action and may have fewer side effects than pilocarpine. The usual dose is 30 mg 3 times daily.

CONTRAINDICATIONS, PRECAUTIONS, AND ADVERSE EFFECTS
Contraindications to the use of muscarinic agonists include asthma, chronic obstructive pulmonary disease, urinary or GI tract obstruction, acid-peptic disease, cardiovascular disease, hypotension, and hyperthyroidism (muscarinic agonists may precipitate atrial fibrillation in hyperthyroid patients). Common adverse effects include diaphoresis; diarrhea, abdominal cramps, nausea/vomiting, and other GI side effects; a sensation of tightness in the urinary bladder; difficulty in visual accommodation; and hypotension. The adverse effects are of limited concern with topical administration for ophthalmic use.

TOXICOLOGY
Poisoning from the ingestion of plants containing pilocarpine, muscarine, or arecoline is characterized chiefly by exaggeration of their various parasympathomimetic effects and resembles that produced by consumption of mushrooms of the genus Inocybe. Treatment consists of the parenteral administration of atropine in doses sufficient to cross the blood-brain barrier and measures to support the respiratory and cardiovascular systems.

MUSHROOM POISONING (MYCETISM). High concentrations of muscarine
are present in various species of *Inocybe* and *Clitocybe*. The symptoms of intoxication attributable to muscarine develop within 30-60 min of ingestion; they include salivation, lacrimation, nausea, vomiting, headache, visual disturbances, abdominal colic, diarrhea, bronchospasm, bradycardia, hypotension, and shock. Treatment with atropine (1-2 mg intramuscularly every 30 min) effectively blocks these effects.

Other mushroom species produce toxins unrelated to ACh. Intoxication by *Amanita* species arises from the neurologic and hallucinogenic properties of muscimol (a GABA<sub>A</sub> agonist), ibotenic acid, and other isoxazole derivatives that stimulate excitatory and inhibitory amino acid receptors. Mushrooms from *Psilocybe* and *Panaeolus* species contain hallucinogens [psilocybin (a 5HT<sub>2A</sub> pro-agonist) and related derivatives of tryptamine]. *Gyromitra* species (false morels) produce GI disorders and a delayed hepatotoxicity. The most serious mycetism is produced by *Amanita phalloides*, other *Amanita* species, *Lepiota*, and *Galerina* species. These species account for > 90% of all fatal cases. Ingestion of as little as 50 g of *A. phalloides* (deadly nightcap) can be fatal. The principal toxins are the amatoxins (α- and β-amanitin), a group of cyclic octapeptides that inhibit RNA polymerase II and thereby block mRNA synthesis. Initial symptoms, which often are unnoticed or when present are due to other toxins, include diarrhea and abdominal cramps. A symptom-free period lasting up to 24 h is followed by hepatic and renal malfunction. Death occurs in 4-7 days from renal and hepatic failure. Treatment is largely supportive.

Because the severity of toxicity and treatment strategies for mushroom poisoning depend on the species ingested, seek their identification. Regional poison control centers in the U.S. maintain up-to-date information on the incidence of poisoning in the region and treatment procedures.

**MUSCARINIC RECEPTOR ANTAGONISTS**

Muscarinic antagonists prevent the effects of ACh by blocking its binding to muscarinic receptors on effector cells. In general, muscarinic antagonists cause little blockade of nicotinic receptors. However, the quaternary ammonium antagonists generally exhibit a greater degree of nicotinic blocking activity and therefore are more likely to interfere with ganglionic or neuromuscular transmission. An
important consideration in the therapeutic use of muscarinic antagonists is the fact that physiological functions in different organs vary in their sensitivity to muscarinic receptor blockade (Table 9–2).

The clinical picture of a high (toxic) dose of atropine may be remembered by an old mnemonic device that summarizes the symptoms: Red as a beet, Dry as a bone, Blind as a bat, Hot as firestone, and Mad as a hatter.

The muscarinic receptor antagonists include:

- The naturally occurring alkaloids, atropine and scopolamine
- Semisynthetic derivatives of these alkaloids, which primarily differ from the parent compounds in their disposition in the body or their duration of action
- Synthetic derivatives, some of which show selectivity for subtypes of muscarinic receptors

Noteworthy agents among the latter 2 categories are homatropine and tropicamide, which have a shorter duration of action than atropine, and methscopolamine, ipratropium, and tiotropium, which are quaternized and do not cross the blood-brain barrier or readily cross membranes. The synthetic derivatives possessing some degree of receptor selectivity include pirenzepine, which shows selectivity for M₁ receptors; and darifenacin and solifenacin, which show selectivity for M₃ receptors.

Small doses of atropine depress salivary and bronchial secretion and sweating. Much larger doses are required to inhibit gastric motility and secretion, which
are associated with unwanted side effects. This hierarchy of relative sensitivities is not a consequence of differences in the affinity of atropine for the muscarinic receptors at these sites; atropine lacks selectivity toward different muscarinic receptor subtypes. More likely determinants include the degree to which the functions of various end organs are regulated by parasympathetic tone, the “spareness” of receptors and signaling mechanisms, the involvement of intramural neurons and reflexes.

Most clinically available muscarinic antagonists are nonselective and their actions differ little from those of atropine. No subtype-selective antagonist, including pirenzepine, is completely selective. In fact, the clinical efficacy of some agents may arise from a balance of antagonistic actions on 2 or more receptor subtypes. Atropine and related compounds compete with ACh and other muscarinic agonists for a common binding site on the muscarinic receptor. Because antagonism by atropine is competitive, it can be overcome if the concentration of ACh at muscarinic receptors of the effector organ is increased sufficiently.

PHARMACOLOGICAL EFFECTS OF MUSCARINIC ANTAGONISTS

The pharmacological effects of atropine provide a good background for understanding the therapeutic uses of the various muscarinic antagonists. The effects of other muscarinic antagonists will be mentioned only when they differ significantly from those of atropine. Table 9–2 summarizes the major pharmacological effects of increasing doses of atropine.

CARDIOVASCULAR SYSTEM

Heart. Although the dominant response is tachycardia, the heart rate often decreases transiently with average clinical doses (0.4−0.6 mg). The slowing is modest (4−8 beats per minute) and is usually absent after rapid intravenous injection. Larger doses of atropine cause progressive tachycardia by blocking M₂ receptors on the SA nodal pacemaker cells, thereby antagonizing parasympathetic (vagal) tone to the heart. The resting heart rate is increased by ~35−40 beats per minute in young men given 2 mg of atropine intramuscularly.
The maximal heart rate (e.g., in response to exercise) is not altered by atropine. The influence of atropine is most noticeable in healthy young adults, in whom vagal tone is considerable. In infancy and old age, even large doses of atropine may fail to accelerate the heart. Atropine often produces cardiac arrhythmias, but without significant cardiovascular symptoms.

Atropine can abolish many types of reflex vagal cardiac slowing or asystole, such as from inhalation of irritant vapors, stimulation of the carotid sinus, pressure on the eyeballs, peritoneal stimulation, or injection of contrast dye during cardiac catheterization. Atropine also prevents or abruptly abolishes bradycardia or asystole caused by choline esters, acetylcholinesterase inhibitors, or other parasympathomimetic drugs, as well as cardiac arrest from electrical stimulation of the vagus. The removal of vagal tone to the heart by atropine also may facilitate AV conduction.

*Circulation.* Atropine, alone, has little effect on blood pressure, since most vessels lack significant cholinergic innervation. However, in clinical doses, atropine completely counteracts the peripheral vasodilation and sharp fall in blood pressure caused by choline esters. In toxic and occasionally in therapeutic doses, atropine can dilate cutaneous blood vessels, especially those in the blush area (atropine flush). This may be a compensatory reaction permitting the radiation of heat to offset the atropine-induced rise in temperature that can accompany inhibition of sweating.

*RESPIRATORY SYSTEM.* Atropine inhibits the secretions of the nose, mouth, pharynx, and bronchi, and thus dries the mucous membranes of the respiratory tract. Atropine can inhibit the bronchoconstriction caused by histamine, bradykinin, and the eicosanoids, which presumably reflects the participation of reflex parasympathetic (vagal) activity in the bronchoconstriction elicited by these agents. The ability to block the indirect bronchoconstrictive effects of these mediators forms the basis for the use of muscarinic receptor antagonists, along with β adrenergic receptor agonists, in the treatment of asthma and COPD (see Chapter 36).

*EYE.* Muscarinic receptor antagonists block the cholinergic responses of the pupillary sphincter muscle of the iris and the ciliary muscle controlling lens curvature (see Chapter 64). Thus, they dilate the pupil (*mydriasis*) and paralyze accommodation (cycloplegia). Locally applied atropine produces ocular effects
of considerable duration; accommodation and pupillary reflexes may not fully recover for 7-12 days. Other muscarinic receptor antagonists with shorter durations of action are therefore preferred as mydriatics in ophthalmologic practice (see Chapter 64). Muscarinic receptor antagonists administered systemically have little effect on intraocular pressure except in patients predisposed to angle-closure glaucoma, in whom the pressure may occasionally rise dangerously.

**GI TRACT.** Muscarinic receptor antagonists are used as antispasmodic agents for GI disorders and in the treatment of peptic ulcer disease. Although atropine can completely abolish the effects of ACh (and other parasympathomimetic drugs) on GI motility and secretion, it inhibits only incompletely the GI responses to vagal stimulation. This difference can be attributed to the fact that preganglionic vagal fibers innervating the GI tract synapse not only with postganglionic cholinergic fibers, but also with a network of noncholinergic intramural neurons. In addition, vagal stimulation of gastrin secretion is mediated by gastrin-releasing peptide (GRP), not ACh. The gastric parietal cell secretes acid in response to at least 3 agonists: gastrin, histamine, and ACh; furthermore, stimulation of muscarinic receptors on enterochromaffin-like cells will cause histamine release. Atropine inhibits the component of acid secretion that results from muscarinic stimulation of enterochromaffin cells and parietal cells (see Figure 45–1).

**Secretions.** Salivary secretion is particularly sensitive to inhibition by muscarinic receptor antagonists, which can completely abolish the copious, watery secretion induced by parasympathetic stimulation. The mouth becomes dry, and swallowing and talking may become difficult. *Gastric secretion* during the cephalic and fasting phases is also reduced markedly by muscarinic receptor antagonists. In contrast, the intestinal phase of gastric secretion is only partially inhibited. Although muscarinic antagonists can reduce gastric secretion, the doses required also affect salivary secretion, ocular accommodation, micturition, and GI motility (see Table 9–2). Thus, histamine H₂ receptor antagonists and proton pump inhibitors have replaced muscarinic antagonists as inhibitors of acid secretion (see Chapter 45).

**Motility.** The parasympathetic nerves enhance both tone and motility and relax sphincters, thereby favoring the passage of gastrointestinal contents. Muscarinic
antagonists produce prolonged inhibitory effects on the motor activity of the stomach, duodenum, jejunum, ileum, and colon, characterized by a reduction in tone, amplitude and frequency of peristaltic contractions. Relatively large doses are needed to produce such inhibition. This probably can be explained by the ability of the enteric nervous system to regulate motility independently of parasympathetic control (see Chapter 8 and Figure 46–1).

OTHER SMOOTH MUSCLE

Urinary Tract. Muscarinic antagonists decrease the normal tone and amplitude of contractions of the ureter and bladder, and often eliminate drug-induced enhancement of ureteral tone. However, this inhibition cannot be achieved in the absence of inhibition of salivation and lacrimation and blurring of vision (see Table 9–2).

Biliary Tract. Atropine exerts a mild antispasmodic action on the gallbladder and bile ducts in humans. However, this effect usually is not sufficient to overcome or prevent the marked spasm and increase in biliary duct pressure induced by opioids, for which nitrates (see Chapter 27) are more effective.

SWEAT GLANDS AND TEMPERATURE. Small doses of atropine inhibit the activity of sweat glands innervated by sympathetic cholinergic fibers, and the skin becomes hot and dry. Sweating may be depressed enough to raise the body temperature, but only notably so after large doses or at high environmental temperatures.

CNS. Atropine has minimal effects on the CNS at therapeutic doses, although mild stimulation of the parasympathetic medullary centers may occur. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, hallucinations, or delirium. With still larger doses, stimulation is followed by depression, leading to circulatory collapse and respiratory failure after a period of paralysis and coma. In contrast to atropine, scopolamine has prominent central effects at low therapeutic doses; atropine therefore is preferred over scopolamine for many purposes. The basis for this difference is probably the greater permeation of scopolamine across the blood-brain barrier. Specifically, scopolamine in therapeutic doses normally causes CNS depression manifest as drowsiness, amnesia, fatigue, and dreamless sleep, with a reduction in REM sleep. Scopolamine is effective in preventing
motion sickness.

Muscarinic receptor antagonists have long been used in the treatment of Parkinson disease. These agents can be effective adjuncts to treatment with levodopa (see Chapter 22). Muscarinic receptor antagonists also are used to treat the extrapyramidal symptoms that commonly occur as side effects of conventional antipsychotic drug therapy (see Chapter 16). Certain antipsychotic drugs are relatively potent muscarinic receptor antagonists and, perhaps for this reason, cause fewer extrapyramidal side effects.

**IPRATROPIUM AND TIOTROPIUM.** The quaternary ammonium compounds ipratropium and tiotropium are used exclusively for their effects on the respiratory tract. When inhaled, their action is confined almost completely to the mouth and airways. Dry mouth is the only frequently reported side effect, as the absorption of these drugs from the lungs or the GI tract is very inefficient. Ipratropium appears to block all subtypes of muscarinic receptors and accordingly also antagonizes the inhibition of ACh release by presynaptic M₂ receptors on parasympathetic postganglionic nerve terminals in the lung; the resulting increase in ACh release may counteract its blockade of M₃ receptor-mediated bronchoconstriction. In contrast, tiotropium shows some selectivity for M₁ and M₃ receptors; its lower affinity for M₂ receptors minimizes its presynaptic effect to enhance ACh release.

**ABSORPTION, DISTRIBUTION, AND ELIMINATION.** The belladonna alkaloids and the tertiary synthetic and semisynthetic derivatives are absorbed rapidly from the GI tract. They also enter the circulation when applied locally to the mucosal surfaces of the body. Absorption from intact skin is limited, although efficient absorption does occur in the postauricular region for some agents, allowing delivery by transdermal patch. Systemic absorption of inhaled or orally ingested quaternary muscarinic receptor antagonists is limited even from the conjunctiva of the eye. Quaternary agents do not cross the blood-brain barrier. Atropine has a $t_{1/2}$ of ~4 h; hepatic metabolism accounts for the elimination of about half of a dose; the remainder is excreted unchanged in the urine.
Ipratropium is administered as an aerosol or solution for inhalation whereas tiotropium is administered as a dry powder. As with most drugs administered by inhalation, ~90% of the dose is swallowed. Most of the swallowed drug appears in the feces. Maximal responses develop over 30-90 min, with tiotropium having the slower onset. The effects of ipratropium last for 4-6 h, while tiotropium’s effects persist for 24 h.

**THERAPEUTIC USES OF MUSCARINIC RECEPTOR ANTAGONISTS**

Muscarinic receptor antagonists have been used in the treatment of a wide variety of clinical conditions, predominantly to inhibit effects of parasympathetic activity in the respiratory tract, urinary tract, GI tract, eye, and heart. Their CNS effects have resulted in their use in the treatment of Parkinson disease, the management of extrapyramidal side effects of antipsychotic drugs, and the prevention of motion sickness.

**RESPIRATORY TRACT.** Ipratropium (Atrovent, others) and tiotropium (Spiriva) are important agents in the treatment of chronic obstructive pulmonary disease. These agents often are used with inhaled long-acting β₂ adrenergic receptor agonists. Ipratropium is administered 4 times daily via a metered-dose inhaler or nebulizer; tiotropium is administered once daily via a dry powder inhaler (see Chapter 36). Ipratropium also is used in nasal inhalers for the treatment of the rhinorrhea associated with the common cold or with allergic or nonallergic perennial rhinitis.

**GENITOURINARY TRACT.** Overactive urinary bladder can be successfully treated with muscarinic receptor antagonists. Muscarinic antagonists can be used to treat enuresis in children, particularly when a progressive increase in bladder capacity is the objective, and to reduce urinary frequency and increase bladder capacity in spastic paraplegia. The muscarinic receptor antagonists indicated for overactive bladder are oxybutynin (Ditropan, others), tolterodine (Detrol), trospium chloride (Sanctura), darifenacin (Enablex), solifenacin (Vesicare), and fesoterodine (Toviaz); available preparations and dosages are summarized in Table 9–3. The most important adverse reactions are consequences of muscarinic receptor blockade and include xerostomia, blurred vision, and GI
side effects such as constipation and dyspepsia. CNS-related antimuscarinic effects, including drowsiness, dizziness, and confusion, can occur and are particularly problematic in elderly patients.

*Preparations are designated as follows: IR, immediate-release tablet; ER, extended-release tablet or capsule.

<sup>a</sup>Doses may need to be reduced in patients taking drugs that inhibit CYP3A4.

<sup>b</sup>Longer times in indicated ranges are seen in poor metabolizers.

<sup>c</sup>Doses should be reduced in patients with significant renal or hepatic impairment.

<sup>d</sup>Doses should be reduced in patients with significant renal impairment; dosage adjustments also may be needed in patients with hepatic impairment.

<sup>e</sup>Doses may need to be reduced in patients taking drugs that inhibit CYPs 3A4 or 2D6.

**GI TRACT.** Although muscarinic receptor antagonists can reduce gastric motility and the secretion of gastric acid, antisecretory doses produce pronounced side effects (see Table 9–2). As a consequence, patient compliance in the long-term management of symptoms of acid-peptic disease with these drugs is poor. Pirenzepine, a tricyclic drug similar in structure to imipramine, has selectivity for M<sub>1</sub> over M<sub>2</sub> and M<sub>3</sub> receptors. However, pirenzepine’s affinities for M<sub>1</sub> and M<sub>4</sub> receptors are comparable, so it does not possess total M<sub>1</sub> selectivity. Telenzepine, an analog of pirenzepine, has higher potency and similar selectivity for M<sub>1</sub> muscarinic receptors. Both drugs are used in the treatment of acid-peptic disease in Europe, Japan, and Canada, but not currently in the U.S. At therapeutic doses of pirenzepine, the incidence of xerostomia, blurred vision, and central muscarinic disturbances is relatively low. Central effects are not seen because of the drug’s limited penetration into the CNS. H<sub>2</sub> receptor antagonists
and proton pump inhibitors generally are the current drugs of choice to reduce gastric acid secretion (see Chapter 45).

The belladonna alkaloids (atropine, hyoscyamine sulfate [ANASPraz, others], and scopolamine) alone or in combination with sedatives (phenobarbital [DONNatal, others]) or anti-anxiety agents (chlordiazepoxide [LIBrax]) have been used in a variety of conditions known to involve irritable bowel and increased tone (spasticity) or motility of the GI. Glycopyrrolate (ROBINul, others), a muscarinic antagonist structurally unrelated to the belladonna alkaloids, also is used to reduce GI tone and motility; as a quaternary amine, it is less likely to cause adverse CNS effects. The belladonna alkaloids and synthetic substitutes are very effective in reducing excessive salivation, such as drug-induced salivation and that associated with heavy-metal poisoning and Parkinson disease. A subtherapeutic dose of atropine is included with diphenoxylate in antidiarrheal LOMOTIL to discourage overuse.

Dicyclomine hydrochloride (BENTyl, others) is a weak muscarinic receptor antagonist that also has nonspecific direct spasmylytic effects on smooth muscle of the GI tract. It is occasionally used in the treatment of diarrhea-predominant irritable bowel syndrome.

**EYE.** Effects limited to the eye are obtained by topical administration of muscarinic receptor antagonists to produce mydriasis and cycloplegia. Cycloplegia is not attainable without mydriasis and requires higher concentrations or more prolonged application of a given agent. Homatropine hydrobromide (ISOPTO HOMATROPINE, others), a semisynthetic derivative of atropine, cyclopentolate hydrochloride (CYCLOGYL, others), and tropicamide (MYDRIACYL, others) are agents used in ophthalmological practice. These agents are preferred to topical atropine or scopolamine because of their shorter duration of action (see Chapter 64).

**CARDIOVASCULAR SYSTEM.** The cardiovascular effects of muscarinic receptor antagonists are of limited clinical utility. Atropine may be considered in the initial treatment of patients with acute myocardial infarction in whom excessive vagal tone causes sinus bradycardia or AV nodal block. Dosing must be judicious; doses that are too low can cause a paradoxical bradycardia (described earlier), while excessive doses will cause tachycardia that may extend the infarct by increasing the demand for oxygen. Atropine may reduce the
degree of AV block when increased vagal tone is a major factor in the conduction defect, such as the second-degree AV block that can be produced by digitalis.

**CNS.** Scopolamine is the most effective prophylactic agent for short (4-6 h) exposures to severe motion, and probably for exposures of up to several days. All agents used to combat motion sickness should be given prophylactically. A transdermal preparation of scopolamine (TRANSDERM SCOP), used for the prevention of motion sickness, is applied to the postauricular mastoid region, an area where transdermal absorption of the drug is especially efficient, resulting in the delivery of ~0.5 mg of scopolamine over 72 h. Dry mouth is common, drowsiness is not infrequent, and blurred vision occurs in some individuals. Mydriasis and cycloplegia can occur. Rare but severe psychotic episodes have been reported. Centrally acting muscarinic antagonists are efficacious in preventing extrapyramidal side effects such as dystonias or parkinsonian symptoms in patients treated with antipsychotic drugs (see Chapter 16). The muscarinic antagonists used for Parkinson disease and drug-induced extrapyramidal symptoms include benztropine mesylate (COGENTIN, others), trihexyphenidyl hydrochloride (ARTANE, others), and biperiden; all are tertiary amines that readily gain access to the CNS.

**USES IN ANESTHESIA.** Atropine commonly is given to block responses to vagal reflexes induced by surgical manipulation of visceral organs. Atropine or glycopyrrolate is used with neostigmine to block its parasympathomimetic effects when the latter agent is used to reverse skeletal muscle relaxation after surgery (see Chapter 11). Serious cardiac arrhythmias have occasionally occurred.

**ANTICHOLINESTERASE POISONING.** The use of atropine in large doses for the treatment of poisoning by anticholinesterase organophosphorus insecticides is discussed in Chapter 10. Atropine also may be used to antagonize the parasympathomimetic effects of pyridostigmine or other anticholinesterases administered in the treatment of myasthenia gravis. It is most useful early in therapy, before tolerance to muscarinic side effects of anticholinesterases have developed.

**OTHER THERAPEUTIC USES OF MUSCARINIC ANTAGONISTS.** Methscopolamine bromide (PAMINE) is a quaternary ammonium derivative of
Scopolamine is primarily used in combination products for the temporary relief of symptoms of allergic rhinitis, sinusitis, and the common cold.

**CONTRAINDICATIONS AND ADVERSE EFFECTS**

Most contraindications, precautions, and adverse effects of muscarinic antagonists are predictable consequences of muscarinic receptor blockade: xerostomia, constipation, blurred vision, dyspepsia, and cognitive impairment. Important contraindications to the use of muscarinic antagonists include urinary tract obstruction, GI obstruction, and uncontrolled (or susceptibility to attacks of) angle-closure glaucoma.

**TOXICOLOGY OF DRUGS WITH ANTIMUSCARINIC PROPERTIES**

The deliberate or accidental ingestion of natural belladonna alkaloids is a major cause of poisonings. Many histamine H$_1$ receptor antagonists, phenothiazines, and tricyclic antidepressants also block muscarinic receptors and, in sufficient dosage, produce syndromes that include features of atropine intoxication.

Among the tricyclic antidepressants, protriptyline and amitriptyline are the most potent muscarinic receptor antagonists, with an affinity for the receptor that is ~ one-tenth of that reported for atropine. Since these drugs are administered in therapeutic doses considerably higher than the effective dose of atropine, antimuscarinic effects are often observed clinically (see Chapter 15) and overdose with suicidal intent is a danger in the population using antidepressants. Fortunately, most of the newer antidepressants and SSRIs have more limited anticholinergic properties. The newer antipsychotic drugs, classified as “atypical” and characterized by their low propensity for inducing extrapyramidal side effects, also include agents that are potent muscarinic receptor antagonists (e.g., clozapine and olanzapine). A paradoxical side effect of clozapine is increased salivation and drooling, possibly the result of partial agonist properties of this drug.
Infants and young children are especially susceptible to the toxic effects of muscarinic antagonists. Indeed, cases of intoxication in children have resulted from conjunctival instillation for ophthalmic refraction and other ocular effects. Systemic absorption occurs either from the nasal mucosa after the drug has traversed the nasolacrimal duct or from the GI tract if the drug is swallowed. Poisoning with diphenoxylate-atropine (LOMOTIL, others), used to treat diarrhea, has been extensively reported in the pediatric literature. Transdermal preparations of scopolamine used for motion sickness have been noted to cause toxic psychoses, especially in children and in the elderly. Jimson weed contains a variety of belladonna alkaloids; serious intoxication can result from ingestion and smoking of the plant.

Table 9–2 shows the oral doses of atropine causing undesirable responses or symptoms of overdosage. These symptoms are predictable results of blockade of parasympathetic innervation. In cases of full-blown atropine poisoning, the syndrome may last 48 h or longer. Intravenous injection of the anticholinesterase agent physostigmine may be used for confirmation. Depression and circulatory collapse are evident only in cases of severe intoxication; the blood pressure declines, convulsions may ensue, respiration becomes inadequate, and death due to respiratory failure may follow. If marked excitement is present and more specific treatment is not available, a benzodiazepine is the most suitable agent for sedation and for control of convulsions. Phenothiazines or agents with antimuscarinic activity should not be used, because their antimuscarinic action is likely to intensify toxicity. Support of respiration and control of hyperthermia may be necessary.
chapter 10
Anticholinesterase Agents

Acetylcholinesterase (AChE) terminates the action of acetylcholine (ACh) at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites (see Chapter 8). Drugs that inhibit AChE are called anticholinesterase (anti-ChE) agents. They cause ACh to accumulate in the vicinity of cholinergic nerve terminals and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems. The anti-ChE agents have received extensive application as toxic agents, in the form of agricultural insecticides, pesticides, and potential chemical warfare “nerve gases.” Nevertheless, some compounds of this class are used therapeutically for the treatment of Alzheimer disease.

History. Physostigmine, also called eserine, is an alkaloid obtained from the Calabar or ordeal bean, the dried, ripe seed of Physostigma venenosum, a West African perennial. The Calabar bean once was used by native tribes of West Africa as an “ordeal poison” in trials for witchcraft, in which guilt was judged by death from the poison, innocence by survival after ingestion of a bean. The recent suggestion that we apply this test to politicians was narrowly rejected on humanitarian grounds.

Prior to World War II, only the “reversible” anti-ChE agents were generally known, of which physostigmine is the prototype. Shortly before and during World War II, a new class of highly toxic chemicals, the organophosphates, was developed, first as agricultural insecticides and later as potential chemical warfare agents. The extreme toxicity of these compounds is due to their “irreversible” inactivation of AChE, which results in prolonged enzyme inhibition. Because the pharmacological actions of both the reversible and irreversible anti-ChE agents are qualitatively similar, they are discussed here as a group.
STRUCTURE OF ACETYLCHOLINESTERASE. AChE exists in 2 general molecular classes: simple homomeric oligomers of catalytic subunits and heteromeric associations of catalytic subunits with structural subunits. The homomeric forms are found as soluble species in the cell, presumably destined for export or for association with the outer membrane of the cell, typically through an attached glycoprophospholipid. One heteromeric form, largely found in neuronal synapses, is a tetramer of catalytic subunits disulfide-linked to a 20-kDa lipid-linked subunit and localized to the outer surface of the cell membrane. The other heteromeric form consists of tetramers of catalytic subunits, disulfide linked to each of 3 strands of a collagen-like structural subunit. This molecular species, whose molecular mass approaches $10^6$ Da, is associated with the basal lamina of junctional areas of skeletal muscle. A separate, structurally related gene encodes butyrylcholinesterase, which is synthesized in the liver and is primarily found in plasma.

The active center of mammalian AChE is at the base of a 2 nm gorge, at the bottom of which lie the catalytic triad (Ser203, His447, and Glu334), an acyl pocket, and a choline subsite; a “peripheral” site lies at the mouth of the gorge. The interactions of ligands with AChE can be usefully considered by examining their interactions with these domains (see Figure 10–1). The catalytic mechanism resembles that of other hydrolases; the serine hydroxyl group is rendered highly nucleophilic through a charge-relay system involving the carboxylate anion from glutamate, the imidazole of histidine, and the hydroxyl of serine (Figure 10–1A). During enzymatic attack of ACh, an ester with trigonal geometry, a tetrahedral intermediate between enzyme and substrate is formed (see Figure 10–1A) that collapses to an acetyl enzyme conjugate with the concomitant release of choline. The acetyl enzyme is very labile to hydrolysis, which results in the formation of acetate and active enzyme. AChE is one of the most efficient enzymes known: 1 molecule of AChE can hydrolyze $6 \times 10^5$ ACh molecules/min; this yields a turnover time of 100 μsec.
Figure 10–1 Steps involved in the hydrolysis of acetylcholine by acetylcholinesterase and in the inhibition and reactivation of the enzyme. Only the 3 residues of the catalytic triad are depicted. The associations and reactions shown are: A. Acetylcholine (ACh) catalysis: binding of ACh, formation of a tetrahedral transition state, formation of the acetyl enzyme with liberation of choline, rapid hydrolysis of the acetyl enzyme with return to the original state. B. Reversible binding and inhibition by edrophonium. C. Neostigmine reaction with and inhibition of AChE: reversible binding of neostigmine, formation of the dimethyl carbamoyl enzyme, slow hydrolysis of the dimethyl carbamoyl enzyme. D. Diisopropyl fluorophosphate (DFP) reaction and inhibition of AChE: reversible binding of DFP, formation of the diisopropyl phosphoryl enzyme, formation of the aged monoisopropyl phosphoryl enzyme. Hydrolysis of the diisopropyl enzyme is very slow (not shown). The aged monoisopropyl phosphoryl enzyme is virtually resistant to hydrolysis and reactivation. The tetrahedral transition state of ACh hydrolysis resembles the conjugates formed by the tetrahedral phosphate inhibitors and accounts for their potency. Amide bond hydrogens from Gly121 and Gly122 stabilize the carbonyl and phosphoryl oxygens. E. Reactivation of the diisopropyl phosphoryl enzyme by pralidoxime (2-PAM). 2-PAM attack of the phosphorus on the phosphorylated enzyme will
form a phospho-oxime with regeneration of active enzyme.

MECHANISM OF ACTION OF AChE INHIBITORS. Anti-ChE agents are divided into 3 classes whose interactions with AChE are depicted Figure 10–1: noncovalent “reversible’ inhibitors,” carbamoylating inhibitors, and organophosphate inhibitors.

• **Reversible inhibitors**, such as edrophonium and tacrine, bind to the choline subsite (Figure 10–1B). Additional reversible inhibitors include donepezil, propidium, and the peptidic snake toxin fasciculin.

• **Carbamoylating inhibitors** with a carbamoyl ester linkage, such as physostigmine and neostigmine, are hydrolyzed by AChE, generating the carbamoylated enzyme (Figure 10–1C). In contrast to the acetyl enzyme, methylcarbamoyl AChE and dimethylcarbamoyl AChE are far more stable (the $t_{1/2}$ for hydrolysis of the dimethylcarbamoyl enzyme is 15-30 min). Sequestration of the enzyme in its carbamoylated form thus precludes the enzyme-catalyzed hydrolysis of ACh for extended periods of time. When administered systemically, the duration of inhibition is 3-4 h.

• **Organophosphate inhibitors**, such as diisopropyl fluorophosphate (DFP), form very stable conjugates with AChE, with the active center serine phosphorylated or phosphonylated (Figure 10–1D). If the alkyl groups in the phosphorylated enzyme are ethyl or methyl, spontaneous regeneration of active enzyme requires several hours. Secondary (as in DFP) or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and significant regeneration of active enzyme usually is not observed. The stability of the phosphorylated enzyme is strengthened through “aging,” which results from the loss of 1 of the alkyl groups.

Thus, the terms reversible and irreversible as applied to the carbamoyl ester and organophosphate anti-ChE agents, respectively, reflect only quantitative differences in rates of decarbamoylation or dephosphorylation of the conjugated enzyme. Both chemical classes react covalently with the active center serine in essentially the same manner as does ACh.

**ACTION AT EFFECTOR ORGANS.** The characteristic pharmacological effects of the anti-ChE agents are due primarily to
the prevention of hydrolysis of ACh by AChE at sites of cholinergic transmission. Transmitter thus accumulates, enhancing the response to released ACh. Virtually all acute effects of moderate doses of organophosphates are attributable to this action.

The consequences of enhanced concentrations of ACh at motor endplates are unique to these sites and are discussed later. The tertiary amine and particularly the quaternary ammonium anti-ChE compounds may have additional direct actions at certain cholinergic receptor sites (e.g., the effects of neostigmine on the spinal cord and neuromuscular junction are based on a combination of its anti-ChE activity and direct cholinergic stimulation).

CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIPS

NONCOVALENT INHIBITORS. While these agents interact by reversible and noncovalent association with the active site in AChE, they differ in their disposition in the body and their affinity for the enzyme.

*Edrophonium*, a quaternary drug whose activity is limited to peripheral nervous system synapses, has a moderate affinity for AChE (see Figure 10–1B). Its volume of distribution is limited and renal elimination is rapid, accounting for its short duration of action. By contrast, *tacrine* and *donepezil* have higher affinities for AChE, are more hydrophobic, and readily cross the blood-brain barrier to inhibit AChE in the CNS.

“REVERSIBLE” CARBAMATE INHIBITORS. Drugs of this class that are of therapeutic interest include physostigmine, neostigmine, and rivastigmine. Their interaction with AChE is depicted in Figure 10–1C.
The essential moiety of the physostigmine molecule is the methyl carbamate of an amine-substituted phenol. An increase in anti-ChE potency and duration of action can result from the linking of 2 quaternary ammonium moieties. An example is the miotic agent demecarium, which consists of 2 neostigmine molecules connected by a series of 10 methylene groups. The second quaternary group confers additional stability to the interaction. Carbamoylating inhibitors with high lipid solubilities (e.g., rivastigmine), which readily cross the blood-brain barrier and have longer durations of action, are approved or in clinical trial for the treatment of Alzheimer disease (see Chapter 22).

The carbamate insecticides carbaryl (SEVIN), propoxur (BAYGON), and aldicarb (TEMIK), which are used extensively as garden insecticides, inhibit ChE in a fashion identical with other carbamoylating inhibitors. The symptoms of poisoning closely resemble those of the organophosphates.

**ORGANOPHOSPHORUS COMPOUNDS.** The general formula for this class of ChE inhibitors is shown at the top of Table 10–1. The group includes DFP, soman, malathion, and echothiophate.

Table 10–1

**Representative Organophosphorus Compounds**
DFP produces virtually irreversible inactivation of AChE and other esterases by diisopropylphosphorylation followed by “aging” (conversion to the monoisopropylphosphoryl AChE (see Figure 10–1D). Its high lipid solubility, low molecular weight, and volatility facilitate inhalation, transdermal absorption, and penetration into the CNS. The “nerve gases”—tabun, sarin, and soman—are among the most potent synthetic toxins known; they are lethal to laboratory animals in nanogram doses. Insidious employment of these agents has occurred in warfare and terrorism attacks. Because of their low volatility and stability in aqueous solution, parathion and methylparathion were widely used as insecticides; however, acute and chronic toxicity has limited their use. These compounds are inactive in inhibiting AChE in vitro; paraoxon is the active
metabolite produced in vivo via a substitution of phosphoryl oxygen for sulfur carried out by hepatic CYPs. This reaction also occurs in the insect, typically with more efficiency than in mammals and many other animals. Other insecticides possessing the phosphorothioate structure have been widely employed, including diazinon (SPECTRACIDE, others) and chlorpyrifos (DURSBAN, LORSBAN). Both of these agents have been placed under restricted use because of evidence of chronic toxicity in the newborn animal. They have been banned since 2005.

_Malathion_ (CHEMATHION, MALA-SPRAY) also requires replacement of a sulfur atom with oxygen in vivo, conferring resistance in mammalian species. This insecticide can be detoxified by hydrolysis of the carboxyl ester linkage by plasma carboxylesterases, and plasma carboxylesterase activity dictates species resistance to malathion. The detoxification reaction is much more rapid in mammals and birds than in insects. Malathion has been employed in aerial spraying of relatively populous areas for control of citrus orchard-destructive Mediterranean fruit flies and mosquitoes that harbor and transmit viruses harmful to human beings (e.g., West Nile encephalitis virus). Evidence of acute toxicity from malathion arises only with suicide attempts or deliberate poisoning. The lethal dose in mammals is ~1 g/kg. Exposure to the skin results in a small fraction (<10%) of systemic absorption. Malathion is used topically in the treatment of pediculosis (lice) infestations.

Of the quaternary organophosphate AChE inhibitors (see Table 10–1, group D), only _echothiophate_ is useful clinically and it is limited to ophthalmic administration. Being positively charged, it is not volatile and does not readily penetrate the skin.

**PHARMACOLOGICAL PROPERTIES**

Anti-ChE agents potentially can produce all the following effects:

- Stimulation of muscarinic receptor responses at autonomic effector organs
- Stimulation, followed by depression or paralysis, of all autonomic ganglia and skeletal muscle (nicotinic actions)
- Stimulation, with occasional subsequent depression, of cholinergic receptor sites in the CNS
In general, compounds containing a quaternary ammonium group do not penetrate cell membranes readily; hence, anti-ChE agents in this category are absorbed poorly from the GI tract or across the skin and are excluded from the CNS by the blood-brain barrier after moderate doses. However, such compounds act preferentially at the neuromuscular junctions of skeletal muscle, exerting their action both as anti-ChE agents and as direct agonists. They have comparatively less effect at autonomic effector sites and ganglia.

By contrast, the more lipid-soluble agents are well absorbed after oral administration, have ubiquitous effects at both peripheral and central cholinergic sites, and may be sequestered in lipids for long periods of time. Lipid-soluble organophosphorus agents also are well absorbed through the skin, and the volatile agents are transferred readily across the alveolar membrane.

The actions of anti-ChE agents where the receptors are largely of the muscarinic type are blocked by atropine. The sites of action of anti-ChE agents of therapeutic importance are the CNS, eye, intestine, and the neuromuscular junction of skeletal muscle; other actions are of toxicological consequence.

**EYE.** When applied locally to the conjunctiva, anti-ChE agents cause conjunctival hyperemia and constriction of the pupillary sphincter muscle around the pupillary margin of the iris (miosis) and the ciliary muscle (block of accommodation reflex with resultant focusing to near vision). Miosis is apparent in a few minutes and can last several hours to days. The block of accommodation is more transient and generally disappears before termination of miosis. Intraocular pressure, when elevated, usually falls as the result of facilitation of outflow of the aqueous humor (see Chapter 64).

**GI TRACT.** In humans, neostigmine enhances gastric contractions and increases the secretion of gastric acid. The lower portion of the esophagus is stimulated by neostigmine; in patients with marked achalasia and dilation of the esophagus, the drug can cause a salutary increase in tone and peristalsis. Neostigmine also augments motor activity of the small and large bowel; the colon is particularly stimulated. Propulsive waves are increased in amplitude and frequency, and movement of intestinal contents is thus promoted. The effect of anti-ChE agents on intestinal motility probably represents a combination of actions at the
ganglion cells of the myenteric (Auerbach) plexus and at the smooth muscle fibers (see Chapter 46).

NEUROMUSCULAR JUNCTION. Most of the effects of potent anti-ChE drugs on skeletal muscle can be explained adequately on the basis of their inhibition of AChE at neuromuscular junctions. However, there is good evidence for an accessory direct action of neostigmine and other quaternary ammonium anti-ChE agents on skeletal muscle.

The lifetime of free ACh within the nerve-muscle synapse (~200 μsec) is shorter than the decay of the endplate potential or the refractory period of the muscle. Therefore, each nerve impulse gives rise to a single wave of depolarization on the muscle fiber. After inhibition of AChE, the residence time of ACh in the synapse increases, allowing for lateral diffusion and interaction of the transmitter with multiple receptors. This successive stimulation of neighboring receptors site in the endplate results in a prolongation of the decay time of the endplate potential. Consequently, asynchronous excitation and fasciculations of muscle fibers occur. With sufficient inhibition of AChE, depolarization of the endplate predominates, and depolarization blockade ensues (see Chapter 11). When ACh persists in the synapse, it also may depolarize the axon terminal, resulting in antidromic firing of the motoneuron; this effect contributes to fasciculations that involve the entire motor unit.

The anti-ChE agents will reverse the antagonism caused by competitive neuromuscular blocking agents. Neostigmine is not effective against the skeletal muscle paralysis caused by succinylcholine; this agent also produces neuromuscular blockade by depolarization, and depolarization will be enhanced by neostigmine.

ACTIONS AT OTHER SITES. Secretory glands that are innervated by postganglionic cholinergic fibers include the bronchial, lacrimal, sweat, salivary, gastric (antral G cells and parietal cells), intestinal, and pancreatic acinar glands. Low doses of anti-ChE agents augment secretory responses to nerve stimulation, and higher doses actually produce an increase in the resting rate of secretion. Anti-ChE agents increase contraction of smooth muscle fibers of bronchioles and ureters, and ureters may show increased peristaltic activity.

The cardiovascular actions of anti-ChE agents are complex; they reflect both
ganglionic and postganglionic effects of accumulated ACh on the heart and blood vessels and actions in the CNS. The predominant effect on the heart from the peripheral action of accumulated ACh is bradycardia, resulting in a fall in cardiac output. Higher doses usually cause a fall in blood pressure, often as a consequence of effects of anti-ChE agents on the medullary vasomotor centers of the CNS.

Anti-ChE agents augment vagal influences on the heart, thereby shortening the effective refractory period of atrial muscle fibers and increasing the refractory period and conduction time at the SA and AV nodes. At the ganglionic level, accumulating ACh initially is excitatory on nicotinic receptors, but at higher concentrations, ganglionic blockade ensues as a result of persistent depolarization. The excitatory action on the parasympathetic ganglion cells can reinforce the diminished cardiac output, whereas enhanced cardiac function would result from the action of ACh on sympathetic ganglion cells. ACh also elicits excitation followed by inhibition at the central medullary vasomotor and cardiac centers. These effects are complicated by the hypoxemia resulting from the bronchoconstrictor and secretory actions of increased ACh on the respiratory system; hypoxemia, in turn, can reinforce both sympathetic tone and ACh-induced discharge of epinephrine from the adrenal medulla. Hence, it is not surprising that an increase in heart rate is seen with severe ChE inhibitor poisoning. Hypoxemia is a major factor in the CNS depression after large doses of anti-ChE agents. The CNS-stimulant effects are antagonized by larger doses of atropine, although not as completely as are the muscarinic effects at peripheral autonomic effector sites.

**ADME.** Physostigmine is absorbed readily from the GI tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures (e.g., pressure on the inner canthus) are not taken to prevent absorption from the nasal mucosa. Parenterally administered physostigmine is largely destroyed within 2-3 h by plasma esterases; renal excretion plays only a minor role in its elimination. Neostigmine and pyridostigmine are absorbed poorly after oral administration; the effective parenteral dose of neostigmine is 0.5-2 mg whereas the equivalent oral dose may be 15-30 mg or more. Neostigmine and pyridostigmine are destroyed by plasma esterases, and the quaternary aromatic alcohols and parent compounds are excreted in the urine; the half-lives of these drugs are 1-2 h.
Organophosphate anti-ChE agents with the highest risk of toxicity are highly lipid-soluble liquids; many have high vapor pressures. The less volatile agents that are commonly used as agricultural insecticides (e.g., diazinon, malathion) generally are dispersed as aerosols or as dusts adsorbed to an inert, finely particulate material. Consequently, the compounds are absorbed rapidly through the skin and mucous membranes following contact with moisture, by the lungs after inhalation, and by the GI tract after ingestion.

Following their absorption, most organophosphates are hydrolyzed by plasma and liver esterases; the hydrolysis products are excreted in the urine. *Plasma and liver esterases are responsible for hydrolysis to the corresponding phosphoric and phosphonic acids. However, the CYPs are responsible for converting the inactive phosphorothioates containing a phosphorus-sulfur (thiono) bond to phosphorates with a phosphorus-oxygen bond, resulting in their activation.* These enzymes also play a role in the inactivation of certain organophosphorus agents, and allelic differences are known to affect rates of metabolism. Plasma and hepatic carboxylesterases (aliesterases) and plasma butyrylcholinesterase are inhibited irreversibly by organophosphates; their scavenging capacity for organophosphates affords partial protection against inhibition of AChE in the nervous system. The carboxylesterases also catalyze hydrolysis of malathion and other organophosphates that contain carboxyl-ester linkages, rendering them less active or inactive. Since carboxylesterases are inhibited by organophosphates, toxicity from simultaneous exposure to 2 organophosphorus insecticides can be synergistic.

**TOXICOLOGY**

The toxicological aspects of the anti-ChE agents are of practical importance to clinicians. In addition to cases of accidental intoxication from the use and manufacture of organophosphorus compounds as agricultural insecticides, these agents have been used frequently for homicidal and suicidal purposes. Organophosphates account for as many as 80% of pesticide-related hospital admissions. Pesticide toxicity is a widespread global problem associated with >200,000 deaths a year; most poisonings occur in Southeast Asia. Occupational exposure occurs most commonly by the dermal and pulmonary routes,
while oral ingestion is most common in cases of nonoccupational poisoning.

**ACUTE INTOXICATION.** The effects of acute intoxication by anti-ChE agents are manifested by muscarinic and nicotinic signs and symptoms, and, except for compounds of extremely low lipid solubility, by signs referable to the CNS. The broad spectrum of effects of acute AChE inhibition on the CNS includes confusion, ataxia, slurred speech, loss of reflexes, Cheyne-Stokes respiration, generalized convulsions, coma, and central respiratory paralysis. Actions on the vasomotor and other cardiovascular centers in the medulla oblongata lead to hypotension.

Systemic effects appear within minutes after inhalation of vapors or aerosols. The onset of symptoms is delayed after GI and percutaneous absorption. The duration of toxic symptoms is determined largely by the properties of the compound: its lipid solubility, whether it must be activated to form the oxon, the stability of the organophosphate-AChE bond, and whether “aging” of the phosphorylated enzyme has occurred.

After local exposure to vapors or aerosols or after their inhalation, ocular and respiratory effects generally appear first. Ocular manifestations include marked miosis, ocular pain, conjunctival congestion, diminished vision, ciliary spasm, and brow ache. With acute systemic absorption, miosis may not be evident due to sympathetic discharge in response to hypotension. In addition to rhinorrhea and hyperemia of the upper respiratory tract, respiratory responses consist of tightness in the chest and wheezing respiration, caused by the combination of bronchoconstriction and increased bronchial secretion. GI symptoms occur earliest after ingestion and include anorexia, nausea and vomiting, abdominal cramps, and diarrhea.

With percutaneous absorption of liquid, localized sweating and muscle fasciculations in the immediate vicinity are generally the earliest symptoms. Severe intoxication is manifested by extreme salivation, involuntary defecation and urination, sweating, lacrimation, penile erection, bradycardia, and hypotension.

Nicotinic actions at the neuromuscular junctions of skeletal muscle usually consist of generalized weakness, involuntary twitchings, scattered fasciculations,
and eventually severe weakness and paralysis. The most serious consequence is paralysis of the respiratory muscles. The time of death after a single acute exposure may range from <5 min to nearly 24 h, depending on the dose, route, agent, and other factors. The cause of death primarily is respiratory failure, usually accompanied by a secondary cardiovascular component. Delayed symptoms appearing after 1-4 days and marked by persistent low blood ChE and severe muscle weakness are termed the intermediate syndrome. Delayed neurotoxicity also may be evident after severe intoxication.

**DIAGNOSIS AND TREATMENT.** In cases of mild or chronic intoxication, determination of the ChE activities in erythrocytes and plasma generally will establish the diagnosis. Although these values vary considerably in the normal population, they usually are depressed well below the normal range before symptoms are evident. Atropine in sufficient dosage effectively antagonizes the actions at muscarinic receptor sites, including increased tracheobronchial and salivary secretion, bronchoconstriction, bradycardia, and to a moderate extent, peripheral ganglionic and central actions.

Atropine should be given in doses sufficient to cross the blood-brain barrier. Following an initial injection of 2-4 mg, given intravenously if possible, otherwise intramuscularly, 2 mg should be given every 5-10 min until muscarinic symptoms disappear, if they reappear, or until signs of atropine toxicity appear. More than 200 mg may be required on the first day. A mild degree of atropine block then should be maintained for as long as symptoms are evident. The AChE reactivators can be of great benefit in the therapy of anti-ChE intoxication, but their use is supplemental to the administration of atropine.

Atropine is ineffective against the peripheral neuromuscular compromise caused by moderate or severe intoxication with an organophosphorus anti-ChE agent; the condition can be reversed by pralidoxime (2-PAM), a cholinesterase reactivator.

The recommended adult dose of pralidoxime is 1-2 g, infused intravenously over ≥5 min. If weakness is not relieved or if it recurs after 20-60 min, the dose should be repeated. Early treatment is very important to assure that the oxime reaches the phosphorylated AChE while the latter still can be reactivated. With severe toxicities from the lipid-soluble agents, it is necessary to continue treatment with atropine and pralidoxime for a week or longer.
General supportive measures also are important, including:

- Termination of exposure, by removal of the patient or application of a gas mask; removal of contaminated clothing; copious washing of contaminated skin or mucous membranes with water; gastric lavage, if indicated
- Maintenance of a patent airway, including endobronchial aspiration
- Artificial respiration; administration of O₂, if required
- Alleviation of persistent convulsions with diazepam (5-10 mg, intravenously)
- Treatment of shock

**CHOLINESTERASE REACTIVATORS.** The phosphorylated esteratic site of AChE undergoes hydrolytic regeneration at a slow or negligible rate, but nucleophilic agents, such as hydroxylamine (NH₂OH), hydroxamic acids (RCONH—OH), and oximes (RCH=NOH), reactivate the enzyme more rapidly than does spontaneous hydrolysis. Reactivation with pralidoxime occurs at a million times the rate of that with hydroxylamine. The oxime is oriented proximally to exert a nucleophilic attack on the phosphorus, forming a phosphoryloxime and regenerating the enzyme (Figure 10–1E). Several bis-quaternary oximes are more potent as reactivators for insecticide and nerve gas poisoning (e.g., HI-6, used in Europe as an antidote).

The reactivating action of oximes in vivo is most marked at the skeletal neuromuscular junction. Following a dose of an organophosphorus compound that produces total blockade of transmission, the intravenous injection of an oxime can restore the response to stimulation of the motor nerve within a few minutes. Antidotal effects are less striking at autonomic effector sites, and the quaternary ammonium group restricts entry into the CNS. Although high doses or accumulation of oximes can inhibit AChE and cause neuromuscular blockade, oximes should be given until one can be assured of clearance of the offending organophosphate. Many organophosphates partition into lipid and are released slowly as the active entity. Current antidotal therapy for organophosphate exposure resulting from warfare or terrorism includes parenteral atropine, an oxime (2-PAM or HI-6), and a benzodiazepine as an anticonvulsant. The oximes and their metabolites are readily eliminated by the kidney.
THERAPEUTIC USES

AVAILABLE AGENTS

Physostigmine salicylate (ANTILIRIUM) is available for injection. Physostigmine sulfate ophthalmic ointment and physostigmine salicylate ophthalmic solution also are available. Pyridostigmine bromide is available for oral (MESTINON) or parenteral (REGONOL, MESTINON) use. Neostigmine bromide (PROSTIGMIN) is available for oral use. Neostigmine methylsulfate (PROSTIGMIN) is marketed for parenteral injection. Ambenonium chloride (MYTELASE) is available for oral use. Tacrine (COGNEX), donepezil (ARICEPT), rivastigmine (EXELON), and galantamine (REMINYL) have been approved for the treatment of Alzheimer disease. Pralidoxime chloride (PROTOPAM CHLORIDE) is the only AChE reactivator currently available in the U.S. and can be obtained in a parenteral formulation. HI-6 is available in several European and Near Eastern countries.

USES. Current use of anti-AChE agents is limited to 4 conditions in the periphery:

• Atony of the smooth muscle of the intestinal tract and urinary bladder
• Glaucoma
• Myasthenia gravis
• Reversal of the paralysis of competitive neuromuscular blocking drugs

and 1 in the CNS:

• Treatment of dementia symptoms of Alzheimer disease
PARALYTIC ILEUS AND ATONY OF THE URINARY BLADDER.
Neostigmine generally is preferred among the anti-ChE agents in the treatment of these conditions. Directly acting muscarinic agonists (see Chapter 9) are employed for the same purposes. The usual subcutaneous dose of neostigmine methylsulfate for postoperative paralytic ileus is 0.5 mg, given as needed. Peristaltic activity commences 10-30 min after parenteral administration, whereas 2-4 h are required after oral administration of neostigmine bromide (15-30 mg). It may be necessary to assist evacuation with a small low enema or gas with a rectal tube. A similar dose of neostigmine is used for the treatment of atony of the detrusor muscle of the urinary bladder. Neostigmine should not be used when the intestine or urinary bladder is obstructed, when peritonitis is present, when the viability of the bowel is doubtful, or when bowel dysfunction results from inflammatory bowel disease.

GLAUCOMA AND OTHER OPHTHALMOLOGIC INDICATIONS. See Chapter 64.

MYASTHENIA GRAVIS. Myasthenia gravis is a neuromuscular disease characterized by weakness and marked fatigability of skeletal muscle; exacerbations and partial remissions occur frequently. The defect in myasthenia gravis is in synaptic transmission at the neuromuscular junction such that mechanical responses to nerve stimulation are not well sustained. Myasthenia gravis is caused by an autoimmune response primarily to the ACh receptor at the postjunctional endplate. Antireceptor antibodies are detectable in sera of 90% of patients with the disease. Immune complexes along with marked ultrastructural abnormalities appear in the synaptic cleft and enhance receptor degradation through complement-mediated lysis in the endplate. In ~10% of patients presenting with a myasthenic syndrome, muscle weakness has a congenital rather than an autoimmune basis, with mutations in the ACh receptor that affect ligand-binding and channel-opening kinetics, or mutations in the form of AChE that contains the collagen-like tail unit. Administration of anti-ChE agents does not result in subjective improvement in most congenital myasthenic patients.

Diagnosis. Although the diagnosis of autoimmune myasthenia gravis usually can be made from the history, signs, and symptoms, its differentiation from certain neurasthenic, infectious, endocrine, congenital, neoplastic, and degenerative neuromuscular diseases can be challenging. Myasthenia gravis is the only condition in which muscular weakness can be improved dramatically by anti-
ChE medication. The edrophonium test for evaluation of possible myasthenia gravis is performed by rapid intravenous injection of 2 mg of edrophonium chloride, followed 45 sec later by an additional 8 mg if the first dose is without effect; a positive response consists of brief improvement in strength, unaccompanied by lingual fasciculation (which generally occurs in nonmyasthenic patients).

An excessive dose of an anti-ChE drug results in a cholinergic crisis, a condition characterized by weakness resulting from generalized depolarization of the motor endplate; other features result from overstimulation of muscarinic receptors. The weakness resulting from depolarization blockade may resemble myasthenic weakness, which is manifest when anti-ChE medication is insufficient. The distinction is of obvious practical importance, because the former is treated by withholding, and the latter by administering, the anti-ChE agent. When the edrophonium test is performed cautiously (limiting the dose to 2 mg and with facilities for respiratory resuscitation available) a further decrease in strength indicates cholinergic crisis, while improvement signifies myasthenic weakness. Atropine sulfate, 0.4-0.6 mg or more intravenously, should be given immediately if a severe muscarinic reaction ensues. Detection of antireceptor antibodies in muscle biopsies or plasma is now widely employed to establish the diagnosis.

**Treatment.** Pyridostigmine, neostigmine, and ambenonium are the standard anti-ChE drugs used in the symptomatic treatment of myasthenia gravis. All can increase the response of myasthenic muscle to repetitive nerve impulses, primarily by the preservation of endogenous ACh. The optimal single oral dose of an anti-ChE agent can be determined empirically. Baseline recordings are made for grip strength, vital capacity, and a number of signs and symptoms that reflect the strength of various muscle groups. The patient then is given an oral dose of pyridostigmine (30-60 mg), neostigmine (7.5-15 mg), or ambenonium (2.5-5 mg). The improvement in muscle strength and changes in other signs and symptoms are noted at frequent intervals until there is a return to the basal state. After an hour or longer in the basal state, the drug is given again, with the dose increased to one and one-half times the initial amount, and the same observations are repeated. This sequence is continued, with increasing increments of one-half the initial dose, until an optimal response is obtained. The interval between oral doses required to maintain muscle strength usually is 2-4 h
for neostigmine, 3-6 h for pyridostigmine, or 3-8 h for ambenonium. However, the dose required may vary from day to day; physical or emotional stress, intercurrent infections, and menstruation usually necessitate an increase in the frequency or size of the dose. Unpredictable exacerbations and remissions of the myasthenic state may require adjustment of dosage.

Pyridostigmine is available in sustained-release tablets containing a total of 180 mg, of which 60 mg is released immediately and 120 mg over several hours; this preparation is of value in maintaining patients for 6–8-h periods, but should be limited to use at bedtime. Muscarinic cardiovascular and GI side effects of anti-ChE agents generally can be controlled by atropine or other anticholinergic drugs (see Chapter 9). However, these anticholinergic drugs mask many side effects of an excessive dose of an anti-ChE agent. In most patients, tolerance develops eventually to the muscarinic effects.

Several drugs, including curariform agents and certain antibiotics and general anesthetics, interfere with neuromuscular transmission (see Chapter 11); their administration to patients with myasthenia gravis requires proper adjustment of anti-ChE dosage and other precautions. Other therapeutic measures are essential elements in the management of this disease. Glucocorticoids promote clinical improvement in a high percentage of patients. Initiation of steroid treatment augments muscle weakness; however, as the patient improves with continued administration of steroids, doses of anti-ChE drugs can be reduced. Immunosuppressive agents such as azathioprine and cyclosporine have been beneficial in more advanced cases (see Chapter 35).

**ALZHEIMER DISEASE.** A deficiency of intact cholinergic neurons, particularly those extending from subcortical areas such as the nucleus basalis of Meynert, has been observed in patients with progressive dementia of the Alzheimer type (see Chapter 22). Using a rationale similar to that in other CNS degenerative diseases, therapy for enhancing concentrations of cholinergic neurotransmitters in the CNS has been used in mild to moderate Alzheimer disease. Long-acting and hydrophobic ChE inhibitors are the only inhibitors with well-documented, albeit limited, efficacy.

Donepezil may improve cognition and global clinical function and delay symptomatic progression of the disease. Side effects are largely attributable to excessive cholinergic stimulation, with nausea, diarrhea, and vomiting being
most frequently reported. The drug is well tolerated in single daily doses. Usually, 5-mg doses are administered at night; if this dose is well tolerated, the dose can be increased to 10 mg daily. Rivastigmine, a long-acting carbamoylating inhibitor, has efficacy, tolerability, and side effects similar to those of donepezil. Galantamine has a side-effect profile similar to those of donepezil and rivastigmine. These 3 cholinesterase inhibitors, which have good affinity, sufficient hydrophobicity to cross the blood-brain barrier, and prolonged durations of action constitute current modes of therapy, along with an excitatory amino acid transmitter mimic, memantine.

INTOXICATION BY ANTICHOLINERGIC DRUGS. In addition to atropine and other muscarinic agents, many other drugs, such as the phenothiazines, antihistamines, and tricyclic antidepressants, have central and peripheral anticholinergic activity. The effectiveness of physostigmine in reversing the anticholinergic effects of these agents has been clearly documented (Physostigmine, a tertiary amine, crosses the blood-brain barrier, in contrast to the quaternary anti-AChE drugs). However, other toxic effects of the tricyclic antidepressants and phenothiazines (see Chapters 15 and 16), such as intraventricular conduction deficits and ventricular arrhythmias, are not reversed by physostigmine. In addition, physostigmine may precipitate seizures; hence, its usually small potential benefit must be weighed against this risk. The initial intravenous or intramuscular dose of physostigmine is 2 mg, with additional doses given as necessary.
Agents Acting at the Neuromuscular Junction and Autonomic Ganglia

The nicotinic acetylcholine (ACh) receptor mediates neurotransmission postsynaptically at the neuromuscular junction and peripheral autonomic ganglia; in the CNS, it largely controls release of neurotransmitters from presynaptic sites. The receptor is called the nicotinic acetylcholine receptor because both the alkaloid nicotine and the neurotransmitter ACh can stimulate the receptor. Distinct subtypes of nicotinic receptors exist at the neuromuscular junction and the ganglia.

THE NICOTINIC ACETYLCHOLINE RECEPTOR

The binding of ACh to the nicotinic ACh receptor initiates an endplate potential (EPP) in muscle or an excitatory postsynaptic potential (EPSP) in peripheral ganglia (see Chapter 8). The nicotinic receptor is the prototype for other pentameric ligand-gated ion channels, which include the receptors for the inhibitory amino acids (γ-aminobutyric acid [GABA] and glycine; see Chapter 14) and serotonin (the 5HT3 receptor) (Figure 11–1).
Figure 11–1 Subunit organization of pentameric ligand-gated ion channels and the ACh binding protein. For each receptor, the amino terminal region of ~210 amino acids is found at the extracellular surface. It is then followed by 4 hydrophobic regions that span the membrane (TM1-TM4), leaving the small carboxyl terminus on the extracellular surface. The TM2 region is α-helical, and TM2 regions from each subunit of the pentameric receptor line the internal pore of the receptor. Two disulfide loops at positions 128-142 and 192-193 are found in the α-subunit of the nicotinic receptor. The 128-142 motif is conserved in the family of pentameric receptors; the vicinal cysteines at 192-193 occur only in α-subunits of the nicotinic receptor and in the ACh binding protein.

NICOTINIC RECEPTOR STRUCTURE. Nicotinic receptors of vertebrate skeletal muscle (N_m) are pentamers composed of 4 distinct subunits (α, β, γ, and δ) in the stoichiometric ratio of 2:1:1:1. In mature, innervated muscle endplates, the γ subunit is replaced by ε, a closely related subunit. The individual subunits are ~40% identical in their amino acid sequences. The 5 subunits of the nicotinic acetylcholine receptor are arranged around a pseudo-axis of symmetry to circumscribe a channel. Agonist-binding sites occur at the subunit interfaces; in muscle, only 2 of the 5 subunit interfaces, αγ and αδ, bind ligands (Figure 11–2). Both of the subunits forming the subunit interface contribute to ligand specificity.
Figure 11–2 Subunit arrangement and molecular structure of the nicotinic acetylcholine receptor. A. Longitudinal view of receptor schematic with the m subunit removed. The remaining subunits, 2 copies of α, 1 of β, and 1 of δ, are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α-helices with slightly bowed structures form the perimeter of the channel and come from the TM2 region of the linear sequence (Figure 11–1). ACh binding sites, indicated by red arrows, occur at the αγ and αδ (not visible) interfaces. B. Nicotinic receptor subunit arrangement, with examples of subunit assembly. Agonist binding sites (red circles) occur at α subunit-containing interfaces. A total of 17 functional receptor isoforms have been observed in vivo, with different ligand specificity, relative Ca²⁺/Na⁺ permeability, and physiological function as determined by their subunit composition. The only isoform found at the neuromuscular junction is that shown here. There are 16 neuronal receptor isoforms found at autonomic ganglia and in the CNS, homo- and heteropentamers of α (α2-α10) and β (β2-β4) subunits.

Neuronal nicotinic (Nₙ) receptors found in ganglia and the CNS also exist as pentamers of 1 or more types of subunits. Subunit types α2 through α10 and β2 through β4 are found in neuronal tissues (see Figure 11–2). Although not all permutations of α and β subunits lead to functional receptors, the diversity in subunit composition is large and exceeds the capacity of ligands to distinguish subtypes on the basis of their selectivity.
NEUROMUSCULAR BLOCKING AGENTS

Modern-day neuromuscular blocking agents fall generally into 2 classes, *depolarizing* and *competitive/nondepolarizing*. At present, only a single depolarizing agent, succinylcholine (ANECTINE, QUELICIN), is in general clinical use; multiple competitive or nondepolarizing agents are available (see Table 11–2).

See the 12th edition of the parent text for the history, sources, and chemistry of
curare, the prototypical South American arrow poison and neuromuscular blocking agent, the action of which was described by Claude Bernard in the 1850s. The 12th edition also shows the structures of the various classes of depolarizing and competitive neuromuscular blockers in Figure 11–3.

Figure 11–3 A pharmacologist’s view of the motor end plate. The structures of the motor end plate (left side of figure) facilitate the series of physiological events leading from nerve action potential (AP) to skeletal muscle contraction (center column). Pharmacological agents can modify neurotransmission and excitation-contraction coupling at myriad sites (righthand column). enhancement; --- blockade; -----. depolarization and phase II block.

Pharmacological Effects

SKELETAL MUSCLE. Competitive antagonists bind the nicotinic ACh receptor of the motor endplate and thereby competitively block the binding of ACh. The depolarizing agents, such as succinylcholine, depolarize the membrane by opening channels in the same manner as ACh. However, they persist longer at the neuromuscular junction primarily because of their resistance to AChE. The depolarization is thus longer lasting, resulting in a brief period of repetitive excitation.
that may elicit transient and repetitive muscle excitation (fasciculations), followed by block of neuromuscular transmission and flaccid paralysis (called phase I block).

The block arises because, after an initial opening, peri-junctional Na$^+$ channels close and will not reopen until the endplate is repolarized. At this point, neural release of ACh results in the binding of ACh to receptors on an already depolarized endplate. These closed perijunctional channels keep the depolarization signal from affecting downstream channels and effectively shield the rest of the muscle from activity at the motor endplate. The characteristics of depolarization and competitive blockade are contrasted in Table 11–3.

Under clinical conditions, with increasing concentrations of succinylcholine and over time, the block may convert slowly from a depolarizing phase I block to a nondepolarizing, phase II block. While the response to peripheral stimulation during phase II block resembles that of the competitive agents, reversal of phase II block by administration of anticholinesterase (anti-ChE) agents (e.g., with neostigmine) is difficult to predict and should be undertaken with much caution.
The characteristics of phase I and phase II blocks are shown in Table 11–1.

**Sequence and Characteristics of Paralysis.** Following intravenous injection of an appropriate dose of a competitive blocking agent, motor weakness progresses to a total flaccid paralysis. Small, rapidly moving muscles such as those of the eyes, jaw, and larynx relax before those of the limbs and trunk. Ultimately, the intercostal muscles and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order to that of their paralysis, and thus the diaphragm ordinarily is the first muscle to regain function.

After a single intravenous dose of 10-30 mg of succinylcholine, muscle fasciculations, particularly over the chest and abdomen, occur briefly; then relaxation occurs within 1 min, becomes maximal within 2 min, and generally disappears within 5 min. Transient apnea usually occurs at the time of maximal effect. Muscle relaxation of longer duration is achieved by continuous intravenous infusion. After infusion is discontinued, the effects of the drug usually disappear rapidly because of its efficient hydrolysis by plasma and hepatic butyrylcholinesterase. Muscle soreness may follow the administration of succinylcholine.

During prolonged depolarization, muscle cells may lose significant quantities of
K$^+$ and gain Na$^+$, Cl$^-$, and Ca$^{2+}$. In patients with extensive injury to soft tissues, the efflux of K$^+$ following continued administration of succinylcholine can be life threatening. There are many conditions for which succinylcholine administration is contraindicated or should be undertaken with great caution. The change in the nature of the blockade produced by succinylcholine (from phase I to phase II) presents an additional complication with long-term infusions.

**CNS.** Tubocurarine and other quaternary neuromuscular blocking agents are virtually devoid of central effects following ordinary clinical doses because of their inability to penetrate the blood-brain barrier.

**AUTONOMIC GANGLIA AND MUSCARINIC SITES.**
Neuromuscular blocking agents show variable potencies in producing ganglionic blockade. Ganglionic blockade by tubocurarine and other stabilizing drugs is reversed or antagonized by anti-ChE agents.

Clinical doses of tubocurarine produce partial blockade both at autonomic ganglia and at the adrenal medulla, which results in a fall in blood pressure and tachycardia. Pancuronium shows less ganglionic blockade at common clinical doses. Atracurium, vecuronium, doxacurium, pipecuronium, mivacurium, and rocuronium are even more selective. The maintenance of cardiovascular reflex responses usually is desired during anesthesia. Pancuronium has a vagolytic action, presumably from blockade of muscarinic receptors, which leads to tachycardia.

Of the depolarizing agents, succinylcholine at doses producing neuromuscular relaxation rarely causes effects attributable to ganglionic blockade. However, cardiovascular effects are sometimes observed, probably owing to the successive stimulation of vagal ganglia (manifested by bradycardia) and sympathetic ganglia (resulting in hypertension and tachycardia).

**MAST CELLS AND HISTAMINE RELEASE.** Tubocurarine produces typical histamine-like wheals when injected intracutaneously or intraarterially in humans, and some clinical responses to neuromuscular blocking agents (e.g., bronchospasm, hypotension, excessive bronchial and salivary secretion) appear to be caused by the release of histamine. Succinylcholine, mivacurium, and
atracurium also cause histamine release, but to a lesser extent unless administered rapidly. The ammonio steroids, pancuronium, vecuronium, pipecuronium, and rocuronium, have even less tendency to release histamine after intradermal or systemic injection. Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than IgE-mediated anaphylaxis.

**ABSORPTION, DISTRIBUTION, AND ELIMINATION**

Quaternary ammonium neuromuscular blocking agents are very poorly absorbed from the GI tract. Absorption is quite adequate from intramuscular sites. Rapid onset is achieved with intravenous administration. The more potent agents must be given in lower concentrations, and diffusional requirements slow their rate of onset.

When long-acting competitive blocking agents such as d-tubocurarine and pancuronium are administered, blockade may diminish after 30 min owing to redistribution of the drug, yet residual blockade and plasma levels of the drug persist. Subsequent doses show diminished redistribution. Long-acting agents may accumulate with multiple doses.

The ammonio steroids contain ester groups that are hydrolyzed in the liver. Typically, the metabolites have about one-half the activity of the parent compound and contribute to the total relaxation profile. Ammonio steroids of intermediate duration of action, such as vecuronium and rocuronium (Table 11–2), are cleared more rapidly by the liver than is pancuronium. The more rapid decay of neuromuscular blockade with compounds of intermediate duration argues for sequential dosing of these agents rather than administering a single dose of a long-duration neuromuscular blocking agent.

Atracurium is converted to less active metabolites by plasma esterases and spontaneous Hofmann elimination. Cisatracurium is also subject to this spontaneous degradation. Because of these alternative routes of metabolism, atracurium and cisatracurium do not exhibit an increased $t_{1/2}$ in patients with impaired renal function and therefore are good choices in this setting.

The extremely brief duration of action of succinylcholine is due largely to its
rapid hydrolysis by the butyrylcholinesterase synthesized by the liver and found in the plasma. Among the occasional patients who exhibit prolonged apnea following the administration of succinylcholine or mivacurium, most have an atypical plasma cholinesterase or a deficiency of the enzyme owing to allelic variations, hepatic or renal disease, or a nutritional disturbance; however, in some, the enzymatic activity in plasma is normal.

Gantacurium is degraded by 2 chemical mechanisms, a rapid cysteine adduction and a slower hydrolysis of the ester bond adjacent to the chlorine. Both processes are purely chemical and hence not dependent on enzymatic activities. The adduction process has a $t_{1/2}$ of 1-2 min and is likely the basis for the ultrashort duration of action of gantacurium. Administration of exogenous cysteine, which may have excitotoxic side effects, can accelerate the antagonism of gantacurium-induced neuromuscular blockade.

**CLINICAL PHARMACOLOGY**

**CHOICE OF AGENT**

Therapeutic selection of a neuromuscular blocking agent should be based on achieving a pharmacokinetic profile consistent with the duration of the interventional procedure and minimizing cardiovascular compromise or other side effects, with attention to drug-specific modes of elimination in patients with renal or hepatic failure (see Table 11–2).

Two characteristics are useful in distinguishing side effects and pharmacokinetic behavior of neuromuscular blocking agents:

- **Duration of drug action.** These agents are categorized as long-, intermediate-, or short-acting agents. Often, the long-acting agents are the more potent, requiring the use of low concentrations (Table 11–3). The necessity of administering potent agents in low concentrations delays their onset.

- **The chemical nature of the agents (Table 11–2).** Apart from a shorter duration of action, newer agents exhibit greatly diminished frequency of side effects, chief of which are ganglionic blockade, block of vagal responses, and histamine release.
The prototypical ammonio steroid, pancuronium, induces virtually no histamine release; however, it blocks muscarinic receptors, and this antagonism is manifested primarily in vagal blockade and tachycardia. Tachycardia is eliminated in the newer ammonio steroids, vecuronium and rocuronium. The benzylisoquinolines appear to be devoid of vagolytic and ganglionic blocking actions but show a slight propensity to cause histamine release. The unusual metabolism of the prototype compound atracurium and its congener mivacurium confers special indications for use of these compounds. For example, atracurium’s disappearance from the body depends on hydrolysis of the ester moiety by plasma esterases and by a spontaneous or Hofmann degradation (cleavage of the N-alkyl portion in the benzylisoquinoline). Hence 2 routes for degradation are available, both of which remain functional in renal failure. Mivacurium is extremely sensitive to catalysis by cholinesterase or other plasma hydrolases, accounting for its short duration of action. Side effects are not yet fully characterized for gantacurium, but transient adverse cardiovascular effects suggestive of histamine release have been observed at doses over 3 times the ED$95$.

**Uses**

**Muscle Relaxation.** The main clinical use of the neuromuscular blocking agents is as an adjuvant in surgical anesthesia to obtain relaxation of skeletal muscle, particularly of the abdominal wall, to facilitate operative manipulations. With muscle relaxation no longer dependent on the depth of general anesthesia, a much lighter level of anesthesia suffices. Thus, the risk of respiratory and cardiovascular depression is minimized, and postanesthetic recovery is shortened. Neuromuscular blocking agents of short duration often are used to facilitate endotracheal intubation and have been used to facilitate laryngoscopy, bronchoscopy, and esophagoscopy in combination with a general anesthetic agent. Neuromuscular blocking agents are administered parenterally, nearly always intravenously.

**Measurement of Neuromuscular Blockade in Humans.** Assessment of neuromuscular block usually is performed by stimulation of the ulnar nerve. Responses are monitored from compound action potentials or muscle tension developed in the adductor pollicis (thumb) muscle. Responses to repetitive or tetanic stimuli are most useful for evaluation of blockade of transmission. Rates
of onset of blockade and recovery are more rapid in the airway musculature (jaw, larynx, and diaphragm) than in the thumb. Hence, tracheal intubation can be performed before onset of complete block at the adductor pollicis, whereas partial recovery of function of this muscle allows sufficient recovery of respiration for extubation.

**Preventing Trauma During Electroshock Therapy.** Electroconvulsive therapy (ECT) of psychiatric disorders occasionally is complicated by trauma to the patient; the seizures induced may cause dislocations or fractures. Inasmuch as the muscular component of the convulsion is not essential for benefit from the procedure, neuromuscular blocking agents, usually succinylcholine, and a short-acting barbiturate, usually methohexital or thiopental, are employed.

**Control of Muscle Spasms and Rigidity.** Botulinum toxins and dantrolene act peripherally to reduce muscle contraction; a variety of other agents act centrally to reduce skeletal muscle tone and spasm. Onabotulinum toxin A (BOTOX), abobotulinum toxin A (DYSPORT), and rimabotulinum toxin B (MYOBLOC), by blocking ACh release, produce flaccid paralysis of skeletal muscle and diminished activity of parasympathetic and sympathetic cholinergic synapses. Inhibition lasts from several weeks to 3-4 months, and restoration of function requires nerve sprouting.

Originally approved for the treatment of the ocular conditions of strabismus and blepharospasm and for hemifacial spasms, botulinum toxin has been used to treat spasms and dystonias, and spasms associated with the lower esophageal sphincter and anal fissures. Botox treatments also have become a popular cosmetic procedure for those seeking a wrinkle-free face. Like the bloom of youth, the reduction of wrinkles is temporary; unlike the bloom of youth, the effect of Botox can be renewed by readministration. The FDA has issued a safety alert, warning of respiratory paralysis from unexpected spread of the toxin from the site of injection (uses are described in Chapter 65).

Dantrolene (DANTRIUM, others) inhibits Ca\(^{2+}\) release from the sarcoplasmic reticulum of skeletal muscle by limiting the capacity of Ca\(^{2+}\) and calmodulin to activate RYR1. Because of its efficacy in managing an acute attack of malignant hyperthermia (described under “Toxicology”), dantrolene has been used experimentally in the treatment of muscle rigidity and hyperthermia in neuroleptic malignant syndrome (NMS). Dantrolene is also used in treatment of
Spasticity and hyperreflexia. With its peripheral action, it causes a generalized weakness. Thus, its use should be reserved to nonambulatory patients with severe spasticity. Hepatotoxicity has been reported with continued use, requiring liver function tests.

**Synergisms and Antagonisms.** The comparison of interactions between competitive and depolarizing neuromuscular blocking agents is instructive (Table 11–4) and a good test of one’s understanding of the drugs’ actions. In addition, many other drugs affect transmission at the neuromuscular junction, and thus can affect the choice and dosage of neuromuscular blocking agent used.

Because the anti-ChE agents neostigmine, pyridostigmine, and edrophonium preserve endogenous ACh and also act directly on the neuromuscular junction, they have been used in the treatment of overdosage with competitive blocking agents. Similarly, on completion of the surgical procedure, many anesthesiologists employ neostigmine or edrophonium to reverse and decrease the duration of competitive neuromuscular blockade. A muscarinic antagonist (atropine or glycopyrrolate) is used concomitantly to prevent stimulation of muscarinic receptors and thereby to avoid slowing of the heart rate. Anti-ChE agents will not reverse depolarizing neuromuscular blockade and, in fact, can
enhance it.

Many inhalational anesthetics exert a stabilizing effect on the postjunctional membrane and therefore potentiate the activity of competitive blocking agents. Consequently, when such blocking drugs are used for muscle relaxation as adjuncts to these anesthetics, their doses should be reduced. The rank of order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide-barbiturate-opioid or propofol anesthesia.

Aminoglycoside antibiotics produce neuromuscular blockade by inhibiting ACh release from the preganglionic terminal (through competition with Ca\(^{2+}\)) and to a lesser extent by noncompetitively blocking the receptor. The blockade is antagonized by Ca\(^{2+}\) salts but only inconsistently by anti-ChE agents (see Chapter 54). The tetracyclines also can produce neuromuscular blockade, possibly by chelation of Ca\(^{2+}\). Additional antibiotics that have neuromuscular blocking action, through both presynaptic and postsynaptic actions, include polymyxin B, colistin, clindamycin, and lincomycin. Ca\(^{2+}\) channel blockers enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. When neuromuscular blocking agents are administered to patients receiving these agents, dose adjustments should be considered.

Miscellaneous drugs that may have significant interactions with either competitive or depolarizing neuromuscular blocking agents include trimethaphan, lithium, opioid analgesics, procaine, lidocaine, quinidine, phenelzine, carbamazepine, phenytoin, propranolol, dantrolene, azathioprine, tamoxifen, magnesium salts, corticosteroids, digitalis glycosides, chloroquine, catecholamines, and diuretics.

**TOXICOLOGY**

The important untoward responses of the neuromuscular blocking agents include prolonged apnea, cardiovascular collapse, those resulting from histamine release, and rarely, anaphylaxis. Related factors may include alterations in body temperature; electrolyte imbalance, particularly of K\(^+\); low plasma butyrylcholinesterase levels, resulting in a reduction in the rate of destruction of succinylcholine; the presence of latent myasthenia gravis or of
malignant disease such as small cell carcinoma of the lung with Eaton-Lambert myasthenic syndrome; reduced blood flow to skeletal muscles, causing delayed removal of the blocking drugs; and decreased elimination of the muscle relaxants secondary to hepatic dysfunction (cisatracurium, rocuronium, vecuronium) or reduced renal function (pancuronium). Great care should be taken when administering neuromuscular blockers to dehydrated or severely ill patients. Depolarizing agents can cause rapid release of K$^+$ from intracellular sites; this may be a factor in production of the prolonged apnea in patients who receive these drugs while in electrolyte imbalance. Succinylcholine-induced hyperkalemia is a life-threatening complication of that drug.

**Malignant Hyperthermia.** Malignant hyperthermia is a potentially life-threatening event triggered by the administration of certain anesthetics and neuromuscular blocking agents. The clinical features include contracture, rigidity, and heat production from skeletal muscle resulting in severe hyperthermia (increases of up to 1°C/5 min), accelerated muscle metabolism, metabolic acidosis, and tachycardia. Uncontrolled release of Ca$^{2+}$ from the sarcoplasmic reticulum of skeletal muscle is the initiating event. Although the halogenated hydrocarbon anesthetics (e.g., halothane, isoflurane, and sevoflurane) and succinylcholine alone have been reported to precipitate the response, most of the incidents arise from the combination of depolarizing blocking agent and anesthetic. Susceptibility to malignant hyperthermia, an autosomal dominant trait, is associated with certain congenital myopathies such as **central core disease**. In the majority of cases, however, no clinical signs are visible in the absence of anesthetic intervention.

Treatment entails intravenous administration of dantrolene (Dantrium, others), which blocks Ca$^{2+}$ release from the sarcoplasmic reticulum of skeletal muscle (see “Control of Muscle Spasms and Rigidity” earlier in the chapter). Rapid cooling, inhalation of 100% O$_2$, and control of acidosis should be considered adjunct therapy in malignant hyperthermia.

**Respiratory Paralysis.** Treatment of respiratory paralysis arising from an adverse reaction or overdose of a neuromuscular blocking agent should be by positive-
pressure artificial respiration with oxygen and maintenance of a patent airway until recovery of normal respiration is ensured. With the competitive blocking agents, this may be hastened by the administration of neostigmine methylsulfate (0.5-2 mg IV) or edrophonium (10 mg IV, repeated as required up to a total of 40 mg).

**Interventional Strategies for Other Toxic Effects.** Neostigmine effectively antagonizes only the skeletal muscular blocking action of the competitive blocking agents and may aggravate such side effects as hypotension or induce bronchospasm. In such circumstances, sympathomimetic amines may be given to support the blood pressure. Atropine or glycopyrrolate is administered to counteract muscarinic stimulation. Antihistamines are definitely beneficial to counteract the responses that follow the release of histamine, particularly when administered before the neuromuscular blocking agent.

**Reversal of Effects by Chelation Therapy.** Sugammadex (BRIDION), a modified γ-cyclodextrin, is a chelating agent specific for rocuronium and vecuronium. Sugammadex at doses >2 mg/kg is able to reverse neuromuscular blockade from rocuronium within 3 min. In patients with impaired renal function, sugammadex clearance is markedly reduced and this agent should be avoided. Sugammadex is approved for clinical use in Europe but not yet in the U.S. Side effects include dysgeusia and rare hypersensitivity.

**GANGLIONIC NEUROTRANSMISSION**

Neurotransmission in autonomic ganglia involves release of ACh and the rapid depolarization of postsynaptic membranes via the activation of neuronal nicotinic (N_1) receptors by ACh. Intracellular recordings from postganglionic neurons indicate that at least 4 different changes in postsynaptic membrane potential can be elicited by stimulation of the preganglionic nerve (Figure 11–4):
Figure 11–4 Postsynaptic potentials recorded from an autonomic postganglionic nerve cell body after stimulation of the preganglionic nerve fiber. The preganglionic nerve releases ACh onto postganglionic cells. The initial EPSP results from the inward Na\(^+\) current (and perhaps Ca\(^{2+}\) current) through the nicotinic receptor channel. If the EPSP is of sufficient magnitude, it triggers an action potential spike, which is followed by a slow IPSP, a slow EPSP, and a late, slow EPSP. The slow IPSP and slow EPSP are not seen in all ganglia. The electrical events subsequent to the initial EPSP are thought to modulate the probability that a subsequent EPSP will reach the threshold for triggering a spike. Other interneurons, such as catecholamine-containing, small intensely fluorescent (SIF) cells, and axon terminals from sensory, afferent neurons also release transmitters and that may influence the slow potentials of the postganglionic neuron. There are cholinergic, peptidergic, adrenergic, and amino acid receptors on the dendrites and soma of the postganglionic neuron and the interneurons. The preganglionic fiber releases ACh and peptides; the interneurons store and release catecholamines, amino acids, and peptides; the sensory afferent nerve terminals release peptides. The initial EPSP is mediated through nicotinic (\(N_n\)) receptors, the slow IPSP and EPSP through \(M_2\) and \(M_1\) muscarinic receptors, and the late, slow EPSP through various peptidergic receptors.

- An initial excitatory postsynaptic potential (EPSP, via nicotinic receptors) that may result in an action potential
- An inhibitory postsynaptic potential (IPSP) mediated by \(M_2\) muscarinic receptors
- A secondary slow EPSP mediated by \(M_1\) muscarinic receptors
A late, slow EPSP mediated by myriad peptides

There are multiple nicotinic receptor subunits (e.g., α3, α5, α7, β2, and β4) in ganglia, with α3 and α2 being most abundant. The ganglionic nicotinic ACh receptors are sensitive to classical blocking agents such as hexamethonium and trimethaphan.

An action potential is generated in the postganglionic neuron when the initial EPSP attains a critical amplitude. Unlike the neuromuscular junction, discrete endplates with focal localization of receptors do not exist in ganglia; rather, the dendrites and nerve cell bodies contain the receptors. The characteristics of nicotinic-receptor channels of the ganglia and the neuromuscular junction are quite similar.

The events that follow the initial depolarization (IPSP; slow EPSP; late, slow EPSP) are insensitive to hexamethonium or other Nn antagonists. Electrophysiological and neurochemical evidence suggests that catecholamines participate in the generation of the IPSP. Dopamine and norepinephrine cause hyperpolarization of ganglia; however, in some ganglia IPSPs are mediated by M2 muscarinic receptors. The slow EPSP is generated by ACh activation of M1 (Gq-coupled) muscarinic receptors and is blocked by atropine and M1-selective antagonists (see Chapter 9).

Secondary synaptic events modulate the initial EPSP. A variety of peptides, including gonadotropin-releasing hormone, substance P, angiotensin, calcitonin gene–related peptide, vasoactive intestinal polypeptide, neuropeptide Y, and enkephalins, have been identified in ganglia by immunofluorescence. They appear localized to particular cell bodies, nerve fibers, or SIF cells, are released on nerve stimulation, and are presumed to mediate the late slow EPSP. Other neurotransmitter substances (e.g., 5HT and GABA) can modify ganglionic transmission.

**GANGLIONIC-STIMULATING DRUGS**

Drugs that stimulate cholinergic receptor sites on autonomic ganglia have been essential for analyzing the mechanism of ganglionic function; however, these ganglionic agonists have very limited
therapeutic use. They can be grouped into 2 categories. The first group consists of drugs with nicotinic specificity, including nicotine, lobeline, tetramethylammonium (TEA), and dimethylphenylpiperazinium (DMPP). Nicotine’s excitatory effects on ganglia are rapid in onset, are blocked by ganglionic nicotinic-receptor antagonists, and mimic the initial EPSP. The second group consists of muscarinic receptor agonists such as muscarine, McN-A-343, and methacholine (see Chapter 9); their excitatory effects on ganglia are delayed in onset, blocked by atropine-like drugs, and mimic the slow EPSP.

NICOTINE

Nicotine is of considerable medical significance because of its toxicity, presence in tobacco, and propensity for conferring a dependence on its users. The chronic effects of nicotine and the untoward effects of the chronic use of tobacco are considered in Chapter 24.

PHARMACOLOGICAL ACTIONS. In addition to the actions of nicotine on a variety of neuroeffector and chemosensitive sites, the alkaloid can both stimulate and desensitize receptors. The ultimate response of any 1 system represents the summation of stimulatory and inhibitory effects of nicotine. Nicotine can increase heart rate by excitation of sympathetic ganglia or by paralysis of parasympathetic cardiac ganglia, and it can slow heart rate by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. The effects of the drug on the chemoreceptors of the carotid and aortic bodies and on regions of the CNS also can influence heart rate, as can the compensatory baroreceptor reflexes resulting from changes in blood pressure caused by nicotine. Finally, nicotine elicits a discharge of epinephrine from the adrenal medulla, which accelerates heart rate and raises blood pressure.
Peripheral Nervous System. The major action of nicotine consists initially of transient stimulation and subsequently of a more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and may facilitate impulse transmission. Following larger doses, the initial stimulation is followed by a blockade of transmission. Whereas stimulation of the ganglion cells coincides with their depolarization, depression of transmission by adequate doses of nicotine occurs both during the depolarization and after it has subsided. Nicotine also possesses a biphasic action on the adrenal medulla: small doses evoke the discharge of catecholamines; larger doses prevent their release in response to splanchnic nerve stimulation.

The effects of high doses of nicotine on the neuromuscular junction are similar to those on ganglia. However, the stimulant phase is obscured largely by the rapidly developing paralysis. In the latter stage, nicotine also produces neuromuscular blockade by receptor desensitization.

Nicotine, like ACh, stimulates a number of sensory receptors. These include mechanoreceptors that respond to stretch or pressure of the skin, mesentery, tongue, lung, and stomach; chemoreceptors of the carotid body; thermal receptors of the skin and tongue; and pain receptors. Prior administration of hexamethonium prevents stimulation of the sensory receptors by nicotine but has little, if any, effect on the activation of sensory receptors by physiological stimuli.

CNS. Nicotine markedly stimulates the CNS. Low doses produce weak analgesia; with higher doses, tremors leading to convulsions at toxic doses are evident. The excitation of respiration is a prominent action of nicotine: large doses act directly on the medulla oblongata, whereas smaller doses augment respiration reflexly by excitation of the chemoreceptors of the carotid and aortic bodies. Stimulation of the CNS with large doses is followed by depression, and death results from failure of respiration owing to both central paralysis and peripheral blockade of the diaphragm and intercostal muscles that facilitate respiration.

Nicotine induces vomiting by both central and peripheral actions. The primary sites of action of nicotine in the CNS are prejunctional, causing the release of other transmitters. The stimulatory and pleasure–reward actions of nicotine appear to result from release of excitatory amino acids, dopamine, and other
biogenic amines from various CNS centers. Release of excitatory amino acids may account for much of nicotine’s stimulatory action. Chronic exposure to nicotine in several systems causes a marked increase in the density or number of nicotinic receptors, possibly contributing to tolerance and dependence.

**Cardiovascular System.** In general, the cardiovascular responses to nicotine are due to stimulation of sympathetic ganglia and the adrenal medulla, together with the discharge of catecholamines from sympathetic nerve endings. Contributing to the sympathomimetic response to nicotine is the activation of chemoreceptors of the aortic and carotid bodies, which reflexly results in vasoconstriction, tachycardia, and elevated blood pressure.

**GI Tract.** The combined activation of parasympathetic ganglia and cholinergic nerve endings by nicotine results in increased tone and motor activity of the bowel. Nausea, vomiting, and occasionally diarrhea are observed following systemic absorption of nicotine in an individual who has not been exposed to nicotine previously.

**Exocrine Glands.** Nicotine causes an initial stimulation of salivary and bronchial secretions that is followed by inhibition.

**ABSORPTION, DISTRIBUTION, AND ELIMINATION.** Nicotine is readily absorbed from the respiratory tract, buccal membranes, and skin. Severe poisoning has resulted from percutaneous absorption. As a relatively strong base, nicotine has limited absorption from the stomach. Intestinal absorption is far more efficient. Nicotine in chewing tobacco, because it is absorbed more slowly than inhaled nicotine, has a longer duration of effect. The average cigarette contains 6-11 mg nicotine and delivers ~1-3 mg nicotine systemically to the smoker; bioavailability can increase as much as 3-fold with the intensity of puffing and technique of the smoker.

Approximately 80-90% of nicotine is altered in the body, mainly in the liver but also in the kidney and lung. Cotinine is the major metabolite. The $t_{1/2}$ of nicotine following inhalation or parenteral administration is ~2 h. Nicotine and its metabolites are eliminated rapidly by the kidney. The rate of urinary excretion of nicotine diminishes when the urine is alkaline. Nicotine also is excreted in the milk of lactating women who smoke; the milk of heavy smokers may contain 0.5 mg/L.
ACUTE NICOTINE POISONING. Poisoning from nicotine may occur from accidental ingestion of nicotine-containing insecticide sprays or in children from ingestion of tobacco products. The acutely fatal dose of nicotine for an adult is probably n60 mg. Smoking tobacco usually contains 1-2% nicotine. Apparently, the gastric absorption of nicotine from tobacco taken by mouth is delayed because of slowed gastric emptying, so vomiting caused by the central effect of the initially absorbed fraction may remove much of the tobacco remaining in the GI tract.

The onset of symptoms of acute, severe nicotine poisoning is rapid; they include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and marked weakness. Faintness and prostration ensue; the blood pressure falls; breathing is difficult; the pulse is weak, rapid, and irregular; and collapse may be followed by terminal convulsions. Death may result within a few minutes from respiratory failure.

**Therapy.** Vomiting may be induced, or gastric lavage should be performed. Alkaline solutions should be avoided. A slurry of activated charcoal is then passed through the tube and left in the stomach. Respiratory assistance and treatment of shock may be necessary.

SMOKING CESSATION. Two goals of the pharmacotherapy of smoking cessation are the reduction of the craving for nicotine and inhibition of the reinforcing effects of nicotine. Myriad approaches and drug regimens are used, including nicotine replacement, bupropion (see Chapter 15), and nicotinic ACh receptor agonists (see Chapters 15 and 24).

Varenicline (CHANTIX) has been recently introduced as an aid to smoking cessation. The drug interacts with nicotinic ACh receptors. In model systems, varenicline is a partial agonist at $\alpha_4 \beta_2$ receptors and a full agonist at the $\alpha_7$ subtype, with weak activity toward $\alpha_3 \beta_2$- and $\alpha_6$-containing receptors. The drug is effective clinically; however, it is not benign: the FDA has issued a warning about mood and behavioral changes associated with its use.

Nicotine itself is available in several dosage forms to help achieve abstinence from tobacco use. Nicotine is marketed for over-the-counter use as a gum or lozenge (NICOTINE POLACRILEX, NICORETTE, COMMIT, THRIVE, others), transdermal patch (NICODERM, HABITROL, others), a nasal spray (NICOTROL), or a
vapor inhaler (Nicotrol). The efficacy of these dosage forms in producing abstinence from smoking is enhanced when linked to counseling and motivational therapy.

**GANGLIONIC BLOCKING DRUGS**

There are 2 categories of agents that block ganglionic nicotinic receptors. The prototype of the first group, nicotine, initially stimulates the ganglia by an ACh-like action and then blocks them by causing a persistent depolarization. Compounds in the second category (e.g., trimethaphan and hexamethonium) impair transmission. Trimethaphan acts by competition with ACh, analogous to the mechanism of action of curare at the neuromuscular junction. Hexamethonium appears to block the channel after it opens; this action shortens the duration of current flow because the open channel either becomes occluded or closes. Thus the initial EPSP is blocked, and ganglionic transmission is inhibited. The diverse chemicals that block autonomic ganglia without first causing stimulation are:

![Chemical structures of Hexamethonium, Trimethaphan, and Mecamylamine]

Ganglionic blocking agents were the first effective therapy for the treatment of hypertension. However, due to the role of ganglionic transmission in both sympathetic and parasympathetic neurotransmission, the antihypertensive action of ganglionic blocking agents was accompanied by numerous undesirable side effects. Mecamylamine, a secondary amine, is currently licensed as an orphan drug for Tourette syndrome.

**PHARMACOLOGICAL PROPERTIES.** Nearly all the physiological alterations observed after the administration of ganglionic blocking
agents can be anticipated with reasonable accuracy by a careful inspection of Figure 8–1 and Table 8–1, and by knowing which division of the autonomic nervous system exercises dominant control of various organs (Table 11–5). For example, blockade of sympathetic ganglia interrupts adrenergic control of arterioles and results in vasodilation, improved peripheral blood flow in some vascular beds, and a fall in blood pressure.

Generalized ganglionic blockade also may result in atony of the bladder and GI tract, cycloplegia, xerostomia, diminished perspiration, and by abolishing circulatory reflex pathways, postural hypotension. These changes represent the generally undesirable features of ganglionic blockade that severely limit the therapeutic efficacy of ganglionic blocking agents.
Cardiovascular System. Existing sympathetic tone is critical in determining the degree to which blood pressure is lowered by ganglionic blockade; thus, blood pressure may be decreased only minimally in recumbent normotensive subjects but may fall markedly in sitting or standing subjects. Postural hypotension limits the use of ganglionic blockers in ambulatory patients.

Changes in heart rate following ganglionic blockade depend largely on existing vagal tone. In humans, mild tachycardia usually accompanies the hypotension, a sign that indicates fairly complete ganglionic blockade. However, a decrease may occur if the heart rate is high initially.

Cardiac output often is reduced by ganglionic blocking drugs in patients with normal cardiac function, as a consequence of diminished venous return resulting from venous dilation and peripheral pooling of blood. In patients with cardiac failure, ganglionic blockade frequently results in increased cardiac output owing to a reduction in peripheral resistance. In hypertensive subjects, cardiac output, stroke volume, and left ventricular work are diminished. Although total systemic vascular resistance is decreased in patients who receive ganglionic blocking agents, changes in blood flow and vascular resistance of individual vascular beds are variable. Reduction of cerebral blood flow is small unless mean systemic blood pressure falls below 50-60 mm Hg. Skeletal muscle blood flow is unaltered, but splanchnic and renal blood flow decrease.

Absorption, Distribution, and Elimination. The absorption of quaternary ammonium and sulfonium compounds from the enteric tract is incomplete and unpredictable. This is due both to the limited ability of these ionized substances to penetrate cell membranes and to the depression of propulsive movements of the small intestine and gastric emptying. Although the absorption of mecamylamine is less erratic, reduced bowel activity and paralytic ileus are a danger. After absorption, the quaternary ammonium- and sulfonium-blocking agents are confined primarily to the extracellular space and are excreted mostly unchanged by the kidney. Mecamylamine concentrates in the liver and kidney and is excreted slowly in an unchanged form.

Untoward Responses and Severe Reactions. Among the milder untoward responses observed are visual disturbances, dry mouth, conjunctival suffusion, urinary hesitancy, decreased potency, subjective chilliness, moderate constipation, occasional diarrhea, abdominal discomfort, anorexia, heartburn,
nausea, eructation, and bitter taste and the signs and symptoms of syncope caused by postural hypotension. More severe reactions include marked hypotension, constipation, syncope, paralytic ileus, urinary retention, and cycloplegia.
Catecholamines and sympathomimetic drugs are classified as direct-acting, indirect-acting, or mixed-acting sympathomimetics (Figure 12–1).

**Figure 12–1** Classification of adrenergic receptor agonists (sympathomimetic amines) and drugs that produce sympathomimetic-like effects. For each category, a prototypical drug is shown. (*Not actually sympathetic drugs but produce sympathomimetic-like effects.*)

Direct-acting sympathomimetic drugs act directly on 1 or more of the adrenergic receptors. These agents may exhibit considerable selectivity for a specific receptor subtype (e.g., phenylephrine for $\alpha_1$, terbutaline for $\beta_2$) or may have no or minimal selectivity and act on
several receptor types (e.g., epinephrine for $\alpha_1$, $\alpha_2$, $\beta_1$, $\beta_2$, and $\beta_3$ receptors; norepinephrine for $\alpha_1$, $\alpha_2$, and $\beta_1$ receptors).

Indirect-acting drugs increase the availability of norepinephrine (NE) or epinephrine (EPI) to stimulate adrenergic receptors by several mechanisms:

- By releasing or displacing NE from sympathetic nerve varicosities
- By inhibiting the transport of NE into sympathetic neurons (e.g., cocaine), thereby increasing the dwell time of the transmitter at the receptor
- By blocking the metabolizing enzymes, monoamine oxidase (MAO) (e.g., pargyline) or catechol-O-methyltransferase (COMT) (e.g., entacapone), effectively increasing transmitter supply

Drugs that indirectly release NE and also directly activate receptors are referred to as *mixed-acting sympathomimetic drugs* [e.g., ephedrine, dopamine (DA)].

A feature of direct-acting sympathomimetic drugs is that their responses are not reduced by prior treatment with *reserpine* or *guanethidine*, which deplete NE from sympathetic neurons. After transmitter depletion, the actions of direct-acting sympathomimetic drugs actually may increase because the loss of the neurotransmitter induces compensatory changes that upregulate receptors or enhance the signaling pathway. In contrast, the responses of indirect-acting sympathomimetic drugs (e.g., amphetamine, tyramine) are abolished by prior treatment with reserpine or guanethidine. The cardinal feature of mixed-acting sympathomimetic drugs is that their effects are blunted, but not abolished, by prior treatment with reserpine or guanethidine.

Because the actions of NE are more pronounced on $\alpha$ and $\beta_1$ receptors than on $\beta_2$ receptors, many non-catecholamines that release NE have predominantly $\alpha$ receptor–mediated and cardiac effects. However, certain non-catecholamines with both direct and indirect effects on adrenergic receptors show significant $\beta_2$ activity and are used clinically for these effects. Thus, ephedrine, although dependent on release of NE for some of its effects, relieves bronchospasm by its action on $\beta_2$ receptors in bronchial smooth muscle, an effect not seen with NE. Moreover, some non-catecholamines (e.g., phenylephrine) act primarily and
directly on target cells. It therefore is impossible to predict precisely the effects of non-catecholamines solely on their ability to provoke NE release.

**CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIP OF SYMPATHOMIMETIC AMINES.** β-Phenylethylamine (Table 12–1) can be viewed as the parent compound of the sympathomimetic amines, consisting of a benzene ring and an ethylamine side chain. The structure permits substitutions to be made on the aromatic ring, the α- and β-carbon atoms, and the terminal amino group to yield a variety of compounds with sympathomimetic activity. NE, EPI, DA, isoproterenol, and a few other agents have hydroxyl groups substituted at positions 3 and 4 of the benzene ring. Since o-dihydroxybenzene is also known as catechol, sympathomimetic amines with these hydroxyl substitutions in the aromatic ring are termed catecholamines.

  - V = Other local vasoconstriction

- **β Activity**
  - B = Bronchodilator
  - C = Cardiac
  - U = Uterus

**CNS = Central nervous system activity**
Many directly acting sympathomimetic drugs influence both α and β receptors, but the ratio of activities varies among drugs in a continuous spectrum from predominantly α activity (phenylephrine) to predominantly β activity (isoproterenol) (see Table 12–1).

Catecholamines have only a brief duration of action and are ineffective when administered orally, because they are rapidly inactivated in the intestinal mucosa and in the liver before reaching the systemic circulation (see Chapter 8). Compounds without 1 or both hydroxyl substituents are not acted on by COMT, and their oral effectiveness and duration of action are enhanced.

**PHYSIOLOGICAL BASIS OF ADRENERGIC RECEPTOR FUNCTION.** An important factor in the response of any cell or organ to sympathomimetic amines is the density and proportion of α and β adrenergic receptors. For example, NE has relatively little capacity to increase bronchial airflow, since the receptors in bronchial smooth muscle are largely of the β₂ subtype. In contrast, isoproterenol and EPI are potent bronchodilators. Cutaneous blood vessels physiologically express almost exclusively α receptors; thus, NE and EPI cause constriction of such vessels, whereas isoproterenol has little effect. The smooth muscle of blood vessels that supply skeletal muscles has both β₂ and α receptors; activation of β₂ receptors causes vasodilation, and stimulation of α receptors constricts these vessels. In such vessels, the threshold concentration for activation of β₂ receptors by EPI is lower than that for α receptors, but when both types of receptors are activated at high concentrations of EPI, the response to α receptors predominates. Physiological concentrations of EPI primarily cause vasodilation.

The ultimate response of a target organ to sympathomimetic amines is dictated by the direct effects of the agents and the reflex homeostatic adjustments of the organism. Many sympathomimetic amines produce a rise in arterial blood pressure caused by stimulation of vascular α adrenergic receptors. This stimulation elicits compensatory reflexes
that are mediated by the carotid–aortic baroreceptor system. As a result, sympathetic tone is diminished and vagal tone is enhanced; each of these responses leads to slowing of the heart rate. Conversely, when a drug (e.g., a $\beta_2$ agonist) lowers mean blood pressure at the mechanoreceptors of the carotid sinus and aortic arch, the baroreceptor reflex works to restore pressure by reducing parasympathetic (vagal) outflow from the CNS to the heart, and increasing sympathetic outflow to the heart and vessels.

**FALSE-TRANSMITTER CONCEPT.** This hypothesis is a possible explanation for some of the effects of MAO inhibitors. Phenylethylamines normally are synthesized in the GI tract as a result of the action of bacterial tyrosine decarboxylase. The tyramine formed in this fashion usually is oxidatively deaminated in the GI tract and the liver. However, when an MAO inhibitor is administered, tyramine may be absorbed systemically and transported into sympathetic nerve terminals, where its catabolism again is prevented because of the inhibition of MAO at this site; the tyramine then is $\beta$-hydroxylated to octopamine, which is stored in vesicles. As a consequence, NE gradually is displaced by octopamine, and stimulation of the nerve terminal results in the release of a relatively small amount of NE along with a fraction of octopamine. The latter amine has relatively little ability to activate either $\alpha$ or $\beta$ receptors. Thus, a functional impairment of sympathetic transmission parallels long-term administration of MAO inhibitors.

Despite such functional impairment, patients who have received MAO inhibitors may experience severe hypertensive crises if they ingest cheese, beer, or red wine. These and related foods, which are produced by fermentation, contain a large quantity of tyramine, and to a lesser degree, other phenylethylamines. When GI and hepatic MAO are inhibited, the large quantity of tyramine that is ingested is absorbed rapidly and reaches the systemic circulation in high concentration. A massive and precipitous release of NE can result, with consequent hypertension that can be severe enough to cause myocardial infarction or a stroke (see Chapter 15).

**ENDOGENOUS CATECHOLAMINES**
**EPINEPHRINE**

EPI (adrenaline) is a potent stimulant of both α and β adrenergic receptors. Most of the responses listed in Table 8–1 are seen after injection of EPI, although the occurrence of sweating, piloerection, and mydriasis depends on the physiological state of the subject. Particularly prominent are the actions on the heart and on vascular and other smooth muscle.

**BLOOD PRESSURE.** EPI is one of the most potent vasopressor drugs known. If a pharmacological dose is given rapidly by an intravenous route, it evokes a characteristic effect on blood pressure, which rises rapidly to a peak that is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pressure, so that the pulse pressure increases. As the response wanes, the mean pressure may fall below normal before returning to control levels.

The mechanism of the rise in blood pressure due to EPI is:

- A direct myocardial stimulation that increases the strength of ventricular contraction (*positive inotropic action*)
- An increased heart rate (*positive chronotropic action*)
- Vasoconstriction in many vascular beds—especially in the precapillary resistance vessels of skin, mucosa, and kidney—along with marked constriction of the veins

The pulse rate, at first accelerated, may be slowed markedly at the height of the rise of blood pressure by compensatory vagal discharge (baroreceptor reflex). Small doses of EPI (0.1 μg/kg) may cause the blood pressure to fall. The depressor effect of small doses and the biphasic response to larger doses are due to greater sensitivity to EPI of vasodilator β₂ receptors than of constrictor α receptors.

Absorption of EPI after subcutaneous injection is slow due to local vasoconstrictor action; the effects of doses as large as 0.5-1.5 mg can be
duplicated by intravenous infusion at a rate of 10-30 μg/min. There is a moderate increase in systolic pressure due to increased cardiac contractile force and a rise in cardiac output (Figure 12–2). Peripheral resistance decreases, owing to a dominant action on β2 receptors of vessels in skeletal muscle, where blood flow is enhanced; as a consequence, diastolic pressure usually falls. Because the mean blood pressure is not, as a rule, greatly elevated, compensatory baroreceptor reflexes do not appreciably antagonize the direct cardiac actions. Heart rate, cardiac output, stroke volume, and left ventricular work per beat are increased as a result of direct cardiac stimulation and increased venous return to the heart, which is reflected by an increase in right atrial pressure. The details of the effects of intravenous infusion of EPI, NE, and isoproterenol in humans are compared in Table 12–2 and Figure 12–2.

*See text for details.
**VASCULAR EFFECTS.** In the vasculature, EPI acts chiefly on the smaller arterioles and precapillary sphincters, although veins and large arteries also respond to the drug. Various vascular beds react differently, which results in a substantial redistribution of blood flow. Injected EPI markedly decreases cutaneous blood flow, constricting precapillary vessels and small venules. Cutaneous vasoconstriction accounts for a marked decrease in blood flow in the hands and feet. Blood flow to skeletal muscles is increased by therapeutic doses in humans. This is due in part to a powerful $\beta_2$-mediated vasodilator action that is only partially counterbalanced by a vasoconstrictor
action on the α receptors that also are present in the vascular bed.

The effect of EPI on cerebral circulation is related to systemic blood pressure. In usual therapeutic doses, the drug has relatively little constrictor action on cerebral arterioles. Indeed, autoregulatory mechanisms tend to limit the increase in cerebral blood flow caused by increased blood pressure.

Doses of EPI that have little effect on mean arterial pressure consistently increase renal vascular resistance and reduce renal blood flow by as much as 40%. Since the glomerular filtration rate is only slightly and variably altered, the filtration fraction is consistently increased. Excretion of Na⁺, K⁺, and Cl⁻ is decreased; urine volume may be increased, decreased, or unchanged. Maximal tubular reabsorptive and excretory capacities are unchanged. The secretion of renin is increased as a consequence of a direct action of EPI on β₁ receptors in the juxtaglomerular apparatus. Arterial and venous pulmonary pressures are raised. Although direct pulmonary vasoconstriction occurs, redistribution of blood from the systemic to the pulmonary circulation, due to constriction of the more powerful musculature in the systemic great veins, doubtless plays an important part in the increase in pulmonary pressure. Very high concentrations of EPI may cause pulmonary edema precipitated by elevated pulmonary capillary filtration pressure and possibly by “leaky” capillaries.

Coronary blood flow is enhanced by EPI or by cardiac sympathetic stimulation under physiological conditions. The increased flow, which occurs even with doses that do not increase the aortic blood pressure, is the result of 2 factors. The first is the increased relative duration of diastole at higher heart rates; this is partially offset by decreased blood flow during systole because of more forceful contraction of the surrounding myocardium and an increase in mechanical compression of the coronary vessels. The increased flow during diastole is further enhanced if aortic blood pressure is elevated by EPI; as a consequence, total coronary flow may be increased. The second factor is a metabolic dilator effect that results from the increased strength of contraction and myocardial O₂ consumption due to the direct effects of EPI on cardiac myocytes. This vasodilation is mediated in part by adenosine released from cardiac myocytes, which tends to override a direct vasoconstrictor effect of EPI that results from
activation of α receptors in coronary vessels.

**CARDIAC EFFECTS.** EPI is a powerful cardiac stimulant. It acts directly on the predominant β₁ receptors of the myocardium and of the cells of the pacemaker and conducting tissues; β₂, β₃, and α receptors also are present in the heart. Direct responses to EPI include increases in contractile force, accelerated rate of rise of isometric tension, enhanced rate of relaxation, decreased time to peak tension, increased excitability, acceleration of the rate of spontaneous beating, and induction of automaticity in specialized regions of the heart. In accelerating the heart, EPI preferentially shortens systole so that the duration of diastole usually is not reduced.

EPI normally shortens the refractory period of the human atrioventricular (AV) node by direct effects on the heart, although doses of EPI that slow the heart through reflex vagal discharge may indirectly tend to prolong it. EPI also decreases the grade of AV block that occurs as a result of disease, drugs, or vagal stimulation. Depression of sinus rate and AV conduction by vagal discharge probably plays a part in EPI-induced ventricular arrhythmias, because various drugs that block the vagal effect confer some protection. The actions of EPI in enhancing cardiac automaticity are effectively antagonized by β receptor antagonists such as propranolol. However, α₁ receptors exist in most regions of the heart, and their activation prolongs the refractory period and strengthens myocardial contractions. Cardiac arrhythmias have been seen in patients after inadvertent intravenous administration of conventional subcutaneous doses of EPI. EPI as well as other catecholamines may cause myocardial cell death, particularly after intravenous infusions. Acute toxicity is associated with contraction band necrosis and other pathological changes; prolonged sympathetic stimulation of the heart, such as in congestive cardiomyopathy, may promote apoptosis of cardiomyocytes.

**EFFECTS ON SMOOTH MUSCLES.** The effects of EPI on the smooth muscles of different organs and systems depend on the type of adrenergic receptor in the muscle (see Table 8–1). In general, EPI relaxes GI smooth muscle due to activation of both α and β receptors.
Intestinal tone and the frequency and amplitude of spontaneous contractions are reduced. The stomach usually is relaxed and the pyloric and ileocecal sphincters are contracted, but these effects depend on the preexisting tone of the muscle. If tone already is high, EPI causes relaxation; if low, contraction.

The responses of uterine muscle to EPI vary with species, phase of the sexual cycle, state of gestation, and dose given. During the last month of pregnancy and at parturition, EPI inhibits uterine tone and contractions (see Chapter 66). EPI relaxes the detrusor muscle of the bladder as a result of activation of β receptors and contracts the trigone and sphincter muscles owing to its α-agonist activity. This can result in hesitancy in urination and may contribute to retention of urine in the bladder. Activation of smooth muscle contraction in the prostate promotes urinary retention.

**RESPIRATORY EFFECTS.** EPI has a powerful bronchodilator action, most evident when bronchial muscle is contracted because of disease, as in bronchial asthma, or in response to drugs or various autacoids.

The beneficial effects of EPI in asthma also may arise from inhibition of antigen-induced release of inflammatory mediators from mast cells, and to a lesser extent from diminution of bronchial secretions and congestion within the mucosa. Inhibition of mast cell secretion is mediated by β₂ receptors, while the effects on the mucosa are mediated by α receptors. however, glucocorticoids have much more profound anti-inflammatory effects (see Chapters 33 and 34).

**EFFECTS ON THE CNS.** EPI, a polar compound, penetrates poorly into the CNS and hence is not a powerful CNS stimulant. While the drug may cause restlessness, apprehension, headache, and tremor in many persons, these effects in part may be secondary to the effects of EPI on the cardiovascular system, skeletal muscles, and intermediary metabolism; that is, they may be the result of somatic manifestations of anxiety.

**METABOLIC EFFECTS.** EPI elevates the concentrations of glucose and lactate in blood (see Chapter 8). Insulin secretion is inhibited through an interaction with α₂ receptors and is enhanced by activation of α₂ receptors; the predominant effect seen with EPI is inhibition. Glucagon secretion is enhanced by an action
on the β receptors of the α cells of pancreatic islets. EPI also decreases the uptake of glucose by peripheral tissues. EPI stimulates glycogenolysis in most tissues through β receptors. EPI raises the concentration of free fatty acids in blood by stimulating β receptors in adipocytes. The calorigenic action of EPI (increase in metabolism) is reflected in humans by an increase of 20-30% in O₂ consumption after conventional doses.

**MISCELLANEOUS EFFECTS.** EPI reduces circulating plasma volume by loss of protein-free fluid to the extracellular space, thereby increasing hematocrit and plasma protein concentration. EPI rapidly increases the number of circulating polymorphonuclear leukocytes, likely due to β receptor–mediated demargination of these cells. EPI accelerates blood coagulation and promotes fibrinolysis. EPI stimulates lacrimation and a scanty mucus secretion from salivary glands. EPI also acts directly on white, fast-twitch muscle fibers to prolong the active state, thereby increasing peak tension.

EPI promotes a fall in plasma K⁺, largely due to stimulation of K⁺ uptake into cells, particularly skeletal muscle, due to activation of β₂ receptors. This is associated with decreased renal K⁺ excretion.

**ABSORPTION, FATE, AND EXCRETION.** EPI is ineffective after oral administration. Absorption from subcutaneous tissues occurs relatively slowly. Absorption is more rapid after intramuscular injection. When concentrated solutions are nebulized and inhaled, the actions of the drug largely are restricted to the respiratory tract; however, systemic reactions such as arrhythmias may occur, particularly if larger amounts are used. EPI is rapidly inactivated in the liver by COMT and MAO (see Figure 8–7 and Table 8–4).

EPI is available in a variety of formulations geared for different routes of administration, including self-administration for anaphylactic reactions (EpiPen). EPI is unstable in alkaline solution; when exposed to air or light, it turns pink from oxidation to adrenochrome and then brown from formation of polymers. EPI injection is available in 1 mg/mL (1:1000), 0.1 mg/mL (1:10,000), and 0.5 mg/mL (1:2000) solutions. Subcutaneous dose ranges from 0.3-0.5 mg. The intravenous route is used cautiously if an immediate and reliable effect is mandatory. If the solution is given by vein, it must be adequately diluted and
injected very slowly.

**TOXICITY, ADVERSE EFFECTS, AND CONTRAINDICATIONS.**
EPI may cause restlessness, throbbing headache, tremor, and palpitations. The effects rapidly subside with rest, quiet, recumbency, and reassurance. More serious reactions include cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental, rapid intravenous injection of EPI may result in cerebral hemorrhage from the sharp rise in blood pressure. Angina may be induced by EPI in patients with coronary artery disease. The use of EPI generally is contraindicated in patients who are receiving nonselective β receptor antagonists, because its unopposed actions on vascular α₁ receptors may lead to severe hypertension and cerebral hemorrhage.

**THERAPEUTIC USES.** A major use of EPI is to provide rapid, emergency relief of hypersensitivity reactions, including anaphylaxis, to drugs and other allergens. EPI also is used to prolong the action of local anesthetics, presumably by decreasing local blood flow (see Chapter 20). Its cardiac effects may be of use in restoring cardiac rhythm in patients with cardiac arrest due to various causes. It also is used as a topical hemostatic agent on bleeding surfaces such as in the mouth or in bleeding peptic ulcers during endoscopy of the stomach and duodenum. Inhalation of EPI may be useful in the treatment of post-intubation and infectious croup.

**NOREPINEPHRINE**

Norepinephrine (levarterenol, l-noradrenaline, NE) is a major chemical mediator liberated by mammalian postganglionic sympathetic nerves (see Table 12–1).

NE constitutes 10-20% of the catecholamine content of human adrenal medulla and as much as 97% in some pheochromocytomas.

**PHARMACOLOGICAL PROPERTIES.** The pharmacological actions
of NE and EPI are compared in Table 12–2. Both drugs are direct agonists on effector cells; their actions differ mainly in the ratio of their effectiveness in stimulating $\alpha$ and $\beta_2$ receptors. They are approximately equipotent in stimulating $\beta_1$ receptors. NE is a potent $\alpha$ agonist, has relatively little action on $\beta_2$ receptors, and is somewhat less potent than EPI on the $\alpha$ receptors of most organs.

**ABSORPTION, FATE, AND EXCRETION.** NE, like EPI, is ineffective when given orally and is absorbed poorly from sites of subcutaneous injection. It is rapidly inactivated in the body by uptake and the actions of COMT and MAO. Small amounts normally are found in the urine. The excretion rate may be greatly increased in patients with pheochromocytoma.

**CARDIOVASCULAR EFFECTS.** In response to infused NE (see Figure 12–2), systolic and diastolic pressures, and usually pulse pressure, are increased. Cardiac output is unchanged or decreased, and total peripheral resistance is raised. Compensatory vagal reflex activity slows the heart, overcoming a direct cardioaccelerator action, and stroke volume is increased. The peripheral vascular resistance increases in most vascular beds, and renal blood flow is reduced. NE constricts mesenteric vessels and reduces splanchnic and hepatic blood flow. Coronary flow usually is increased, probably owing both to indirectly induced coronary dilation, as with EPI, and to elevated blood pressure. Although generally a poor $\beta_2$ receptor agonist, NE may increase coronary blood flow directly by stimulating $\beta_2$ receptors on coronary vessels. Patients with Prinzmetal variant angina pectoris may be supersensitive to the $\alpha$ adrenergic vasoconstrictor effects of NE.

**ADVERSE EFFECTS AND PRECAUTIONS.** The untoward effects of NE are similar to those of EPI, although there typically is greater elevation of blood pressure with NE. Care must be taken that necrosis and sloughing do not occur at the site of intravenous injection owing to extravasation of the drug. Impaired circulation at injection sites may be relieved by infiltrating the area with phentolamine, an $\alpha$ receptor antagonist. Blood pressure must be determined frequently during the infusion and particularly during adjustment of the rate of
the infusion. Reduced blood flow to organs such as kidney and intestines is a constant danger with the use of NE.

**THERAPEUTIC USES AND STATUS.** NE (LEVOPHED, others) is used as a vasoconstrictor to raise or support blood pressure under certain intensive care conditions (discussed below).

**DOPAMINE**

DA (see Table 12–1) is the immediate metabolic precursor of NE and EPI; it is a central neurotransmitter important in the regulation of movement (see Chapters 14, 16, and 22) and possesses important intrinsic pharmacological properties. In the periphery, it is synthesized in epithelial cells of the proximal tubule and is thought to exert local diuretic and natriuretic effects. DA is a substrate for both MAO and COMT and thus is ineffective when administered orally.

**PHARMACOLOGICAL PROPERTIES.**

**Cardiovascular Effects.** The cardiovascular effects of DA are mediated by several distinct types of receptors that vary in their affinity for DA (see Chapter 13). At low concentrations, the primary interaction of DA is with vascular D_1 receptors, especially in the renal, mesenteric, and coronary beds. By activating adenylyl cyclase and raising intracellular concentrations of cyclic AMP, D_1 receptor stimulation leads to vasodilation. Infusion of low doses of DA causes an increase in glomerular filtration rate, renal blood flow, and Na\(^+\) excretion. Activation of D_1 receptors on renal tubular cells decreases Na\(^+\) transport by cyclic AMP-dependent and cyclic AMP-independent mechanisms. The renal tubular actions of DA that cause natriuresis may be augmented by the increase in renal blood flow and the small increase in the glomerular filtration rate that follow its administration. The resulting increase in hydrostatic pressure in the peritubular capillaries and reduction in oncotic pressure may contribute to diminished reabsorption of Na\(^+\) by the proximal tubular cells. As a consequence, DA has pharmacologically appropriate effects in the management of states of low cardiac output associated with compromised renal function, such as severe congestive heart failure.
At higher concentrations, DA exerts a positive inotropic effect on the myocardium, acting on $\beta_1$ adrenergic receptors. DA also causes the release of NE from nerve terminals, which contributes to its effects on the heart. Tachycardia is less prominent during infusion of DA than of isoproterenol. DA usually increases systolic blood pressure and pulse pressure and either has no effect on diastolic blood pressure or increases it slightly. Total peripheral resistance usually is unchanged when low or intermediate doses of DA are given. At high concentrations, DA activates vascular $\alpha_1$ receptors, leading to more general vasoconstriction.

**PRECAUTIONS, ADVERSE REACTIONS, AND CONTRAINDICATIONS.**

Before DA is administered to patients in shock, hypovolemia should be corrected by transfusion of whole blood, plasma, or other appropriate fluid. Untoward effects due to overdosage generally are attributable to excessive sympathomimetic activity (although this also may be the response to worsening shock). Nausea, vomiting, tachycardia, anginal pain, arrhythmias, headache, hypertension, and peripheral vasoconstriction may be encountered during DA infusion. Extravasation of large amounts of DA during infusion may cause ischemic necrosis and sloughing. Rarely, gangrene of the fingers or toes has followed prolonged infusion of the drug. DA should be avoided if the patient has received an MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

**THERAPEUTIC USES.** DA is used in the treatment of severe congestive heart failure, particularly in patients with oliguria and low or normal peripheral vascular resistance. The drug may improve physiological parameters in the treatment of cardiogenic and septic shock. While DA may acutely improve cardiac and renal function in severely ill patients with chronic heart disease or renal failure, there is relatively little evidence supporting long-term benefit in clinical outcome.

Dopamine hydrochloride is used only intravenously, administered at a rate of 2-5 $\mu$g/kg/min; this rate may be increased gradually up to 20-50 $\mu$g/kg/min as necessary. During the infusion, patients require clinical assessment of myocardial function, perfusion of vital organs such as the brain, and the production of urine. Reduction in urine flow, tachycardia, or the development of arrhythmias may be indications to slow or terminate the infusion. The duration
of action of DA is brief, and hence the rate of administration can be used to control the intensity of effect.

Related drugs include fenoldopam and dopexamine. Fenoldopam (CORLOPAM, others), a benzazepine derivative, is a rapidly acting vasodilator used for control of severe hypertension (e.g., malignant hypertension with end-organ damage) in hospitalized patients for ≤48 h. Fenoldopam is an agonist for peripheral D₁ receptors and binds with moderate affinity to α₂ adrenergic receptors; it has no significant affinity for D₂ receptors or α₁ or β adrenergic receptors. Fenoldopam is a racemic mixture; the R-isomer is the active component. It dilates a variety of blood vessels, including coronary arteries, afferent and efferent arterioles in the kidney, and mesenteric arteries. Less than 6% of an orally administered dose is absorbed because of extensive first-pass metabolism. The elimination $t_{1/2}$ of intravenously infused fenoldopam is ~10 min. Adverse effects are related to the vasodilation and include headache, flushing, dizziness, and tachycardia or bradycardia.

Dopexamine (DOPACARD) is a synthetic analog related to DA with intrinsic activity at dopamine D₁ and D₂ receptors as well as at β₂ receptors; it may have other effects such as inhibition of catecholamine uptake. It has favorable hemodynamic actions in patients with severe congestive heart failure, sepsis, and shock. In patients with low cardiac output, dopexamine infusion significantly increases stroke volume with a decrease in systemic vascular resistance. Tachycardia and hypotension can occur, but usually only at high infusion rates. Dopexamine is not currently available in the U.S.

**β ADRENERGIC RECEPTOR AGONISTS**

β agonists play a major role only in the treatment of bronchoconstriction in patients with asthma (reversible airway obstruction) or chronic obstructive pulmonary disease (COPD). Minor uses include management of preterm labor, treatment of complete heart block in shock, and short-term treatment of cardiac decompensation after surgery or in patients with congestive heart failure or myocardial infarction. β Receptor agonists may be used to stimulate the rate and force of cardiac contraction. The chronotropic
effect is useful in the emergency treatment of arrhythmias such as torsade de pointes, bradycardia, or heart block (see Chapter 29).

**ISOPROTERENOL**

Isoproterenol (see Table 12–1) is a potent, nonselective β receptor agonist with very low affinity for α receptors. Consequently, isoproterenol has powerful effects on all β receptors and almost no action at α receptors.

**PHARMACOLOGICAL ACTIONS.** The major cardiovascular effects of isoproterenol (compared with EPI and NE) are illustrated in Figure 12–2. IV infusion of isoproterenol lowers peripheral vascular resistance, primarily in skeletal muscle but also in renal and mesenteric vascular beds. Diastolic blood pressure falls. Systolic blood pressure may remain unchanged or rise, although mean arterial pressure typically falls. Cardiac output is increased because of the positive inotropic and chronotropic effects of the drug in the face of diminished peripheral vascular resistance. The cardiac effects of isoproterenol may lead to palpitations, sinus tachycardia, and more serious arrhythmias.

Isoproterenol relaxes almost all varieties of smooth muscle when the tone is high, but this action is most pronounced on bronchial and GI smooth muscle. It prevents or relieves bronchoconstriction. Its effect in asthma may be due in part to an additional action to inhibit antigen-induced release of histamine and other mediators of inflammation; this action is shared by β₂-selective stimulants.

**ABSORPTION, FATE, AND EXCRETION.** Isoproterenol is readily absorbed when given parenterally or as an aerosol. It is metabolized primarily in the liver and other tissues by COMT. Isoproterenol is a relatively poor substrate for MAO and is not taken up by sympathetic neurons to the same extent as are EPI and NE. The duration of action of isoproterenol therefore may be longer than that of EPI, but it still is brief.

**TOXICITY AND ADVERSE EFFECTS.** Palpitations, tachycardia, headache,
and flushing are common. Cardiac ischemia and arrhythmias may occur, particularly in patients with underlying coronary artery disease.

**THERAPEUTIC USES.** Isoproterenol (ISUPREL, others) may be used in emergencies to stimulate heart rate in patients with bradycardia or heart block, particularly in anticipation of inserting an artificial cardiac pacemaker or in patients with the ventricular arrhythmia torsade de pointes. In disorders such as asthma and shock, isoproterenol largely has been replaced by other sympathomimetic drugs (see below and Chapter 36).

**DOBUTAMINE**

The pharmacological effects of *dobutamine* (see Table 12–1) are due to direct interactions with α and β receptors and are complex.

Dobutamine possesses a center of asymmetry; both enantiomeric forms are present in the racemic mixture used clinically. The (−) isomer of dobutamine is a potent agonist at α₁ receptors and is capable of causing marked pressor responses; (+)-dobutamine is a potent α₁ receptor antagonist, which can block the effects of (−)-dobutamine. Both isomers are full agonists at β receptors, but the (+) isomer is a more potent β receptor agonist than the (−) isomer (~10-fold).

**CARDIOVASCULAR EFFECTS.** The cardiovascular effects of racemic dobutamine are a composite of the pharmacological properties of the (−) and (+) stereoisomers. Dobutamine has relatively more prominent inotropic than chronotropic effects on the heart compared to isoproterenol. Although not completely understood, this useful selectivity may arise because peripheral resistance is relatively unchanged. Alternatively, cardiac α₁ receptors may contribute to the inotropic effect. At equivalent inotropic doses, dobutamine enhances automaticity of the sinus node to a lesser extent than does isoproterenol; however, enhancement of atrioventricular and intraventricular conduction is similar for both drugs.

**ADVERSE EFFECTS.** Blood pressure and heart rate may increase significantly during dobutamine administration requiring reduction of infusion rate. Patients with a history of hypertension may exhibit an exaggerated pressor response more frequently. Because dobutamine facilitates AV conduction, patients with atrial
fibrillation are at risk of marked increases in ventricular response rates; digoxin or other measures may be required to prevent this from occurring. Some patients may develop ventricular ectopic activity. As with any inotropic agent, dobutamine may increase the size of a myocardial infarct by increasing myocardial O₂ demand. The efficacy of dobutamine over a period of more than a few days is uncertain; there is evidence for the development of tolerance.

THERAPEUTIC USES. Dobutamine (DOBUTREX) is indicated for the short-term treatment of cardiac decompensation that may occur after cardiac surgery or in patients with congestive heart failure or acute myocardial infarction. Dobutamine increases cardiac output and stroke volume in such patients, usually without a marked increase in heart rate. Alterations in blood pressure or peripheral resistance usually are minor. An infusion of dobutamine in combination with echocardiography is useful in the noninvasive assessment of patients with coronary artery disease.

Dobutamine has a t₁/₂ ~2 min; the onset of effect is rapid, steady-state concentrations are achieved within 10 min, and major metabolites are conjugates of dobutamine and 3-O-methyldobutamine. The rate of infusion required to increase cardiac output is 2.5-10 μg/kg/min; higher infusion rates occasionally are required. The rate and duration of the infusion are determined by the clinical and hemodynamic responses of the patient.

β₂-SELECTIVE ADRENERGIC RECEPTOR AGONISTS

In the treatment of asthma or COPD, drugs with preferential affinity for β₂ receptors compared with β₁ receptors have been developed. The selectivity, however, is not absolute, and is lost at high concentrations of these drugs. Moreover up to 40% of the β receptors in the human heart are β₂ receptors, activation of which can cause cardiac stimulation. A useful strategy to enhance preferential activation of pulmonary β₂ receptors is the administration by inhalation of small doses of the drug in aerosol form. This approach typically leads to effective activation of β₂ receptors in the bronchi but very low systemic drug concentrations. Consequently, there is less potential to activate cardiac β₁ or β₂ receptors or to stimulate β₂
receptors in skeletal muscle, which can cause tremor and thereby limit oral therapy.

Administration of β agonists by aerosol (see Chapter 36) typically leads to a very rapid therapeutic response, generally within minutes, although some agonists such as salmeterol have a delayed onset of action. Only ~10% of an inhaled dose actually enters the lungs; much of the remainder is swallowed and ultimately may be absorbed.

In the treatment of asthma and COPD, β receptor agonists are used to activate pulmonary receptors that relax bronchial smooth muscle and decrease airway resistance. β receptor agonists also may suppress the release of leukotrienes and histamine from mast cells in lung tissue, enhance mucociliary function, and decrease microvascular permeability.

**SHORT-ACTING β₂ ADRENERGIC AGONISTS**

**METAPROTERENOL.** Metaproterenol (called orciprenaline in Europe), along with terbutaline and fenoterol, belongs to the structural class of resorcinol bronchodilators that have hydroxyl groups at positions 3 and 5 of the phenyl ring (rather than at positions 3 and 4 as in catechols) (see Table 12–1). Consequently, metaproterenol is resistant to methylation by COMT. It is excreted primarily as glucuronic acid conjugates. Metaproterenol is considered to be β₂-selective, although it probably is less selective than albuterol or terbutaline and hence is more prone to cause cardiac stimulation.

Effects occur within minutes of inhalation and persist for several hours. After oral administration, onset of action is slower, but effects last 3-4 h. Metaproterenol is used for the long-term treatment of obstructive airway diseases, asthma, and for treatment of acute bronchospasm. Side effects are similar to the short- and intermediate-acting sympathomimetic bronchodilators.

**ALBUTEROL.** Albuterol (VENTOLIN-HFA, PROVENTIL-HFA, others; see Table 12–1) is a selective β₂ receptor agonist with pharmacological properties and therapeutic indications similar to
those of terbutaline. It is administered either by inhalation or orally for the symptomatic relief of bronchospasm.

When administered by inhalation, it produces significant bronchodilation within 15 min, and effects persist for 3-4 h. The cardiovascular effects of albuterol are considerably weaker than those of isoproterenol when doses that produce comparable bronchodilation are administered by inhalation. Oral albuterol has the potential to delay preterm labor. Although rare, CNS and respiratory side effects are sometimes observed.

**LEVALBUTEROL.** Levalbuterol (XOPENEX) is the R-enantiomer of albuterol that is used to treat asthma and COPD. Levalbuterol is β2-selective and acts like other β2 adrenergic agonists and has similar pharmacokinetic and pharmacodynamics properties to albuterol.

**PIRBUTEROL.** Pirbuterol is a relatively selective β2 agonist. Pirbuterol acetate (MAXAIR) is available for inhalation therapy; dosing is typically every 4-6 h.

**TERBUTALINE.** Terbutaline is a β2-selective bronchodilator. It contains a resorcinol ring and thus is not a substrate for COMT methylation. It is effective when taken orally, subcutaneously, or by inhalation (not marketed for inhalation in the U.S.).

Effects are observed rapidly after inhalation or parenteral administration; after inhalation its action may persist 3-6 h. With oral administration, the onset of effect may be delayed 1-2 h. Terbutaline (Brethine, others) is used for the long-term treatment of obstructive airway diseases and for treatment of acute bronchospasm, and also is available for parenteral use for the emergency treatment of status asthmaticus (see Chapter 36).

**ISOETHARINE.** Isoetharine selectivity for β2 receptors may not approach that of some of the other agents. Although resistant to metabolism by MAO, it is a catecholamine and thus is a good substrate for COMT. It is used only by inhalation for the treatment of acute episodes of bronchoconstriction. Isoetharine is not marketed in the U.S.
**BITOLTEROL.** Bitolterol (TORNALATE) is a β₂ agonist in which the hydroxyl groups in the catechol moiety are protected by esterification. Esterases in the lung and other tissues hydrolyze this prodrug to the active form, colterol, or terbutynorepinephrine. The duration of effect of bitolterol after inhalation ranges from 3-6 h. Bitolterol has been discontinued in the U.S.

**FENOTEROL.** Fenoterol (BEROTEC) is a β₂-selective receptor agonist. After inhalation, it has a prompt onset of action, and its effect typically is sustained for 4-6 h. The possible association of fenoterol use with increased deaths from asthma, although controversial, has led to its withdrawal from the market.

**PROCATEROL.** Procaterol (MASCACIN, others) is a β₂-selective receptor agonist. After inhalation, it has a prompt onset of action that is sustained for ~5 h. Procaterol is not available in the U.S.

**LONG-ACTING β₂ ADRENERGIC AGONISTS (LABA)**

**SALMETEROL.** Salmeterol (SEREVENT) is a β₂-selective agonist with a prolonged duration of action (>12 h); it has at least 50-fold greater selectivity for β₂ receptors than albuterol. It provides symptomatic relief and improves lung function and quality of life in patients with COPD. It has additive effects when used in combination with inhaled ipratropium or oral theophylline. It is highly lipophilic and has a sustained duration of action. It also may have anti-inflammatory activity.

Salmeterol is metabolized by CYP3A4 to α-hydroxy-salmeterol, which is eliminated primarily in the feces. The onset of action of inhaled salmeterol is relatively slow, so it is not suitable monotherapy for acute breakthrough attacks of bronchospasm. Salmeterol generally is well tolerated. Salmeterol should not be used more than twice daily (morning and evening) and should not be used to treat acute asthma symptoms, which should be treated with a short-acting β₂ agonist (e.g., albuterol) when breakthrough symptoms occur despite twice-daily use of salmeterol. The use of LABA is recommended only for patients in whom inhaled corticosteroids alone either have failed to achieve good asthma control or for initial therapy.
FORMOTEROL. Formoterol (FORADIL, others) is a long-acting $\beta_2$-selective receptor agonist. Significant bronchodilation occurs within minutes of inhalation of a therapeutic dose, which may persist for up to 12 h. It is highly lipophilic and has high affinity for $\beta_2$ receptors. Its major advantage over many other $\beta_2$-selective agonists is this prolonged duration of action. Formoterol is FDA-approved for treatment of asthma, bronchospasm, prophylaxis of exercise-induced bronchospasm, and COPD. It can be used concomitantly with short-acting $\beta_2$ agonists, glucocorticoids (inhaled or systemic), and theophylline.

ARFORMOTEROL. Arformoterol (BROVANA), the (R, R) enantiomer of formoterol, is a selective long-acting $\beta_2$ agonist that has twice the potency of racemic formoterol. It is used for the long-term treatment of bronchoconstriction in patients with COPD, including chronic bronchitis and emphysema. Systemic exposure to arformoterol is due to pulmonary absorption with plasma levels reaching peak levels in 0.25-1 h. Plasma protein binding is 52-65%. It is primarily metabolized by CYP2D6 and CYP2C19. It does not inhibit any of the common CYPs.

INDACATEROL. Indacaterol is a once-daily long-acting $\beta$ adrenergic agonist, classified as an ultra-LABA, was recently approved for treatment of COPD.

It has a fast onset of action, long duration, and appears well tolerated. Indacaterol behaves as a potent $\beta_2$ agonist with high intrinsic efficacy, which, in contrast to salmeterol, does not antagonize the bronchorelaxant effect of short-acting $\beta_2$ adrenergic agonists. Evidence indicates that indacaterol has a longer duration of action than salmeterol and formoterol. Indacaterol is not indicated for the treatment of asthma.

Carmoterol is also an ultra-LABA that is currently in phase III clinical trials in the U.S.

RITODRINE. Ritodrine is a $\beta_2$-selective agonist that was developed specifically for use as a uterine relaxant. Nevertheless, its pharmacological properties closely resemble those of the other agents in this group.
The pharmacokinetic properties of ritodrine are complex and incompletely defined, especially in pregnant women. Ritodrine may be administered intravenously to selected patients to arrest premature labor. However, β2-selective agonists may not have clinically significant benefits on perinatal mortality and may actually increase maternal morbidity. Ritodrine is not available in the U.S. See Chapter 66 for the pharmacology of tocolytic agents.

**ADVERSE EFFECTS OF β2-SELECTIVE AGONISTS.** The major adverse effects of β receptor agonists occur as a result of excessive activation of β receptors. Patients with underlying cardiovascular disease are particularly at risk for significant reactions. However, the likelihood of adverse effects can be greatly decreased in patients with lung disease by administering the drug by inhalation.

Tremor is a relatively common adverse effect of the β2-selective receptor agonists. Tolerance generally develops to this effect. This adverse effect can be minimized by starting oral therapy with a low dose of drug and progressively increasing the dose as tolerance to the tremor develops. Feelings of restlessness, apprehension, and anxiety may limit therapy with these drugs, particularly oral or parenteral administration.

Tachycardia is a common adverse effect of systemically administered β receptor agonists. Stimulation of heart rate occurs primarily by means of β1 receptors. During a severe asthma attack, heart rate actually may decrease during therapy with a β agonist, presumably because of improvement in pulmonary function with consequent reduction in endogenous cardiac sympathetic stimulation. In patients without cardiac disease, β agonists rarely cause significant arrhythmias or myocardial ischemia; however, patients with underlying coronary artery disease or preexisting arrhythmias are at greater risk. The risk of adverse cardiovascular effects also is increased in patients who are receiving MAO inhibitors. In general, at least 2 weeks should elapse between the use of MAO inhibitors and administration of β2 agonists or other sympathomimetics.

When given parenterally, these drugs may increase the concentrations of plasma glucose, lactate, and free fatty acids and decrease the concentration of K+. The decrease in K+ concentration is especially important in patients with cardiac disease taking digoxin and diuretics. In some diabetic patients, hyperglycemia
may be worsened and higher doses of insulin may be required. These adverse effects are far less likely with inhalation therapy.

**β3-SELECTIVE ADRENERGIC RECEPTOR AGONISTS**

**MIRABEGRON.** *(Myrbetriq)*, a selective β3 adrenergic agonist, is approved for the treatment of overactive bladder (urinary urgency, frequency, urge incontinence). The drug activates β3 adrenergic receptors on the detrusor muscle of the bladder to facilitate filling of the bladder and storage of urine. The drug is administered orally with a starting dose of 25 mg once daily. Side effects may include hypertension, nasopharyngitis, urinary tract infection, and headache. Mirabegron is an inhibitor of CYPs 2D6 and 3A.

**α1-SELECTIVE ADRENERGIC RECEPTOR AGONISTS**

Activation of α adrenergic receptors in vascular smooth muscle results in contraction, causing increases in peripheral vascular resistance and increases in blood pressure. Although the clinical utility of these drugs is limited, they may be useful in the treatment of some patients with hypotension, including orthostatic hypotension, or shock. *Phenylephrine and methoxamine* (discontinued in the U.S.) are direct-acting vasoconstrictors and are selective activators of α1 receptors. *Mephentermine and metaraminol* act both directly and indirectly. *Midodrine* is a prodrug that is converted, after oral administration, to *desglymidodrine*, a direct-acting α1 agonist.

**PHENYLEPHRINE.** Phenylephrine *(Neosynephrine, others)* is a α1-selective agonist; it activates β receptors only at much higher concentrations. The drug causes marked arterial vasoconstriction during intravenous infusion. Phenylephrine *(Neosynephrine, others)* also is used as a nasal decongestant and as a mydriatic in various nasal and ophthalmic formulations *(see Chapter 64).*

**Mephentermine.** Mephentermine acts both directly and indirectly. After an intramuscular injection, the onset of action is prompt (within 5-15 min), and effects may last for several hours. Because the drug releases NE, cardiac
contraction is enhanced, and cardiac output and systolic and diastolic pressures usually are increased. The change in heart rate is variable, depending on the degree of vagal tone. Adverse effects are related to CNS stimulation, excessive rises in blood pressure, and arrhythmias. Mephentermine is used to prevent hypotension, which frequently accompanies spinal anesthesia. The drug has been discontinued in the U.S.

**METARAMINOL.** Metaraminol exerts direct effects on vascular α adrenergic receptors. Metaraminol also is an indirectly acting agent that stimulates the release of NE. The drug has been used in the treatment of hypotensive states or off-label to relieve attacks of paroxysmal atrial tachycardia, particularly those associated with hypotension (see Chapter 29).

**MIDODRINE.** Midodrine (PROAMATINE, others) is an orally effective α₁ receptor agonist. It is a prodrug, converted to an active metabolite, desglymidodrine. Midodrine-induced rises in blood pressure are associated with both arterial and venous smooth muscle contraction. A frequent complication in these patients is supine hypertension. This can be minimized by administering the drug during periods when the patient will remain upright, and elevating the head of the bed. Typical dosing, achieved by careful titration of blood pressure responses, varies between 2.5 and 10 mg thrice daily.

**α₂-SELECTIVE ADRENERGIC RECEPTOR AGONISTS**

α₂-Selective adrenergic agonists are used primarily for the treatment of systemic hypertension. Their efficacy as antihypertensive agents is somewhat surprising, as many blood vessels contain postsynaptic α₂ adrenergic receptors that promote vasoconstriction (see Chapter 8). Clonidine, the prototypic α₂ agonist, lowers blood pressure by activation of α₂ receptors in the CNS. Some α₂ agonists are used to reduce intraocular pressure.

**CLONIDINE**

Intravenous infusion of clonidine causes an acute rise in blood pressure, because of activation of postsynaptic α₂ receptors in
vascular smooth muscle. This transient vasoconstriction (not usually seen with oral administration) is followed by a more prolonged hypotensive response that results from decreased sympathetic outflow from the CNS. The effect appears to result, at least in part, from activation of $\alpha_2$ receptors in the lower brainstem region. Clonidine also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate. In addition, some of the antihypertensive effects of clonidine may be mediated by activation of presynaptic $\alpha_2$ receptors that suppress the release of NE, ATP, and NPY from postganglionic sympathetic nerves. Clonidine decreases the plasma concentration of NE and reduces its excretion in the urine.

![CLONIDINE]

**ABSORPTION, FATE, AND EXCRETION.** Clonidine is well absorbed after oral administration, with bioavailability $\sim$100%. Peak concentration in plasma and the maximal hypotensive effect are observed 1-3 h after an oral dose. The elimination $t_{1/2}$ is 6-24 h (mean of $\sim$12 h). About half of an administered dose can be recovered unchanged in the urine; the $t_{1/2}$ of the drug may increase with renal failure. A transdermal delivery patch permits continuous administration of clonidine as an alternative to oral therapy. The drug is released at an approximately constant rate for a week; 3-4 days are required to reach steady-state concentrations in plasma. When the patch is removed, plasma concentrations remain stable for $\sim$8 h and then decline gradually over a period of several days; this decrease is associated with a rise in blood pressure.

**ADVERSE EFFECTS.** The major adverse effects of clonidine are dry mouth and sedation, which may diminish in intensity after several weeks of therapy. Sexual dysfunction also may occur. Marked bradycardia is observed in some patients. These effects of clonidine frequently are related to dose, and their incidence may be lower with transdermal administration of clonidine. About 15-20% of patients develop contact dermatitis when using the transdermal system. Withdrawal
reactions follow abrupt discontinuation of long-term therapy with clonidine in some hypertensive patients (see Chapter 27).

**THERAPEUTIC USES.** The major therapeutic use of clonidine (Catapres, others) is in the treatment of hypertension (see Chapter 27). Clonidine also has apparent efficacy in the off-label treatment of a range of other disorders: in reducing diarrhea in some diabetic patients with autonomic neuropathy, in treating and preparing addicted subjects for withdrawal from narcotics, alcohol, and tobacco (see Chapter 24) by ameliorating some of the adverse sympathetic nervous activity associated with withdrawal and decreasing craving for the drug, in reducing the incidence of menopausal hot flashes (transdermal application of Catapres). Acute administration of clonidine has been used in the differential diagnosis of patients with hypertension and suspected pheochromocytoma. Among the other off-label uses of clonidine are atrial fibrillation, attention deficit hyperactivity disorder (ADHD), constitutional growth delay in children, cyclosporine-associated nephrotoxicity, Tourette syndrome, hyperhidrosis, mania, posthepatic neuralgia, psychosis, restless leg syndrome, ulcerative colitis, and allergy-induced inflammatory reactions in patients with extrinsic asthma.

**APRACLONIDINE.** Apraclonidine (IOPIDINE) is a relatively selective α₂ receptor agonist that is used topically to reduce intraocular pressure with minimal systemic effects.

Apreclonidine does not cross the blood-brain barrier and is more useful than clonidine for ophthalmic therapy. Apraclonidine is useful as short-term adjunctive therapy in glaucoma patients whose intraocular pressure is not well controlled by other pharmacological agents. The drug also is used to control or prevent elevations in intraocular pressure that occur in patients after laser trabeculoplasty or iridotomy (see Chapter 64).

**BRIMONIDINE.** Brimonidine (Alphagan, others) is a clonidine derivative and α₂-selective agonist that is administered ocularly to lower intraocular pressure in patients with ocular hypertension or open-angle glaucoma. Unlike apraclonidine, brimonidine can cross the blood-brain barrier and can produce hypotension and sedation, although these CNS effects are slight compared to those of clonidine.

**GUANFACINE.** Guanfacine (Tenex, others) is an α₂ receptor agonist that is
more selective for $\alpha_2$ receptors than is clonidine. Guanfacine lowers blood pressure by activation of brainstem receptors with resultant suppression of sympathetic activity. A sustained-release form (INTUNIV) is FDA-approved for treatment of ADHD in children ages 6-17 years. Guanfacine and clonidine appear to have similar efficacy for the treatment of hypertension and similar pattern of adverse effects. A withdrawal syndrome may occur after the abrupt discontinuation, but it is less frequent and milder than the syndrome that follows clonidine withdrawal; this difference may relate to the longer $t_{1/2}$ of guanfacine.

GUANABENZ. Guanabenz (WYTENSIN, others) is a centrally acting $\alpha_2$ agonist that decreases blood pressure by a mechanism similar to those of clonidine and guanfacine. Guanabenz has a $t_{1/2}$ of 4-6 h and is extensively metabolized by the liver; dosage adjustment may be necessary in patients with hepatic cirrhosis. The adverse effects caused by guanabenz are similar to those seen with clonidine.

METHYLDOPA. Methyldopa ($\alpha$-methyl-3,4-dihydroxyphenylalanine) is a centrally acting antihypertensive agent. It is metabolized to $\alpha$-methylnorepinephrine in the brain, and this compound is thought to activate central $\alpha_2$ receptors and lower blood pressure in a manner similar to that of clonidine (see Chapter 27).

TIZANIDINE. Tizanidine (ZANAFLEX, others) is a muscle relaxant used for the treatment of spasticity associated with cerebral and spinal disorders. It is also an $\alpha_2$ agonist with some properties similar to those of clonidine.

MISCELLANEOUS SYMPATHOMIMETIC AGONISTS

AMPHETAMINE

Amphetamine, racemic $\beta$-phenylisopropylamine (see Table 12–1), has powerful CNS stimulant actions and $\alpha$ and $\beta$ receptor stimulation in the periphery. Unlike EPI, it is effective after oral administration and its effects last for several hours.

CARDIOVASCULAR SYSTEM. Amphetamine given orally raises both systolic and diastolic blood pressure. Heart rate often is reflexly slowed; with large doses, cardiac arrhythmias may occur.
OTHER SMOOTH MUSCLES. In general, smooth muscles respond to amphetamine as they do to other sympathomimetic amines. The contractile effect on the sphincter of the urinary bladder is particularly marked, and for this reason amphetamine has been used in treating enuresis and incontinence. Pain and difficulty in micturition occasionally occur. The GI effects of amphetamine are unpredictable. If enteric activity is pronounced, amphetamine may cause relaxation and delay the movement of intestinal contents; if the gut already is relaxed, the opposite effect may occur. The response of the human uterus varies, but there usually is an increase in tone.

CNS. Amphetamine is one of the most potent sympathomimetic amines in stimulating the CNS. It stimulates the medullary respiratory center, lessens the degree of central depression caused by various drugs, and produces other signs of CNS stimulation. In eliciting of CNS excitatory effects, the d-isomer (dextroamphetamine) is 3-4 times more potent than the l-isomer. The psychic effects depend on the dose and the mental state and personality of the individual. The main results of an oral dose of 10-30 mg include wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often, elation and euphoria; and increase in motor and speech activities. Performance of simple mental tasks is improved, but, although more work may be accomplished, the number of errors may increase. Physical performance (e.g., in athletes) is improved, and the drug often is abused for this purpose. These effects are variable and may be reversed by overdosage or repeated usage. Prolonged use or large doses are nearly always followed by depression and fatigue. Many individuals given amphetamine experience headache, palpitation, dizziness, vasomotor disturbances, agitation, confusion, dysphoria, apprehension, delirium, or fatigue (see Chapter 24).

FATIGUE AND SLEEP. In general, amphetamine prolongs the duration of adequate performance before fatigue appears, and the effects of fatigue are at least partly reversed. Amphetamine reduces the frequency of attention lapses that impair performance after prolonged sleep deprivation and thus improves execution of tasks requiring sustained attention. The need for sleep may be postponed, but it cannot be avoided indefinitely. When the drug is discontinued after long use, the pattern of sleep may take as long as 2 months to return to normal.

ANALGESIA. Amphetamine and some other sympathomimetic amines have a
small analgesic effect, but it is not sufficiently pronounced to be therapeutically useful. However, amphetamine can enhance the analgesia produced by opiates.

*Respiration.* Amphetamine stimulates the respiratory center, increasing the rate and depth of respiration. In normal individuals, usual doses of the drug do not appreciably increase respiratory rate or minute volume. Nevertheless, when respiration is depressed by centrally acting drugs, amphetamine may stimulate respiration.

*Depression of Appetite.* Amphetamine and similar drugs have been used for the treatment of obesity. Weight loss is almost entirely due to reduced food intake and only in small measure to increased metabolism. In humans, tolerance to the appetite suppression develops rapidly.

*Mechanisms of Action in the CNS.* Amphetamine exerts its effects in the CNS by releasing biogenic amines from their storage sites in nerve terminals. The neuronal dopamine transporter (DAT) and the vesicular monoamine transporter 2 (VMAT2) appear to be 2 of the principal targets of amphetamine’s action. The alerting effect of amphetamine, its anorectic effect, and at least a component of its locomotor-stimulating action presumably are mediated by release of NE from central noradrenergic neurons. Some aspects of locomotor activity and the stereotyped behavior induced by amphetamine probably are a consequence of the release of DA from dopaminergic nerve terminals, particularly in the neostriatum. Higher doses are required to produce the behavioral effects. With still higher doses of amphetamine, disturbances of perception and overt psychotic behavior occur, possibly due to release of 5HT from serotonergic neurons and of DA in the mesolimbic system.

**TOXICITY AND ADVERSE EFFECTS.** The acute toxic effects of amphetamine usually are extensions of its therapeutic actions, and as a rule result from overdosage. CNS effects commonly include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggressiveness, changes in libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. However, these psychotic effects can be elicited in any individual if sufficient quantities of amphetamine are ingested for a prolonged period. Fatigue and depression usually follow central stimulation. Cardiovascular effects are common and
include headache, chilliness, pallor or flushing, palpitation, cardiac arrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating occurs. GI symptoms include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning usually terminates in convulsions and coma, and cerebral hemorrhages are the main pathological findings.

The toxic dose of amphetamine varies widely; occasionally occurring after as little as 2 mg, but rare with <15 mg. Severe reactions have occurred with 30 mg, yet doses of 400-500 mg are not uniformly fatal. Larger doses can be tolerated after chronic use of the drug. Treatment of acute amphetamine intoxication may include acidification of the urine by administration of ammonium chloride to enhance the rate of elimination. Sedatives may be required for the CNS symptoms. Severe hypertension may require administration of sodium nitroprusside or an α adrenergic receptor antagonist. Chronic intoxication with amphetamine causes symptoms similar to those of acute overdosage. Weight loss may be marked. A psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia, is the most common serious effect. Recovery is rapid after withdrawal of the drug, but occasionally the condition becomes chronic, with amphetamine hastening the onset of incipient schizophrenia. Amphetamines are schedule II drugs and should be used only under medical supervision. Amphetamine use is inadvisable in patients with anorexia, insomnia, asthenia, psychopathic personality, or a history of homicidal or suicidal tendencies.

**DEPENDENCE AND TOLERANCE.** Psychological dependence often occurs when amphetamine or dextroamphetamine is used chronically, as discussed in Chapter 24. Tolerance almost invariably develops to the anorexigenic effect of amphetamines, and often is seen also in the need for increasing doses to maintain improvement of mood in psychiatric patients. Development of tolerance is not invariable, and cases of narcolepsy have been treated for years without requiring an increase in the initially effective dose.

**THERAPEUTIC USES.** Amphetamine is used chiefly for its CNS effects. Dextroamphetamine is FDA-approved for the treatment of narcolepsy and ADHD (see below).
METHAMPHETAMINE

Methamphetamine (DESOXYN; see Table 12–1) acts centrally to release DA and other biogenic amines, and to inhibit neuronal and vesicular monoamine transporters as well as MAO. Small doses have prominent central stimulant effects without significant peripheral actions; somewhat larger doses produce a sustained rise in systolic and diastolic blood pressures, due mainly to cardiac stimulation. Methamphetamine is a schedule II drug and has high potential for abuse (see Chapter 24).

METHYLPHENIDATE

Methylphenidate is structurally related to amphetamine.

Methylphenidate (RITALIN, others) is a mild CNS stimulant with more prominent effects on mental than on motor activities. However, large doses produce signs of generalized CNS stimulation that may lead to convulsions. In pharmacological properties, it resembles amphetamines. Methylphenidate also shares the abuse potential of the amphetamines and is listed as a schedule II controlled substance in the U.S. Methylphenidate is effective in the treatment of narcolepsy and ADHD. The use of methylphenidate is contraindicated in patients with glaucoma.

DEXMETHYLPHENIDATE. Dexmethylphenidate (FOCALIN) is the $d$-threo enantiomer of racemic methylphenidate. It is FDA-approved as a schedule II drug for the treatment of ADHD.
PEMOLINE. Pemoline (CYLERT, others) is structurally dissimilar to methylphenidate but elicits similar changes in CNS function with minimal effects on the cardiovascular system. It is employed in treating ADHD. It can be given once daily because of its long $t_{1/2}$. Clinical improvement may require treatment for 3-4 weeks. Use of pemoline has been associated with severe hepatic failure and was discontinued in the U.S. in 2006.

EPHEDRINE

Ephedrine is an agonist at both $\alpha$ and $\beta$ receptors; in addition, it enhances release of NE from sympathetic neurons and thus is a mixed-acting sympathomimetic (see Table 12–1 and Figure 12–1).

Only $l$-ephedrine and racemic ephedrine are used clinically. Ephedrine is effective after oral administration. The drug stimulates heart rate and cardiac output and variably increases peripheral resistance; as a result, ephedrine usually increases blood pressure. Activation of $\beta$ receptors in the lungs promotes bronchodilation. Ephedrine is a potent CNS stimulant. After oral administration, the effects of the drug persist for several hours.

THERAPEUTIC USES AND TOXICITY. The use of ephedrine as a bronchodilator in patients with asthma has become less extensive with the development of $\beta_2$-selective agonists. Ephedrine has been used to promote urinary continence. Ephedrine also has been used to treat the hypotension that may occur with spinal anesthesia.

Untoward effects of ephedrine include hypertension and insomnia. Concerns have been raised about the safety of ephedrine. Large amounts of herbal preparations containing ephedrine (ma huang, ephedra) are used around the world. The considerable variability in the content of ephedrine in these preparations is a cause for concern and can lead to inadvertent consumption of dangerous doses of ephedrine and its isomers. The Combat Methamphetamine Epidemic Act of 2005 regulates the sale of ephedrine, phenylpropanolamine, and pseudoephedrine, which can be used as precursors in the illicit manufacture of amphetamine and methamphetamine.

OTHER SYMPATHOMIMETIC AGENTS
Several sympathomimetic drugs are used primarily as vasoconstrictors for local application to the nasal mucous membrane or the eye: propylhexedrine (Benzedrex, others), naphazoline (Privine, Naphcon, others), oxymetazoline (Afrin, Ocuclear, others), and xylometazoline (Otrivin, others). Phenylephrine, pseudoephedrine (Sudafed, others) (a stereoisomer of ephedrine), and phenylpropanolamine have been used most commonly in oral preparations for the relief of nasal congestion. Phenylpropanolamine shares the pharmacological properties of ephedrine and is approximately equal in potency except that it causes less CNS stimulation. Because phenylpropanolamine may increase the risk of hemorrhagic stroke, the drug is no longer licensed for marketing in the U.S.

**THERAPEUTIC USES OF SYMPATHOMIMETIC DRUGS**

**SHOCK.** Shock is an immediately life-threatening impairment of delivery of oxygen and nutrients to the organs of the body. Causes of shock include hypovolemia (due to dehydration or blood loss), cardiac failure (extensive myocardial infarction, severe arrhythmia), obstruction to cardiac output, and peripheral circulatory dysfunction (sepsis or anaphylaxis). The treatment of shock consists of reversing the underlying pathogenesis as well as nonspecific measures aimed at correcting hemodynamic abnormalities. The accompanying fall in blood pressure generally leads to marked activation of the sympathetic nervous system. This, in turn, causes peripheral vasoconstriction and an increase in the rate and force of cardiac contraction. In the initial stages of shock these mechanisms may maintain blood pressure and cerebral blood flow, although blood flow to the kidneys, skin, and other organs may be decreased, leading to impaired production of urine and metabolic acidosis.

The initial therapy of shock involves basic life-support measures. It is essential to maintain blood volume, which often requires monitoring of hemodynamic parameters. Specific therapy (e.g., antibiotics for patients in septic shock) should be initiated immediately. If these measures do not lead to an adequate therapeutic response, it may be
necessary to use vasoactive drugs. Many of these pharmacological approaches, while apparently clinically reasonable, are of uncertain efficacy. Adrenergic receptor agonists may be used in an attempt to increase myocardial contractility or to modify peripheral vascular resistance. In general terms, β receptor agonists increase heart rate and force of contraction, α receptor agonists increase peripheral vascular resistance, and DA promotes dilation of renal and splanchnic vascular beds, in addition to activating β and α receptors.

Cardiogenic shock due to myocardial infarction has a poor prognosis; therapy is aimed at improving peripheral blood flow. Medical intervention is designed to optimize cardiac filling pressure (preload), myocardial contractility, and peripheral resistance (afterload). Preload may be increased by administration of intravenous fluids or reduced with drugs such as diuretics and nitrates. A number of sympathomimetic amines have been used to increase the force of contraction of the heart. Some of these drugs have disadvantages: isoproterenol is a powerful chronotropic agent and can greatly increase myocardial O\textsubscript{2} demand; NE intensifies peripheral vasoconstriction; and EPI increases heart rate and may predispose the heart to dangerous arrhythmias. DA is an effective inotropic agent that causes less increase in heart rate than does isoproterenol. DA also promotes renal arterial dilation; this may be useful in preserving renal function. When given in high doses (>10-20 μg/kg/min), DA activates α receptors, causing peripheral and renal vasoconstriction. Dobutamine has complex pharmacological actions that are mediated by its stereoisomers; the clinical effects of the drug are to increase myocardial contractility with little increase in heart rate or peripheral resistance.

In some patients, hypotension is so severe that vasoconstricting drugs are required to maintain a blood pressure that is adequate for CNS perfusion. α Agonists have been used for this purpose. This approach may be advantageous in patients with hypotension due to failure of the sympathetic nervous system (e.g., after spinal anesthesia or injury). However, in patients with other forms of shock, such as cardiogenic shock, reflex vasoconstriction generally is intense, and α receptor agonists may further compromise blood flow to organs such as the kidneys and gut and adversely increase the work of the heart. Vasodilating drugs such as nitroprusside are more likely to improve blood flow and decrease
cardiac work in such patients by decreasing afterload if a minimally adequate blood pressure can be maintained.

The hemodynamic abnormalities in septic shock are complex and poorly understood. Most patients with septic shock initially have low or barely normal peripheral vascular resistance, possibly owing to excessive effects of endogenously produced NO as well as normal or increased cardiac output. If the syndrome progresses, myocardial depression, increased peripheral resistance, and impaired tissue oxygenation occur. The primary treatment of septic shock is antibiotics. Therapy with drugs such as DA or dobutamine is guided by hemodynamic monitoring.

**HYPOTENSION.** Drugs with predominantly α agonist activity can be used to raise blood pressure in patients with decreased peripheral resistance in conditions such as spinal anesthesia or intoxication with antihypertensive medications. However, hypotension per se is not an indication for treatment with these agents unless there is inadequate perfusion of organs such as the brain, heart, or kidneys. Furthermore, adequate replacement of fluid or blood may be more appropriate than drug therapy for many patients with hypotension.

Patients with orthostatic hypotension often represent a pharmacological challenge. Therapeutic approaches include physical maneuvers and a variety of drugs (fludrocortisone, prostaglandin synthesis inhibitors, somatostatin analogs, caffeine, vasopressin analogs, DA antagonists, and some sympathomimetic drugs). The ideal agent would enhance venous constriction prominently and produce relatively little arterial constriction so as to avoid supine hypertension. No such agent currently is available. Drugs used include α1 agonists and indirect-acting agents. Midodrine shows promise in treating this disorder.

**HYPERTENSION.** Centrally acting α2 agonists such as clonidine are useful in the treatment of hypertension. Drug therapy of hypertension is discussed in Chapter 27.

**ALLERGIC REACTIONS.** EPI is the drug of choice to reverse the manifestations of serious acute hypersensitivity reactions (e.g., from
food, bee sting, or drug allergy).

A subcutaneous injection of EPI rapidly relieves itching, hives, and swelling of lips, eyelids, and tongue. In some patients, careful intravenous infusion of EPI may be required to ensure prompt pharmacological effects. In addition to its cardiovascular effects, EPI is thought to activate β receptors that suppress the release from mast cells of mediators such as histamine and leukotrienes. EPI auto-injectors (EPI PEN, others) are employed widely for the emergency self-treatment of anaphylaxis.

CARDIAC ARRHYTHMIAS. Cardiopulmonary resuscitation in patients with cardiac arrest due to ventricular fibrillation, electromechanical dissociation, or asystole may be facilitated by drug treatment. EPI is an important therapeutic agent in patients with cardiac arrest. α Agonists also help to preserve cerebral blood flow during resuscitation. Consequently, during external cardiac massage, EPI facilitates distribution of the limited cardiac output to the cerebral and coronary circulations. The optimal dose of EPI in patients with cardiac arrest is unclear. Once a cardiac rhythm has been restored, it may be necessary to treat arrhythmias, hypotension, or shock.

LOCAL VASCULAR EFFECTS. EPI is used in many surgical procedures in the nose, throat, and larynx to shrink the mucosa and improve visualization by limiting hemorrhage. Simultaneous injection of EPI with local anesthetics retards the absorption and increases the duration of anesthesia (see Chapter 20). Injection of α agonists into the penis may be useful in reversing priapism, a complication of the use of α receptor antagonists or PDE5 inhibitors (e.g., sildenafil) in the treatment of erectile dysfunction. Both phenylephrine and oxymetazoline are efficacious vasoconstrictors when applied locally during sinus surgery.

NASAL DECONGESTION. α Receptor agonists are used extensively as nasal decongestants. Agonists may be administered either orally or topically. Sympathomimetic decongestants should be used with great caution in patients with hypertension and in men with prostatic enlargement, and they are contraindicated in patients who are taking MAO inhibitors. Oral decongestants are much less likely to cause rebound congestion but carry a greater risk of inducing adverse systemic effects. Patients with uncontrolled hypertension or ischemic heart disease generally should avoid the oral consumption of OTC
products or herbal preparations containing sympathomimetic drugs.

**ASTHMA.** Use of β adrenergic agonists in the treatment of asthma and COPD is discussed in Chapter 36.

**OPHTHALMIC USES.** Ophthalmic use is discussed in Chapter 64.

**NARCOLEPSY AND RELATED SYNDROMES.** Narcolepsy is characterized by hypersomnia. Some patients respond to treatment with tricyclic antidepressants or MAO inhibitors. Alternatively, CNS stimulants such as amphetamine, dextroamphetamine, or methamphetamine may be useful. Therapy with amphetamines is complicated by the risk of abuse and the likelihood of the development of tolerance and behavioral changes. Modafinil (PROVIGIL), a CNS stimulant, may have benefit in narcolepsy. In the U.S., it is a schedule IV controlled substance. Its mechanism of action in narcolepsy is unclear. Armodafinil (NUVIGIL), the R-enantiomer of modafinil (a mixture of R- and S-enantiomers) is also indicated for narcolepsy.

**WEIGHT REDUCTION.** Amphetamine promotes weight loss by suppressing appetite rather than by increasing energy expenditure. Other anorexic drugs include methamphetamine, dextroamphetamine, phentermine, benzphetamine, phendimetrazine, phenmetrazine, diethylpropion, mazindol, phenylpropanolamine, and sibutramine (a mixed adrenergic/serotonergic drug). Phenmetrazine, mazindol, and phenylpropanolamine have been discontinued in the U.S. Available evidence does not support the isolated use of these drugs in the absence of a more comprehensive program that stresses exercise and modification of diet.

**ATTENTION DEFICIT HYPERACTIVITY DISORDER.** This syndrome, usually first evident in childhood, is characterized by excessive motor activity, difficulty in sustaining attention, and impulsiveness. A variety of stimulant drugs have been used in the treatment of ADHD, and they are particularly indicated in moderate-to-severe cases. Methylphenidate is effective in children with ADHD and is the most common intervention. Treatment may start with a dose of 5 mg of methylphenidate in the morning and at lunch; the dose is increased gradually over a period of weeks depending on the response as judged by parents, teachers, and the clinician. The total daily dose generally should not exceed 60 mg; because of its short duration of action, most children require 2 or 3 doses of
methylphenidate each day. Sustained-release preparations of 
*dextroamphetamine*, *methylphenidate* (*RITALIN SR, CONCERTA, METADATE*), 
*methylphenidate hydrochloride* (*QUILLIVANT XR*), *dexamethylphenidate* 
(*FOCALIN XR*), and *amphetamine* (*ADDERALL XR*) may be used once daily in 
children and adults. *Lisdexamfetamine* (*VYVANSE*) can be administered once 
daily and a transdermal formulation of methylphenidate (*DAYTRANA*) is marketed 
for daytime use. Potential adverse effects of these medications include insomnia, 
abdominal pain, anorexia, and weight loss that may be associated with 
suppression of growth in children. A sustained release formulation of *guanfacine* 
(*INTUNIV*), an α₂A receptor agonist, has been approved for use in children (ages 
6-17 years) in treating ADHD.

**Adrenergic Receptor Antagonists**

Adrenergic receptor *antagonists* inhibit the interaction of NE, EPI, 
and other sympathomimetic drugs with α and β receptors (Figure 12–3). Additional background material is presented in Chapter 8. Agents 
that block DA receptors are considered in Chapter 13.

![Classification of adrenergic receptor antagonists](image)

Figure 12–3 *Classification of adrenergic receptor antagonists*. Drugs marked by 
an asterisk (*) also block α₁ receptors.
α ADRENERGIC RECEPTOR ANTAGONISTS

The α1 receptors mediate contraction of arterial, venous, and visceral smooth muscle, while the α2 receptors are involved in suppressing sympathetic output, increasing vagal tone, facilitating platelet aggregation, inhibiting NE and ACh release from nerve endings, and regulating metabolic effects (e.g., suppression of insulin secretion and inhibition of lipolysis). The α2 receptors also mediate contraction of some arteries and veins.

Some of the most important effects of α receptor antagonists observed clinically are on the cardiovascular system. α Receptor antagonists have a wide spectrum of pharmacological specificities and are chemically heterogeneous. Some of these drugs have markedly different affinities for α1 and α2 receptors. More recently, agents that discriminate among the various subtypes of a particular receptor have become available; e.g., tamsulosin has higher potency at α1A than at α1B receptors.

α1 RECEPTOR ANTAGONISTS

GENERAL PHARMACOLOGICAL PROPERTIES. Blockade of α1 receptors inhibits vasoconstriction induced by endogenous catecholamines; vasodilation may occur in both arteriolar resistance vessels and veins. The result is a fall in blood pressure due to decreased peripheral resistance. The magnitude of such effects depends on the activity of the sympathetic nervous system at the time the antagonist is administered, and thus is less in supine than in upright subjects. For most α receptor antagonists, the fall in blood pressure is opposed by baroreceptor reflexes that cause increases in heart rate and cardiac output, as well as fluid retention (effects largely inhibited by β antagonists). These reflexes are exaggerated if the antagonist also blocks α2 receptors on peripheral sympathetic nerve endings, leading to enhanced release of NE and increased stimulation of postsynaptic β1 receptors in the heart and on juxtaglomerular cells.
(see Chapter 8). Blockade of $\alpha_1$ receptors can alleviate some of the symptoms of benign prostatic hyperplasia (BPH). The prostate and lower urinary tract tissues exhibit a high proportion of $\alpha_{1A}$ receptors.

**AVAILABLE AGENTS**

**PRAZOSIN AND RELATED DRUGS.** Due in part to its greater $\alpha_1$ receptor selectivity, this class of $\alpha$ receptor antagonists exhibits greater clinical utility and has largely replaced the nonselective haloalkylamine (e.g., phenoxybenzamine) and imidazoline (e.g., phentolamine) $\alpha$ receptor antagonists. Prazosin is the prototypical $\alpha_1$-selective antagonist.

The affinity of prazosin for $\alpha_1$ adrenergic receptors is ~1000-fold greater than that for $\alpha_2$ adrenergic receptors. Prazosin has similar potencies at $\alpha_{1A}$, $\alpha_{1B}$, and $\alpha_{1D}$ subtypes. Prazosin, doxazosin, and tamsulosin, frequently are used for the treatment of hypertension (see Chapter 27).

**PHARMACOLOGICAL PROPERTIES**

The major effects of prazosin result from its blockade of $\alpha_1$ receptors in arterioles and veins. This leads to a fall in peripheral vascular resistance and in venous return to the heart. Unlike the case with many vasodilating drugs, administration of prazosin usually does not increase heart rate. Prazosin decreases cardiac preload and has little effect on cardiac output and rate. Prazosin also may act in the CNS to suppress sympathetic outflow. Prazosin and related drugs decrease low-density lipoproteins (LDLs) and triglycerides and increase the concentrations of high-density lipoproteins (HDLs).

*Prazosin* (Minipress, others) is well absorbed after oral administration, and bioavailability is ~50-70%. Peak concentrations in plasma generally are reached 1-3 h after an oral dose. The drug is tightly bound to plasma proteins and only 5% of the drug is free in the circulation; diseases that modify the concentration of this protein (e.g., inflammatory processes) may change the free fraction. Prazosin is extensively metabolized in the liver, and little unchanged drug is
excreted by the kidneys. The plasma $t_{1/2}$ is $\sim 3$ h. The initial dose should be 1 mg, usually given at bedtime. The dose is titrated upward depending on the blood pressure. In the off-label treatment of BPH, doses from 1-5 mg twice daily typically are used.

**TERAZOSIN.** Terazosin (HYTRIN, others) is a structural analog of prazosin. It is less potent than prazosin but retains high specificity for $\alpha_1$ receptors; terazosin does not discriminate among $\alpha_{1A}$, $\alpha_{1B}$, and $\alpha_{1D}$ receptors. Terazosin is more soluble in water than is prazosin, and its bioavailability is high (>90%). The $t_{1/2}$ is $\sim 12$ h, and its duration of action is $>18$ h. Terazosin and doxazosin induce apoptosis in prostate smooth muscle cells. This apoptosis may lessen the symptoms associated with chronic BPH. The apoptotic effect of terazosin and doxazosin appears to be related to the quinazoline moiety rather than $\alpha_1$ receptor antagonism. An initial first dose of 1 mg is recommended, that is titrated upward depending on the therapeutic response. Doses of 10 mg/day may be required for maximal effect in BPH.

**DOXAZOSIN.** Doxazosin (CARDURA, others) is a structural analog of prazosin and a highly selective antagonist at $\alpha_1$ receptors. It is nonselective among $\alpha_1$ receptor subtypes. The $t_{1/2}$ of doxazosin is $\sim 20$ h, and its duration of action may extend to 36 h. Bioavailability and extent of metabolism of doxazosin and prazosin are similar. Doxazosin is given initially as a 1-mg dose in the treatment of hypertension or BPH. Doxazosin also may have beneficial actions in the long-term management of BPH related to apoptosis.

**ALFUZOSIN.** Alfuzosin (UROXATRAL) is $\alpha_1$ receptor antagonist with similar affinity at all of the $\alpha_1$ receptor subtypes. It is used in treating BPH but not for treatment of hypertension. Its bioavailability is $\sim 64$%; it has a $t_{1/2}$ of 3-5 h. Alfuzosin is a substrate of CYP3A4. The recommended dosage is one 10-mg extended-release tablet daily to be taken after the same meal each day.

**TAMSULOSIN.** Tamsulosin (FLOMAX), is an $\alpha_1$ receptor antagonist with some selectivity for $\alpha_{1A}$ (and $\alpha_{1D}$) subtypes compared to the $\alpha_{1B}$ subtype. This selectivity may favor blockade of $\alpha_{1A}$ receptors in prostate. Tamsulosin is efficacious in the treatment of BPH with little effect on blood pressure. Tamsulosin is well absorbed, is extensively metabolized by CYPs, and has a $t_{1/2}$ of 5-10 h. Tamsulosin may be administered at a 0.4-mg starting dose. Abnormal
ejaculation is an adverse effect of tamsulosin.

**SILODOSIN.** *Silodosin* (RAPAFLO) exhibits selectivity for the $\alpha_{1A}$ over the $\alpha_{1B}$ receptor. The drug is metabolized by UGT2B7; coadministration with inhibitors of this enzyme (e.g., probenecid, valproic acid, fluconazole) increases systemic exposure to silodosin. The drug is approved for the treatment of BPH. The chief side effect of silodosin is retrograde ejaculation (in 28% of those treated). Silodosin is available as 4-mg and 8-mg capsules.

**ADVERSE EFFECTS**

An adverse effect of prazosin and its congeners is the first-dose effect; marked postural hypotension and syncope sometimes are seen 30-90 min after the initial dose of prazosin. The risk of the first-dose phenomenon is minimized by limiting the initial dose (e.g., 1 mg at bedtime), by increasing the dosage slowly, and by introducing additional antihypertensive drugs cautiously. Nonspecific adverse effects such as headache, dizziness, and asthenia rarely limit treatment with prazosin.

**THERAPEUTIC USES**

_Hypertension._ Prazosin and its congeners have been used successfully in the treatment of essential hypertension (see Chapter 27).

_Congestive Heart Failure._ $\alpha$ Receptor antagonists have been used in the treatment of congestive heart failure, but are not the drugs of choice.

_Benign Prostatic Hyperplasia._ BPH produces symptomatic urethral obstruction that leads to weak stream, urinary frequency, and nocturia. $\alpha_1$ Receptors in the trigone muscle of the bladder and urethra contribute to the resistance to outflow of urine; prazosin reduces this. *Finasteride* (PROPECIA, PROSCAR, others) and *dutasteride* (AVODART), 2 drugs that inhibit conversion of testosterone to dihydrotestosterone (see Chapter 41) and can reduce prostate volume in some patients, are approved as monotherapy and in combination with $\alpha$ receptor antagonists. $\alpha_1$-Selective antagonists have efficacy in BPH owing to relaxation of smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. Combination therapy with doxazosin and finasteride reduces the risk of overall clinical progression of BPH significantly more than treatment with either drug.
alone. Tamsulosin at the recommended dose of 0.4 mg daily and silodosin at 0.8 mg are less likely to cause orthostatic hypotension than are the other drugs. The predominant $\alpha_1$ subtype expressed in the human prostate is the $\alpha_{1A}$ receptor.

Other Disorders. Some studies indicate that prazosin can decrease the incidence of digital vasospasm in patients with Raynaud’s disease; however, its relative efficacy as compared with Ca$^{2+}$ channel blockers is not known. Prazosin may have some benefit in patients with other vasospastic disorders. Prazosin may be useful for the treatment of patients with mitral or aortic valvular insufficiency, presumably by reducing afterload.

$\alpha_2$ ADRENERGIC RECEPTOR ANTAGONISTS

Activation of presynaptic $\alpha_2$ receptors inhibits the release of NE and other cotransmitters from peripheral sympathetic nerve endings. Activation of $\alpha_2$ receptors in the CNS inhibits sympathetic nervous system activity and leads to a fall in blood pressure. Blockade of $\alpha_2$ receptors with selective antagonists such as yohimbine thus can increase sympathetic outflow and potentiate the release of NE from nerve endings. Antagonists that also block $\alpha_1$ receptors give rise to similar effects on sympathetic outflow and release of NE, but the net increase in blood pressure is prevented by inhibition of vasoconstriction.

Although certain vascular beds contain $\alpha_2$ receptors that promote contraction of smooth muscle, these receptors are preferentially stimulated by circulating catecholamines, whereas $\alpha_1$ receptors are activated by NE released from sympathetic nerve fibers. The physiological role of vascular $\alpha_2$ receptors in the regulation of blood flow within various vascular beds is uncertain. The $\alpha_2$ receptors contribute to smooth muscle contraction in the human saphenous vein, whereas $\alpha_1$ receptors are more prominent in dorsal hand veins. The effects of $\alpha_2$ receptor antagonists on the cardiovascular system are dominated by actions in the CNS and on sympathetic nerve endings.
**YOHIMBINE.** Yohimbine (Yocon, Aphrodyne) is a competitive antagonist that is selective for \( \alpha_2 \) receptors. Yohimbine enters the CNS, where it acts to increase blood pressure and heart rate; it also enhances motor activity and produces tremors. Yohimbine also antagonizes effects of 5HT.

In the past, it was used to treat male sexual dysfunction. Some studies suggest that yohimbine also may be useful for diabetic neuropathy and postural hypotension. In the U.S., yohimbine may be sold as a dietary supplement; however, labeling claims that it will increase sexual desire or performance are prohibited.

**NONSELECTIVE \( \alpha \) ADRENERGIC ANTAGONISTS: PHENOXYBENZAMINE AND PHENTOLAMINE**

*Phenoxybenzamine* and *phentolamine* are nonselective \( \alpha \) receptors antagonists. Phenoxybenzamine produces an irreversible antagonism; phentolamine produces a competitive antagonism.

Phenoxybenzamine and phentolamine cause a progressive decrease in peripheral resistance, an increase in cardiac output (due in part to reflex sympathetic nerve stimulation), and enhanced release of NE from cardiac sympathetic nerve due to antagonism of presynaptic \( \alpha_2 \) receptors. Postural hypotension, a prominent feature accompanied by reflex tachycardia that can precipitate cardiac arrhythmias, severely limits the use of these drugs to treat essential hypertension. The \( \alpha_1 \)-selective antagonists have replaced the classical \( \alpha \)-blockers in the management of essential hypertension. Phenoxybenzamine and phentolamine are still marketed for several specialized uses.

*Therapeutic Uses.* A use of phenoxybenzamine (Dibenzyline) is in the treatment of pheochromocytoma, which are tumors of the adrenal medulla and sympathetic neurons that secrete enormous quantities of catecholamines. Phenoxybenzamine is often used in preparing the patient for surgical removal of the tumor. A conservative approach is to initiate treatment with phenoxybenzamine (at a dosage of 10 mg twice daily) 1-3 weeks before the operation. The dose is increased every other day until the desired effect on blood pressure is achieved.
Prolonged treatment with phenoxybenzamine may be necessary in patients with inoperable or malignant pheochromocytoma. In some patients, particularly those with malignant disease, administration of metyrosine, a competitive inhibitor of tyrosine hydroxylase, may be a useful adjuvant (see Chapter 8). β Receptor antagonists also are used but only after the administration of an α receptor antagonist.

Phentolamine can also be used in short-term control of hypertension in patients with pheochromocytoma. Phentolamine has been used locally to prevent dermal necrosis after the inadvertent extravasation of an α receptor agonist.

Toxicity and Adverse Effects. Hypotension is the major adverse effect of phenoxybenzamine and phentolamine. In addition, reflex cardiac stimulation may cause alarming tachycardia, cardiac arrhythmias, and ischemic cardiac events, including myocardial infarction. Reversible inhibition of ejaculation may occur due to impaired smooth muscle contraction in the vas deferens and ejaculatory ducts. Phenoxybenzamine is mutagenic in the Ames test.

ADDITIONAL α ADRENERGIC RECEPTOR ANTAGONISTS

Ergot Alkaloids. The ergot alkaloids were the first adrenergic receptor antagonists to be discovered. Information about the ergot alkaloids can be found in Chapter 13.

INDORAMIN. Indoramin is a selective, competitive α_{1} receptor antagonist that also antagonizes H_{1}- and 5HT receptors. As an α_{1}-selective antagonist, indoramin lowers blood pressure with minimal tachycardia. The drug also decreases the incidence of attacks of Raynaud phenomenon. Some of the adverse effects of indoramin include sedation, dry mouth, and failure of ejaculation. Indoramin is not available in the U.S.

KETANSERIN. Ketanserin, a 5HT/α_{1} receptor antagonist not available in the U.S., is discussed in Chapter 13.

URAPIDIL. Urapidil is a selective α_{1} receptor antagonist that is not commercially available in the U.S. Blockade of peripheral α_{1} receptors appears to be primarily responsible for the hypotension produced by urapidil, although it
has actions in the CNS as well.

**BUNAZOSIN.** *Bunazosin* is an $\alpha_1$-selective antagonist of the quinazoline class that can lower blood pressure in patients with hypertension; this agent is not available in the U.S.

**NEUROLEPTIC AGENTS.** Chlorpromazine, haloperidol, and other neuroleptic drugs of the phenothiazine and butyrophenone types produce significant blockade of both $\alpha$ and $D_2$ receptors.

**β ADRENERGIC RECEPTOR ANTAGONISTS**

β Antagonists can be distinguished by the following properties:

- Relative affinity for $\beta_1$ and $\beta_2$ receptors
- Intrinsic sympathomimetic activity
- Blockade of $\alpha$ receptors
- Differences in lipid solubility
- Capacity to induce vasodilation
- Pharmacokinetic parameters

β Adrenergic receptor antagonists are classified as non–subtype-selective (first generation), $\beta_1$-selective (second generation), and non–subtype or subtype-selective with additional cardiovascular actions (third generation). These latter drugs have additional cardiovascular properties (especially vasodilation) that seem unrelated to β blockade. *Table 12–3* summarizes important pharmacological and pharmacokinetic properties of β receptor antagonists.

*Table 12–3*

**Pharmacological/Pharmacokinetic Properties of β Adrenergic Receptor Blocking Agents**
Several β receptor antagonists also have local anesthetic or membrane-stabilizing activity that is independent of β-blockade. Such drugs include propranolol, acebutolol, and carvedilol. Pindolol, metoprolol, betaxolol, and labetalol have slight membrane-stabilizing effects.

**CARDIOVASCULAR SYSTEM.** The major therapeutic effects of β receptor antagonists are on the cardiovascular system. It is important to distinguish the effects in normal subjects from those in subjects with cardiovascular disease such as hypertension or myocardial ischemia.

Because catecholamines have positive chronotropic and inotropic actions, β receptor antagonists slow the heart rate and decrease myocardial contractility. When tonic stimulation of β receptors is low,
this effect is correspondingly modest. However, when the sympathetic nervous system is activated, as during exercise or stress, β receptor antagonists attenuate the expected rise in heart rate. Short-term administration of β receptor antagonists such as propranolol decreases cardiac output; peripheral resistance increases in proportion to maintain blood pressure as a result of blockade of vascular β2 receptors and compensatory reflexes, such as increased sympathetic nervous system activity, leading to activation of vascular α receptors. With long-term use of β antagonists, total peripheral resistance returns to initial values or decreases in patients with hypertension. With β antagonists that also are α1 receptor antagonists (e.g., labetalol, carvedilol, and bucindolol), cardiac output is maintained with a greater fall in peripheral resistance.

β Receptor antagonists have significant effects on cardiac rhythm and automaticity, which involves blockade of both β1 receptors and β2 receptors. β Receptor antagonists reduce sinus rate, decrease the spontaneous rate of depolarization of ectopic pacemakers, slow conduction in the atria and in the AV node, and increase the functional refractory period of the AV node.

**ACTIVITY AS ANTIHYPERTENSIVE AGENTS.** β Receptor antagonists generally do not reduce blood pressure in patients with normal blood pressure. However, these drugs lower blood pressure in patients with hypertension. Reduction of β1-stimulated renin release from the juxtaglomerular cells is a putative contributing mechanism (see Chapter 26). Because presynaptic β receptors enhance the release of NE from sympathetic neurons, diminished release of NE from β blockade is a possible response. Long-term administration of β-blockers to hypertensive patients ultimately leads to a fall in peripheral vascular resistance.

Some β antagonists have additional effects that may contribute to their capacity to lower blood pressure. These drugs all produce peripheral vasodilation; properties that have been proposed to contribute to this effect include production
of NO, activation of β2 receptors, blockade of α1 receptors, blockade of Ca2+ entry, opening of K+ channels, and antioxidant activity (Table 12–4 and Figure 12–4). These mechanisms appear to contribute to the antihypertensive effects by enhancing hypotension, increasing peripheral blood flow, and decreasing afterload. Celiprolol and nebivolol also have been observed to produce vasodilation and thereby reduce preload.

*Not currently available in the U.S., where most are under investigation for use.

Figure 12–4 *Mechanisms underlying actions of vasodilating β blockers in blood vessels.* (ROS, reactive oxygen species; sGC, soluble guanylyl cyclase; AC adenylyl cyclase; L-type VGCC, L-type voltage-gated Ca2+ channel.) (Modified
Propranolol and other nonselective β receptor antagonists inhibit the vasodilation caused by isoproterenol and augment the pressor response to EPI. This is particularly significant in patients with pheochromocytoma, in whom β receptor antagonists should be used only after adequate α receptor blockade has been established.

**PULMONARY SYSTEM.** Nonselective β receptor antagonists such as propranolol block β2 receptors in bronchial smooth muscle. This usually has little effect on pulmonary function in normal individuals. However, in patients with COPD, such blockade can lead to life-threatening bronchoconstriction. Although β1-selective antagonists or antagonists with intrinsic sympathomimetic activity are less likely than propranolol to increase airway resistance in patients with asthma, these drugs should be used only with great caution, if at all, in patients with bronchospastic diseases.

**METABOLIC EFFECTS.** Catecholamines promote glycogenolysis and mobilize glucose in response to hypoglycemia. Nonselective β blockers may delay recovery from hypoglycemia in type 1 (insulin-dependent) diabetes mellitus, but infrequently in type 2 diabetes mellitus. β Receptor antagonists can interfere with the counter-regulatory effects of catecholamines secreted during hypoglycemia by blunting the perception of symptoms such as tremor, tachycardia, and nervousness. Use β adrenergic receptor antagonists with great caution in patients with labile diabetes and frequent hypoglycemic reactions; if such a drug is indicated, use a β1-selective antagonist.

β Receptor antagonists can attenuate the release of free fatty acids from adipose tissue. Nonselective β receptor antagonists consistently reduce HDL cholesterol, increase LDL cholesterol, and increase triglycerides. In contrast, β1-selective antagonists, including celiprolol, carteolol, nebivolol, carvedilol, and bevantolol, reportedly improve the serum lipid profile of dyslipidemic patients. Propranolol and atenolol increase triglycerides, whereas chronic celiprolol, carvedilol, and
carteolol reduce plasma triglycerides. In contrast to classical β-blockers, which decrease insulin sensitivity, the vasodilating β receptor antagonists (e.g., celiprolol, nepadilol, carteolol, carvedilol, and dilevalol) increase insulin sensitivity in patients with insulin resistance.

Other Effects. β Receptor antagonists block catecholamine-induced tremor. They also block inhibition of mast-cell degranulation by catecholamines.

ADVERSE EFFECTS AND PRECAUTIONS

The most common adverse effects of β receptor antagonists arise as pharmacological consequences of blockade of β receptors. β Receptor blockade may cause or exacerbate heart failure in patients with compensated heart failure, acute myocardial infarction, or cardiomegaly. Nonetheless, there is convincing evidence that chronic administration of β receptor antagonists is efficacious in prolonging life in the therapy of heart failure in selected patients (see Chapter 28). The use of β adrenergic receptor antagonists is contraindicated in patients with asthma, COPD, sinus bradycardia, and cardiogenic shock.

Bradycardia is a normal response to β receptor blockade; however, in patients with partial or complete AV conduction defects, β antagonists may cause life-threatening bradyarrhythmias. *A* *b* *r* *u* *p* *t* * d* *i* *s* *t* *i* *n* *u* *t* *i* *n* *o* *u* *n* *t* *i* *o* *n* * o* *f* * β* *r* *e* *c* *e* *p* *t* *or* *a* *nt* *a* *g* *o* *n* *i* *s* *t* *s* *a* *f* *t* *e* *r* *l* *o* *n* *g* *-t* *e* *r* *m* *t* *r* *e* *a* *t* *m* *e* *n* *t* *c* *a* *n* *e* *x* *a* *c* *e* *r* *b* *a* *t* *e* * a* *ng* *i* *n* *a* *a* *n* *d* *m* *a* *y* *i* *n* *c* *e* *a* *r* *e* *t* *h* *e* *r* *i* *s* *k* *o* *f* * s* *u* *d* *d* *e* *a* *t* *h*. A major adverse effect of β receptor antagonists is caused by blockade of β₂ receptors in bronchial smooth muscle. Because the selectivity of current β blockers for β₁ receptors is modest, these drugs should be avoided if at all possible in patients with asthma. As noted above, β blockade may blunt recognition of hypoglycemia by patients.

DRUG INTERACTIONS. Aluminum salts, cholestyramine, and colestipol may decrease the absorption of β-blockers. Drugs such as phenytoin, rifampin, and phenobarbital, as well as smoking, induce hepatic biotransformation enzymes and may decrease plasma concentrations of β receptor antagonists. Cimetidine and hydralazine may increase the bioavailability of propranolol and metoprolol.
by affecting hepatic blood flow. β Receptor antagonists can impair the clearance of lidocaine. The antihypertensive effects of β receptor antagonists can be opposed by indomethacin and other NSAIDs (see Chapter 34).

**THERAPEUTIC USES**

**CARDIOVASCULAR DISEASES.** β Receptor antagonists are used extensively in the treatment of hypertension, angina and acute coronary syndromes, and congestive heart failure (see Chapters 27 and 28). These drugs also are used frequently in the treatment of supraventricular and ventricular arrhythmias (see Chapter 29).

β Receptor antagonists, particularly propranolol, are used in the treatment of hypertrophic obstructive cardiomyopathy. Propranolol is useful for relieving angina, palpitations, and syncope in patients with this disorder. β-blockers also may attenuate catecholamine-induced cardiomyopathy in pheochromocytoma.

**GLAUCOMA.** β Receptor antagonists are very useful in the treatment of chronic open-angle glaucoma.

Six drugs are currently available: carteolol (OCUPRESS, others), betaxolol (BETOPTIC, others), levobunolol (BETAGAN, others), metipranolol (OPTIPRANOLOL, others), timolol (TIMOPTIC, others), and levobetaxolol (BETAXON). These agents decrease the production of aqueous humor. Glaucoma and therapies are presented in Chapter 64.

**OTHER USES.** β Receptor antagonists control many of the cardiovascular signs and symptoms of hyperthyroidism and are useful adjuvants to more definitive therapy. In addition, propranolol inhibits the peripheral conversion of thyroxine to triiodothyronine, an effect that may be independent of β receptor blockade (see Chapter 39). Propranolol, timolol, and metoprolol are effective for the prophylaxis of migraine. Tachycardia, muscle tremors, and other evidence of increased sympathetic activity are reduced by β-blockers.

**NONSELECTIVE β ADRENERGIC RECEPTOR ANTAGONISTS**

**PROPRANOLOL**
Propranolol interacts with β₁ and β₂ receptors with equal affinity, lacks intrinsic sympathomimetic activity, and does not block α receptors.

Propranolol is used for the treatment of hypertension and angina. The initial oral dose is 40-80 mg/day, titrated upward until the optimal response is obtained (typically <320 mg/day). Propranolol also is used for supraventricular arrhythmias/tachycardias, ventricular arrhythmias/tachycardias, premature ventricular contractions, digitalis-induced tachyarrhythmias, myocardial infarction, pheochromocytoma, essential tremor, and the prophylaxis of migraine. It also is used for several off-label indications including parkinsonian tremors (sustained-release only), akathisia induced by antipsychotic drugs, variceal bleeding in portal hypertension, and anxiety disorder.

Propranolol is highly lipophilic and is almost completely absorbed after oral administration. The drug is highly metabolized by the liver during its first passage through the portal circulation; on average, only ~25% reaches the systemic circulation. Individual variation in hepatic clearance of propranolol contributes to enormous variability in plasma concentrations (~20-fold) after oral administration. The degree of hepatic extraction of propranolol declines as the dose is increased. The bioavailability of propranolol may be increased by the concomitant ingestion of food. Propranolol readily enters the CNS. Sustained-release formulations of propranolol (INDERAL LA, others) have been developed to maintain therapeutic concentrations of propranolol in plasma throughout a 24-h period.

NADOLOL

Nadolol (CORGARD, others) is a long-acting antagonist with equal affinity for β₁ and β₂ receptors.

A distinguishing characteristic of nadolol is its relatively long t₁/₂. It can be used to treat hypertension and angina pectoris. Unlabeled uses have included migraine prophylaxis, parkinsonian tremors, and variceal bleeding in portal hypertension. The t₁/₂ of the drug in plasma is ~20 h. Nadolol is largely excreted intact in the urine and may accumulate in patients with renal failure.
TIMOLOL

Timolol (BLOCADREN, others) is a potent, nonselective β receptor antagonist used for hypertension, congestive heart failure, acute myocardial infarction, and migraine prophylaxis.

The ocular formulation of timolol (TIMOPTIC, others), used for the treatment of glaucoma, may be extensively absorbed systemically (see Chapter 64); adverse effects can occur in susceptible patients, such as those with asthma or congestive heart failure.

PINDOLOL

Pindolol (VISKEN, others) is a nonselective β receptor antagonist with intrinsic sympathomimetic activity.

Pindolol has low membrane-stabilizing activity and low lipid solubility. It is a weak partial β agonist; such drugs may be preferred as antihypertensive agents in individuals with diminished cardiac reserve or a propensity for bradycardia. It is used to treat angina pectoris and hypertension.

β₁-SELECTIVE ADRENERGIC RECEPTOR ANTAGONISTS

METOPROLOL

Metoprolol (LOPRESSOR, others) is a β₁-selective receptor antagonist.

It is highly absorbed after oral administration, but bioavailability is relatively low (~40%) because of first-pass metabolism. Plasma concentrations of the drug vary widely (up to 17-fold) possibly due to genetically determined differences in the rate of metabolism in the liver by CYP2D6. The $t_{1/2}$ of metoprolol is 3-4 h, but can double in CYP2D6 poor metabolizers who have a 5X higher risk for developing adverse effects. An extended-release formulation (TOPROL XL) is available for once-daily administration.

For the treatment of hypertension, the usual initial dose is 100 mg/day. The drug sometimes is effective when given once daily, although it frequently is used in 2
divided doses. Dosage may be increased at weekly intervals until optimal reduction of blood pressure is achieved. Metoprolol generally is used in 2 divided doses for the treatment of stable angina. For the initial treatment of patients with acute myocardial infarction, an intravenous formulation of metoprolol tartrate is available. Metoprolol generally is contraindicated for the treatment of acute myocardial infarction in patients with heart rates of <45 beats/min, heart block greater than first-degree (PR interval ≥0.24 second), systolic blood pressure <100 mm Hg, or moderate to severe heart failure. Metoprolol also has been proven to be effective in chronic heart failure.

**ATENOLOL**

Atenolol (TENORMIN, others) is a β₁-selective antagonist.

Atenolol is incompletely absorbed (~50%) and is excreted largely unchanged in the urine with elimination $t_{1/2}$ 5-8 h. The drug accumulates in patients with renal failure, and dosage should be adjusted for patients whose creatinine clearance is <35 mL/min. The initial dose of atenolol for the treatment of hypertension usually is 50 mg/day, given once daily, and may be increased to 100 mg. Atenolol has been shown to be efficacious, in combination with a diuretic, in elderly patients with isolated systolic hypertension.

**ESMOLOL**

Esmolol (BREVIBLOC, others) is a β₁-selective antagonist with a rapid onset and a very short duration of action.

Esmolol is used when β-blockade of short duration is desired or in critically ill patients in whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. Esmolol is given by slow IV injection. The drug is hydrolyzed rapidly by esterases in erythrocytes and has a $t_{1/2}$ of ~8 min. Peak hemodynamic effects occur within 6-10 min of administration of a loading dose, and there is substantial attenuation of β blockade within 20 min of stopping an infusion. Because esmolol is used in urgent settings where immediate onset of β blockade is warranted, a partial loading dose typically is administered, followed by a continuous infusion of the drug. If an adequate therapeutic effect is not observed within 5 min, the same
loading dose is repeated, followed by a maintenance infusion at a higher rate. This process may need to be repeated to approach desired end point (e.g., lowered heart rate or blood pressure).

ACEBUTOLOL. Acebutolol (Sectral, others) is a β1-selective antagonist with some intrinsic sympathomimetic and membrane-stabilizing activity. Acebutolol is well absorbed, and undergoes significant first-pass metabolism to an active metabolite, diacetolol, which accounts for most of the drug’s activity. Acebutolol has been used to treat hypertension, cardiac arrhythmias, and acute myocardial infarction. The initial dose in hypertension is 400 mg/day; given as a single or 2 divided doses. Optimal responses usually occur with doses of 400-800 mg per day (range, 200-1200 mg).

BISOPROLOL. Bisoprolol (Zebeta) is a highly selective β1 receptor antagonist that is approved for the treatment of hypertension. Bisoprolol can be considered a standard treatment option when selecting a β-blocker for use in combination with ACE inhibitors and diuretics in patients with chronic heart failure and in treating hypertension. Bisoprolol generally is well tolerated; side effects include dizziness, bradycardia, hypotension, and fatigue. It is eliminated by renal excretion (50%) and liver metabolism (50%).

BETAXOLOL. Betaxolol (Betoptic, Lokern, Kerlone, others) is a selective β1 receptor antagonist with slight membrane-stabilizing properties. Betaxolol is used to treat hypertension, angina pectoris, and glaucoma. It is usually well tolerated and side effects are mild and transient. In glaucoma it reduces intraocular pressure.

β RECEPTOR ANTAGONISTS WITH ADDITIONAL CARDIOVASCULAR EFFECTS (THIRD-GENERATION β-BLOCKERS)

Third-generation β-blockers possess vasodilating actions produced through a variety of mechanisms (see Table 12–4 and Figure 12–4).

LABETALOL

Labetalol (Normodyne, Trandate, others) is representative of a class of drugs that act as competitive antagonists at both α1 and β
receptors. The pharmacological properties of the drug are complex, because each isomer displays different relative activities.

The properties of the mixture include selective blockade of $\alpha_1$ receptors (as compared with the $\alpha_2$ subtype), blockade of $\beta_1$ and $\beta_2$ receptors, partial agonist activity at $\beta_2$ receptors, and inhibition of neuronal uptake of NE (cocaine-like effect) (see Chapter 8). The potency of the mixture for $\beta$ blockade is 5-10 fold that for $\alpha_1$ blockade. The actions of labetalol on both $\alpha_1$ and $\beta$ receptors contribute to the fall in blood pressure observed in patients with hypertension. $\alpha_1$ Receptor blockade leads to relaxation of arterial smooth muscle and vasodilation. $\beta_1$ Blockade contributes to a fall in blood pressure, in part by blocking reflex sympathetic stimulation of the heart. The intrinsic sympathomimetic activity of labetalol at $\beta_2$ receptors may contribute to vasodilation.

Labetalol is available in oral form for therapy of chronic hypertension and as an intravenous formulation for use in hypertensive emergencies. Labetalol has been associated with hepatic injury in a limited number of patients.

**CARVEDILOL**

Carvedilol (COREG) blocks $\beta_1$, $\beta_2$, and $\alpha_1$ receptors, and also has antioxidant and anti-inflammatory effects. Carvedilol produces vasodilation.

Carvedilol is extremely liphophic and is able to protect cell membranes from lipid peroxidation. At high doses, carvedilol exerts $\text{Ca}^{2+}$ channel-blocking activity. Carvedilol does not increase $\beta$ receptor density. Carvedilol improves ventricular function and reduces mortality and morbidity in patients with mild to severe congestive heart failure. Carvedilol is rapidly absorbed following oral administration, with peak plasma concentrations occurring in 1-2 h. No significant changes in the pharmacokinetics of carvedilol are seen in elderly patients with hypertension, and no change in dosage is needed in patients with moderate to severe renal insufficiency. Due to its extensive oxidative metabolism by the liver, carvedilol’s pharmacokinetics can be profoundly affected by drugs that induce or inhibit oxidation. These include the inducer, rifampin, and
inhibitors such as cimetidine, quinidine, fluoxetine, and paroxetine.

**Bucindolol.** Bucindolol (Sandonorm) is a third-generation nonselective β adrenergic antagonist with weak α₁ adrenergic blocking properties. Bucindolol reduces afterload and increases plasma HDL cholesterol, but does not affect plasma triglycerides. Bucindolol is extensively metabolized by the liver and has a $t_{1/2}$ of ~8 h. A new drug application is under review with the FDA.

**Celiprolol.** Celiprolol (Selectol) is a cardioselective β receptor antagonist with weak vasodilating and bronchodilating effects attributed to partial selective β₂ agonist activity. It may antagonize peripheral α₂ adrenergic receptor activity, promote NO production, and inhibit oxidative stress. It is largely unmetabolized and is excreted unchanged in the urine and feces. Celiprolol is used for treatment of hypertension and angina.

**Nebivolol.** Nebivolol (Bystolic) is a selective β₁ receptor antagonist, has endothelial NO-mediated vasodilator activity, and is approved for treatment of hypertension. The $d$-isomer is the active β-blocking component; the $l$-isomer is responsible for enhancing production of NO. It is lipophilic, and concomitant administration of chlorthalidone, hydrochlorothiazide, theophylline, or digoxin with nebivolol may reduce its extent of absorption. The NO-dependent vasodilating action of nebivolol and its high β₁ adrenergic receptor selectivity likely contribute to the drug’s efficacy and improved tolerability (e.g., less fatigue and sexual dysfunction) as an antihypertensive agent. Metabolism occurs via CYP2D6.

**Other β Adrenergic Receptor Antagonists.** There are numerous β adrenergic receptor antagonists on the market as ophthalmologic preparations for the treatment of glaucoma (see Chapter 64).
5-Hydroxytryptamine (5HT, serotonin) and dopamine (DA) have prominent actions in the CNS and the periphery. Fourteen 5HT receptor subtypes and five DA receptor subtypes have been delineated by pharmacological analyses and cDNA cloning. The availability of cloned receptors has allowed the development of subtype-selective drugs and the elucidation of actions of these neurotransmitters at a molecular level.

5-HYDROXYTRYPTAMINE

5HT is found in high concentrations in enterochromaffin cells throughout the GI tract, in storage granules in platelets, and broadly throughout the CNS. 5HT regulates smooth muscle in the cardiovascular system and the GI tract and enhances platelet aggregation.

SYNTHESIS AND METABOLISM OF 5HT. 5HT is synthesized by a 2-step pathway from the tryptophan (Figure 13–1).
Figure 13–1 Synthesis and inactivation of serotonin. Enzymes are identified in red lettering, and cofactors are shown in blue.

Tryptophan is actively transported into the brain by a carrier protein. Levels of tryptophan in the brain reflect its plasma concentration and the plasma concentrations of amino acids that compete for the same transporter. Tryptophan hydroxylase, the rate-limiting enzyme in the synthetic pathway, converts tryptophan to L-5-hydroxytryptophan; the enzyme is not regulated by end-product inhibition. Brain tryptophan hydroxylase is not generally saturated with substrate; consequently, the concentration of tryptophan in the brain influences the synthesis of 5HT.
Aromatic l-amino acid decarboxylase (AADC) converts L-5-hydroxytryptophan to 5HT; it is widely distributed and has broad substrate specificity. The synthesized product, 5HT, is accumulated in secretory granules by a vesicular monoamine transporter (VMAT2); vesicular 5HT is released by exocytosis from serotonergic neurons. In the nervous system, the action of released 5HT is terminated via neuronal uptake by a specific 5HT transporter (SERT), localized in the membrane of serotonergic axon terminals and in the membrane of platelets. This uptake system is the means by which platelets acquire 5HT, since they lack the enzymes required for 5HT synthesis. The amine transporters are distinct from VMAT2, which concentrates amines in intracellular storage vesicles and is a nonspecific amine carrier, whereas the 5HT transporter is specific.

The principal route of metabolism of 5HT involves oxidative deamination by monoamine oxidase (MAO); the aldehyde intermediate thus formed is converted to 5-hydroxyindole acetic acid (5-HIAA) by aldehyde dehydrogenase (see Figure 13–1). 5-HIAA is actively transported out of the brain by a process that is sensitive to the nonspecific transport inhibitor, probenecid. 5-HIAA from brain and peripheral sites of 5HT storage and metabolism is excreted in the urine along with small amounts of 5-hydroxytryptophol sulfate or glucuronide conjugates. The usual range of urinary excretion of 5-HIAA by a normal adult is 2-10 mg daily. Ingestion of ethanol results in elevated amounts of NADH$_2$ (see Chapter 23), which diverts 5-hydroxyindole acetaldehyde from the oxidative route to the reductive pathway and tends to increase the excretion of 5-hydroxytryptophol and correspondingly reduce the excretion of 5-HIAA.

Of the 2 isoforms of monoamine oxidase (MAO; see Chapter 8), MAO-A preferentially metabolizes 5HT and NE. Dopamine and tryptamine are metabolized equally well by both isoforms. Neurons contain both isoforms of MAO, localized primarily in the outer membrane of mitochondria. MAO-B is the principal isoform in platelets, which contain large amounts of 5HT.

PHYSIOLOGICAL FUNCTIONS OF SEROTONIN

MULTIPLE 5HT RECEPTORS

The multiple 5HT receptor subtypes cloned comprise the largest known neurotransmitter-receptor family. The 5HT receptor subtypes
are expressed in distinct but often overlapping patterns and are coupled to different transmembrane-signaling mechanisms (Table 13–1).

*Also referred to as 5HT₁₅⁺.* Also referred to as 5HT₁₅⁻Aka the θ receptor. A 5HT-gated ion channel, aka the M receptor.

Four of seven 5HT receptor families have defined functions. The 5HT₁, 5HT₂, and 5HT4–7 receptor families are members of the superfamily of GPCRs.

- The 5HT₁-receptor subfamily consists of 5 members, all of which
preferentially couple to $G_{i/o}$ and inhibit adenylyl cyclase.

- The 3 subtypes of 5HT$_2$ receptors couple to $G_q/G_{11}$ proteins and activate the PLC-DAG/IP$_3$-Ca$^{2+}$-PKC pathway. 5HT$_2A$ and 5HT$_2C$ receptors also activate phospholipase A$_2$, promoting the release of arachidonic acid.
- The 5HT$_3$ receptor is the only monoamine neurotransmitter receptor that functions as a ligand-operated ion channel. Activation of 5HT$_3$ receptors elicits a rapidly desensitizing depolarization, mediated by the gating of cations.
- 5HT$_4$ receptors couple to $G_s$ to activate adenylyl cyclase and increase intracellular cyclic AMP.

The 5HT$_{1A}$, 5HT$_{1B}$, and 5HT$_{1D}$ receptor subtypes also activate a receptor-operated K$^+$ channel and inhibit a voltage-gated Ca$^{2+}$ channel. The 5HT$_{1A}$ receptor is found in the raphe nuclei of the brainstem, where it functions as an inhibitory somatodendritic autoreceptor on cell bodies of serotonergic neurons (Figure 13–2). The 5HT$_{1D/1B}$ receptor functions as an autoreceptor on axon terminals, inhibiting 5HT release. 5HT$_{1D}$ receptors, abundantly expressed in the substantia nigra and basal ganglia, regulate the firing rate of DA-containing cells and the release of DA at axonal terminals.

![Figure 13–2](image-url)

**Figure 13–2** Two classes of 5HT autoreceptors with differential localizations. Somatodendritic 5HT$_{1A}$ autoreceptors decrease raphe cell firing when activated by 5HT released from axon collaterals of the same or adjacent neurons. The receptor subtype of the presynaptic autoreceptor on axon terminals in the forebrain has different pharmacological properties and has been classified as 5HT$_{1D}$ (in humans) or 5HT$_{1B}$ (in rodents). This receptor modulates the release of
5HT. Postsynaptic 5HT\textsubscript{1} receptors are also indicated.

5HT\textsubscript{2A} receptors are broadly distributed in the CNS (primarily in serotonergic terminal areas, with high densities in prefrontal and parietal areas, and somatosensory cortex), as well as in blood platelets (Figure 13–3) and smooth muscle cells. The 5HT\textsubscript{2C} receptor has been implicated in the control of cerebrospinal fluid production and in feeding behavior and mood.

![Diagram](image)

**Figure 13–3** The local influences of platelet 5HT. The release of 5HT stored in platelets is triggered by aggregation. The local actions of 5HT include feedback actions on platelets (shape change and accelerated aggregation) mediated by interaction with platelet 5HT\textsubscript{2A} receptors, stimulation of NO production mediated by 5HT\textsubscript{1}-like receptors on vascular endothelium, and contraction of vascular smooth muscle mediated by 5HT\textsubscript{2A} receptors. These influences act in concert with many other mediators that are not shown to promote thrombus formation and hemostasis. See Chapter 30 for details of adhesion and aggregation of platelets and factors contributing to thrombus formation and blood clotting.

5HT\textsubscript{3} receptors are located on parasympathetic terminals in the GI tract,
including vagal and splanchnic afferents. In the CNS, a high density of 5HT₃ receptors occurs in the solitary tract nucleus and the area postrema. 5HT₃ receptors in both the GI tract and the CNS participate in the emetic response, providing a basis for the antiemetic property of 5HT₃ receptor antagonists.

In the CNS, 5HT₄ receptors are found on neurons of the superior and inferior colliculi and in the hippocampus. In the GI tract, 5HT₄ receptors are located on neurons of the myenteric plexus and on smooth muscle and secretory cells. In the GI tract, stimulation of the 5HT₄ receptor is thought to evoke secretion and to facilitate the peristaltic reflex. The latter effect may explain the utility of prokinetic benzamides in GI disorders (see Chapter 46).

Two subtypes of the 5HT₅ receptor have been cloned; although the 5HT₅A receptor has been shown to inhibit adenylyl cyclase, functional coupling of the cloned 5HT₅B receptor has not yet been described. Two other cloned receptors, 5HT₆ and 5HT₇, are linked to activation of adenylyl cyclase. 5HT₇ receptors may play a role in the relaxation of smooth muscle in the GI tract and the vasculature. The atypical antipsychotic drug clozapine has a high affinity for 5HT₆ and 5HT₇ receptors; whether this property is related to the broader effectiveness of clozapine compared to conventional antipsychotic drugs is not known (see Chapter 16).

ACTIONS OF 5HT IN PHYSIOLOGICAL SYSTEMS

PLATELETS. Platelets differ from other formed elements of blood in expressing mechanisms for uptake, storage, and endocytotic release of 5HT. 5HT is not synthesized in platelets, but is taken up from the circulation and stored in secretory granules by active transport, similar to the uptake and storage of serotonin by serotonergic nerve terminals.

Thus, Na⁺-dependent transport across the platelet plasma membrane via the 5HT transporter is followed by VMAT2-mediated uptake into storage granules creating a gradient of 5HT as high as 1000:1 with an internal concentration of 0.6 M in the storage vesicles.

When platelets make contact with injured endothelium (see Chapter
30), they release substances that promote platelet aggregation, and secondarily, they release 5HT (see Figure 13–3). 5HT binds to platelet 5HT$_{2A}$ receptors and elicits a weak aggregation response that is markedly augmented by the presence of collagen. If the damaged blood vessel is injured to a depth where vascular smooth muscle is exposed, 5HT exerts a direct vasoconstrictor effect, thereby contributing to hemostasis, which is enhanced by locally released autocoids (thromboxane A$_2$, kinins, and vasoactive peptides). Conversely, 5HT may interact with endothelial cells to stimulate production of NO and antagonize its own vasoconstrictor action, as well as the vasoconstriction produced by other locally released agents.

CARDIOVASCULAR SYSTEM. The classical response of blood vessels to 5HT is contraction, particularly in the splanchnic, renal, pulmonary, and cerebral vasculatures. 5HT also induces a variety of responses by the heart that are the result of activation of multiple 5HT receptor subtypes, stimulation or inhibition of autonomic nerve activity, or dominance of reflex responses to 5HT.

Thus, 5HT has positive inotropic and chronotropic actions on the heart that may be blunted by simultaneous stimulation of afferent nerves from baroreceptors and chemoreceptors. Activation of 5HT$_3$ receptors on vagus nerve endings elicits the Bezold-Jarisch reflex, causing extreme bradycardia and hypotension. The local response of arterial blood vessels to 5HT also may be inhibitory, the result of the stimulation of endothelial NO production and prostaglandin synthesis and blockade of NE release from sympathetic nerves. Conversely, 5HT amplifies the local constrictor actions of NE, ANGII, and histamine, which reinforce the hemostatic response to 5HT.

GI TRACT. Enterochromaffin cells in the gastric mucosa are the site of the synthesis and most of the storage of 5HT in the body and are the source of circulating 5HT. Motility of gastric and intestinal smooth muscle may be either enhanced or inhibited by at least 6 subtypes of 5HT receptors (Table 13–2).

*Ach, acetylcholine.

Basal release of enteric 5HT is augmented by mechanical stretching, such as that caused by food, and by efferent vagal stimulation. Released 5HT enters the portal vein and is subsequently metabolized by MAO-A in the liver. 5HT that survives hepatic oxidation may be captured by platelets or rapidly removed by the endothelium of lung capillaries and inactivated. 5HT released from enterochromaffin cells also acts locally to regulate GI function. Abundant 5HT₃ receptors on vagal and other afferent neurons and on enterochromaffin cells play a pivotal role in emesis (see Chapter 46). Enteric 5HT triggers peristaltic contraction when released in response to acetylcholine, sympathetic nerve stimulation, increases in intraluminal pressure, and lowered pH.

**CNS.** All of the cloned 5HT receptors are expressed in the brain; 5HT influences a multitude of brain functions, including sleep, cognition, sensory perception, motor activity, temperature regulation, nociception, mood, appetite, sexual behavior, and hormone secretion. The roles of specific 5HT receptors in these functions have been defined in receptor knockout mice (Table 13–3).

Table 13–3

| Physiological Roles of 5HT Receptors Defined by Phenotypes in Knockout Mice |
The principal cell bodies of 5HT neurons are located in raphe nuclei of the brainstem and project throughout the brain and spinal cord (see Chapter 14). In addition to being released at discrete synapses, release of serotonin also seems to occur at sites of axonal varicosities that do not form distinct synaptic contacts. 5HT released at nonsynaptic varicosities is thought to diffuse to outlying targets, rather than acting on discrete synaptic targets, perhaps acting as a neuromodulator as well as a neurotransmitter (see Chapter 14). Serotonergic nerve terminals contain the proteins needed to synthesize 5HT from L-tryptophan. Newly formed 5HT is rapidly accumulated in synaptic vesicles (through VMAT2), where it is protected from MAO. 5HT released by nerve-impulse flow is reaccumulated into the presynaptic terminal by the 5HT transporter, SERT (SLC6A4; see Chapter 5). Presynaptic reuptake is a highly efficient mechanism for terminating the action of 5HT released by nerve-impulse flow. MAO localized in postsynaptic elements and surrounding cells rapidly inactivates 5HT that escapes neuronal reuptake and storage.

**ELECTROPHYSIOLOGY.** The physiological consequences of 5HT release vary with the brain area and the neuronal element involved, as well as with the 5HT receptor subtype(s) expressed (Table 13–4).

**BEHAVIOR**

*SLEEP-WAKE CYCLE.* 5HT plays a role in sleep-wake cycle.

Depletion of 5HT with *p-Chlorophenylalanine*, a tryptophan hydroxylase inhibitor, elicits insomnia that is reversed by the 5HT precursor, 5-hydroxytryptophan. Conversely, treatment with L-tryptophan or with nonselective 5HT agonists accelerates sleep onset and prolongs total sleep time. 5HT antagonists reportedly can increase and decrease slow-wave sleep, probably reflecting interacting or opposing roles for subtypes of 5HT receptors. One relatively consistent finding in humans and in laboratory animals is an increase in slow-wave sleep following administration of a selective 5HT_{2A/2C}-receptor antagonist such as ritanserin.

*AGGRESSION AND IMPULSIVITY.* 5HT serves a critical role in aggression and impulsivity.

Human studies reveal a correlation between low cerebrospinal fluid 5-HIAA and violent impulsivity and aggression. Knockout mice lacking the 5HT_{1B} receptor exhibit extreme aggression, suggesting either a role for 5HT_{1B} receptors in the development of neuronal pathways important in aggression or a direct role in the mediation of aggressive behavior. A human genetic study identified a point mutation in the gene encoding MAO-A, which was associated with extreme aggressiveness and mental retardation; this has been confirmed in knockout mice lacking MAO-A.

</table>
anxiety and depressive disorders, like the effects of selective serotonin reuptake inhibitors (SSRIs), strongly suggest a role for 5HT in the neurochemical mediation of these disorders.

Inhibition of neuronal reuptake of 5HT via the transporter SERT (SLC6A4) prolongs the dwell-time of 5HT in the synapse. SSRIs, such as fluoxetine (PROZAC, others), potentiate and prolong the action of 5HT released by neuronal activity. When coadministered with L-5-hydroxytryptophan, SSRIs elicit a profound activation of serotonergic responses. SSRIs (citalopram [CELEXA], escitalopram [LEXAPRO], fluoxetine, fluvoxamine, paroxetine [PAXIL], and sertraline [ZOLOFT]) are the most widely used treatment for endogenous depression (see Chapter 15).

**APPETITE.** Sibutramine (MERIDIA), an inhibitor of the reuptake of 5HT, NE, and DA, is used as an appetite suppressant in the management of obesity.

Sibutramine is classified as a selective serotonin-norepinephrine reuptake inhibitor (SNRI). Other SNRIs include duloxetine (CYMBALTA; approved for depression, anxiety, peripheral neuropathy, and fibromyalgia), venlafaxine (EFFEXOR; approved for the treatment of depression, anxiety, and panic disorders), desvenlafaxine (PRISTIQ; approved for depression), and milnacipran (SAVELLA; approved for fibromyalgia).

**5HT RECEPTOR AGONISTS AND ANTAGONISTS**

**5HT RECEPTOR AGONISTS**

Direct-acting 5HT receptor agonists have widely different chemical structures, as well as diverse pharmacological properties and are used in the pharmacotherapy of migraine, anxiety, depression, chemotherapy-induced emesis, and disorders of GI motility (Table 13–5).

**Table 13–5**

Serotonergic Drugs: Primary Actions and Clinical Indications
5HT RECEPTOR AGONISTS AND MIGRAINE. 5HT seems to be a key mediator in the pathogenesis of migraine. Consistent with the 5HT hypothesis of migraine, 5HT receptor agonists are a mainstay for acute treatment of migraine headaches. The efficacy of antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and as yet undefined environmental and genetic factors.

5HT\textsubscript{1B/1D} RECEPTOR AGONISTS: THE TRIPTANS. The triptans are indole derivatives that are effective, acute antimigraine agents. Their capacity to decrease the nausea and vomiting of migraine is an important advance in the treatment of the condition. Available compounds include almotriptan (AXERT), eletriptan (RELPAX), frovatriptan (FROVA), naratriptan (AMERGE), rizatriptan (MAXALT, others), sumatriptan (IMITREX, others), and zolmitriptan (ZOMIG). Sumatriptan for migraine headaches is also marketed in a fixed-dose combination with naproxen (TREXIMET).

![Sumatriptan Structure]

**Pharmacological Properties.** The pharmacological effects of the triptans appear
to be limited to the 5HT$_1$ family of receptors, providing evidence that this receptor subclass plays an important role in the acute relief of a migraine attack. The triptans interact potently with 5HT$_{1B}$ and 5HT$_{1D}$ receptors and have a low or no affinity for other subtypes of 5HT receptors, as well as $\alpha_1$ and $\alpha_2$ adrenergic, $\beta$ adrenergic, dopaminergic, muscarinic cholinergic, and benzodiazepine receptors. Clinically effective doses of the triptans correlate well with their affinities for both 5HT$_{1B}$ and 5HT$_{1D}$ receptors, supporting the hypothesis that 5HT$_{1B}$ and/or 5HT$_{1D}$ receptors are the most likely receptors involved in the mechanism of action of acute antimigraine drugs.

**Mechanism of Action.** The mechanism of the efficacy of 5HT$_{1B/1D}$ agonists in migraine is not resolved. One hypothesis of migraine suggests that unknown events lead to the abnormal dilation of carotid arteriovenous anastomoses in the head and shunting of carotid arterial blood flow, producing cerebral ischemia and hypoxia perceived as migraine pain; activation of 5HT$_{1B/1D}$ receptors may cause constriction of intracranial blood vessels including arteriovenous anastomoses, closing the shunts and restoring blood flow to the brain. An alternative hypothesis proposes that both 5HT$_{1B}$ and 5HT$_{1D}$ receptors serve as presynaptic autoreceptors that may block the release of pro-inflammatory neuropeptides from the nerve terminal in the perivascular space, which could account for their efficacy in the acute treatment of migraine.

**Absorption, Fate, and Excretion.** When given subcutaneously, sumatriptan reaches its peak plasma concentration in $\sim$12 min. Following oral administration, peak plasma concentrations occur within 1-2 h. Bioavailability following the subcutaneous route of administration is $\sim$97%; after oral administration or nasal spray, bioavailability is only 14-17%. The elimination $t_{1/2}$ is $\sim$1-2 h. Sumatriptan is metabolized predominantly by MAO-A, and its metabolites are excreted in the urine.

Zolmitriptan reaches its peak plasma concentration 1.5-2 h after oral administration. Zolmitriptan is converted to an active $N$-desmethyl metabolite, which has severalfold higher affinity for 5HT$_{1B}$ and 5HT$_{1D}$ receptors than does the parent drug. Both the metabolite and the parent drug have half-lives of 2-3 h.

Naratriptan, administered orally, reaches its peak plasma concentration in 2-3 h. It is the second longest acting of the triptans, with a $t_{1/2}$ of $\sim$6 h. Fifty percent of
an administered dose of naratriptan is excreted unchanged in the urine, and ~30% is excreted as products of oxidation by CYPs.

Rizatriptan reaches peak plasma levels within 1-1.5 h after oral ingestion of the drug. An orally disintegrating dosage form has a somewhat slower rate of absorption. The principal route of metabolism of rizatriptan is by oxidative deamination by MAO-A.

**ADVERSE EFFECTS AND CONTRAINDICATIONS.** Rare but serious cardiac events have been associated with the administration of 5HT\textsubscript{1} agonists, including coronary artery vasospasm, transient myocardial ischemia, atrial and ventricular arrhythmias, and myocardial infarction, predominantly in patients with risk factors for coronary artery disease. In general, however, only minor side effects are seen with the triptans in the acute treatment of migraine. After subcutaneous injection of sumatriptan, patients often experience irritation at the site of injection (transient mild pain, stinging, or burning sensations). The most common side effect of sumatriptan nasal spray is a bitter taste. Orally administered triptans can cause paresthesias; asthenia and fatigue; flushing; feelings of pressure, tightness, or pain in the chest, neck, and jaw; drowsiness; dizziness; nausea; and sweating.

Because triptans may cause an acute, usually small, increase in blood pressure, they also are contraindicated in patients with uncontrolled hypertension. Naratriptan is contraindicated in patients with severe renal or hepatic impairment. Rizatriptan should be used with caution in patients with renal or hepatic disease but is not contraindicated in such patients. Eletriptan is contraindicated in hepatic disease. Almotriptan, rizatriptan, sumatriptan, and zolmitriptan are contraindicated in patients who have taken an MAO inhibitor within the preceding 2 weeks, and all triptans are contraindicated in patients with near-term prior exposure to ergot alkaloids or other 5HT agonists.

**TRIPTANS IN TREATMENT OF MIGRAINE.** The triptans are effective in the acute treatment of migraine (with or without aura).

Approximately 70% of individuals report significant headache relief from a 6-mg subcutaneous dose of sumatriptan. This dose may be repeated once within a 24-h period. The oral dose of sumatriptan is 25-100 mg, which may be repeated
after 2 h up to a total dose of 200 mg over a 24-h period. When administered by nasal spray, from 5-20 mg of sumatriptan is recommended, repeatable after 2 h up to a maximum dose of 40 mg over a 24-h period. The onset of action with nasal spray is as early as 15 min. Zolmitriptan is given orally in a dose of 1.25-2.5 mg, which can be repeated after 2 h, up to a maximum dose of 10 mg over 24 h. Naratriptan is given orally in a dose of 1-2.5 mg, repeated after 4 h (maximum dose 5 mg/24-h period). The oral dose of rizatriptan is 5-10 mg. The dose can be repeated after 2 h up to a maximum dose of 30 mg over a 24-h period.

**ERGOT ALKALOIDS.** Ergot is the product of a fungus (*Claviceps purpurea*) that grows on rye and other grains. The pharmacological effects of the ergot alkaloids are varied and complex; in general, the effects result from their actions as partial agonists or antagonists at serotonergic, dopaminergic, and adrenergic receptors. The history, chemistry, and pharmacological properties of the ergot alkaloids are covered in detail in Chapter 13 of the 12th edition of the parent text. The main uses of the ergot alkaloids are:

- In treatment of migraine (ergotamine tartrate and dihydroergotamine mesylate, in many dosage formulations; methysergide for prophylaxis)
- To control the secretion of prolactin (*bromocriptine*, taking advantage of its DA agonist effect)
- To increase uterine tone (all natural ergot alkaloids have this effect but ergonovine and its semisynthetic derivative methylergonovine have replaced other ergot preparations as uterine-stimulating agents in obstetrics)

**ERGOT IN THE TREATMENT OF MIGRAINE.** The multiple pharmacological effects of ergot alkaloids have complicated the determination of their precise mechanism of action in the acute treatment of migraine. The actions of ergot alkaloids at 5HT$_{1B/1D}$ receptors likely mediate their *acute* antimigraine effects. The use of ergot alkaloids for migraine should be restricted to patients having frequent, moderate migraine or infrequent, severe migraine attacks. Ergot preparations should be administered as soon as possible after the onset of a headache. GI absorption of ergot alkaloids is erratic, perhaps contributing to the large variation in patient response to these drugs.
USE OF ERGOT ALKALOIDS IN POSTPARTUM HEMORRHAGE. All of the natural ergot alkaloids markedly increase the motor activity of the uterus. As the dose is increased, contractions become more forceful and prolonged, resting tone is dramatically increased, and sustained contracture can result. This characteristic is quite compatible with their use postpartum or after abortion to control bleeding and maintain uterine contraction. In current obstetric practice, ergot alkaloids are used primarily to prevent postpartum hemorrhage.

ADVERSE EFFECTS AND CONTRAINDICATIONS OF ERGOT ALKALOIDS. Ergot alkaloids are contraindicated in women who are, or may become, pregnant because the drugs may cause fetal distress and miscarriage. Ergot alkaloids also are contraindicated in patients with peripheral vascular disease, coronary artery disease, hypertension, impaired hepatic or renal function, and sepsis. Ergot alkaloids should not be taken within 24 h of the use of the triptans or used with other drugs that can cause vasoconstriction.

METHYSERGIDE. Methysergide (SANSERT; 1-methyl-\textit{d}-lysergic acid butanolamide) interacts with 5HT\textsubscript{1} receptors, but its therapeutic effects appear primarily to reflect blockade of 5HT\textsubscript{2A} and 5HT\textsubscript{2C} receptors.

Although methysergide is an ergot derivative, it has only weak vasoconstrictor and oxytocic activity. Methysergide is used for the prophylactic treatment of migraine and other vascular headaches. A potentially serious complication of prolonged treatment is inflammatory fibrosis, giving rise to various syndromes that include pleuropulmonary fibrosis, and coronary and endocardial fibrosis. Usually the fibrosis regresses after drug withdrawal, although persistent cardiac valvular damage has been reported. If methysergide is used chronically, treatment should be interrupted for 3 weeks or more every 6 months. Methysergide is not available in the U.S.

\textit{D-LYSERGIC ACID DIETHYLAMIDE (LSD)}. LSD is a nonselective 5HT agonist. This ergot derivative profoundly alters human behavior, eliciting sensory distortion (especially visual) and hallucinations at doses as low as 1 \textmu g/kg. The potent, mind-altering effects of LSD explain its abuse by humans.
LSD interacts with brain 5HT receptors as an agonist/partial agonist. LSD mimics 5HT at 5HT\textsubscript{1A} autoreceptors on raphe cell bodies, producing a marked slowing of the firing rate of serotonergic neurons. In the raphe, LSD and 5HT are equi-effective; however, in areas of serotonergic axonal projections (such as visual relay centers), LSD is far less effective than is 5HT. In an animal behavioral model, the discriminative stimulus effects of LSD and other hallucinogenic drugs appear to be mediated by activation of 5HT\textsubscript{2A} receptors. LSD also interacts potently with many other 5HT receptors, including cloned receptors whose functions have not yet been determined. The hallucinogenic phenethylamine derivatives are selective 5HT\textsubscript{2A/2C} receptor agonists. Current theories of the mechanism of action of LSD and other hallucinogens focus on 5HT\textsubscript{2A} receptor-mediated disruption of thalamic gating with sensory overload of the cortex. Positron emission tomography imaging studies revealed that administration of the hallucinogen psilocybin (the active component of “shrooms”) mimics the pattern of brain activation found in schizophrenic patients experiencing hallucinations. This action of psilocybin is blocked by pretreatment with a 5HT\textsubscript{2A/2C} antagonist.

**BUSPIRONE (BUSPAR, OTHERS).** Buspirone, gepirone, and ipsapirone are selective partial agonists at 5HT\textsubscript{1A} receptors. Buspirone has been effective in the treatment of anxiety (see Chapter 15). Buspirone mimics the antianxiety properties of benzodiazepines but does not interact with GABA\textsubscript{A} receptors and or display the sedative and anticonvulsant properties of benzodiazepines.

**VILAZODONE (VIIBRYD).** Vilazadone is an SSRI and a partial agonist at the 5HT\textsubscript{1A} receptor. It is FDA-approved in adults for treatment of major depressive disorder.

**m-CHLOROPHENYLPIPERAZINE (MCPP).** The actions of mCPP in vivo primarily reflect activation of 5HT\textsubscript{1B} and/or 5HT\textsubscript{2A/2C} receptors; mCPP is an active metabolite of the antidepressant drug trazodone.

Animal studies suggest a greater involvement of the 5HT\textsubscript{2C} receptor in the
anxiogenic actions of mCPP. mCPP elevates cortisol and prolactin secretion, probably through a combination of 5HT_1 and 5HT_{2A/2C} receptor activation. It also increases growth hormone secretion, apparently by a 5HT independent mechanism.

**LORCASERIN (Belviq).** Lorcaserin is a 5HT_{2C} receptor agonist approved for weight loss.

The drug is thought to decrease food consumption and promote satiety by selectively activating 5HT_{2C} receptors on anorexigenic proopiomelanocortin (POMC) neurons in the arcuate nucleus of the hypothalamus.

**5HT RECEPTOR ANTAGONISTS**

The properties of 5HT receptor antagonists vary widely. Ergot alkaloids and related compounds tend to be nonspecific 5HT receptor antagonists; however, a few ergot derivatives, such as metergoline, bind preferentially to members of the 5HT_2 receptor family. A number of selective antagonists for 5HT_{2A/2C} and 5HT_3 receptors are currently available. Ketanserin is the prototypic 5HT_{2A} receptor antagonist. A large series of 5HT_3 receptor antagonists are being explored for treatment of various GI disturbances (e.g., ondansetron [ZOFRAN, others], dolasetron [ANZEMET], granisetron [KYTRIL, others], and palonosetron [ALOXI]). All 5HT_3 receptor antagonists have proven to be highly efficacious in the treatment of chemotherapy-induced nausea, and alosetron (LOTRONEX) is licensed for irritable bowel syndrome (see Chapter 46).

**KETANSERIN.** Ketanserin (SUFREXAL, others) potently blocks 5HT_{2A} receptors, less potently blocks 5HT_{2C} receptors, and has no significant effect on 5HT_3 or 5HT_4 receptors or any members of the 5HT_1-receptor family. Ketanserin also blocks α adrenergic receptors and histamine H_1 receptors.
Ketanserin lowers blood pressure in patients with hypertension, causing a reduction comparable to that seen with α adrenergic receptor antagonists or diuretics. This effect likely relates to its blockade of α₁ adrenergic receptors. Ketanserin inhibits 5HT-induced platelet aggregation. Its oral bioavailability is ~50%, and its plasma t₁/₂ is 12-25 h. The primary mechanism of inactivation is hepatic metabolism. Ketanserin is not marketed in the U.S. Chemical relatives of ketanserin such as ritanserin are more selective 5HT₂A receptor antagonists with low affinity for α₁ adrenergic receptors. Ritanserin, as well as most other 5HT₂A receptor antagonists, also potently antagonize 5HT₂C receptors.

ATYPICAL ANTIPSYCHOTIC DRUGS. Clozapine (CLOZARIL, others), a 5HT₂A/2C receptor antagonist, represents a class of atypical antipsychotic drugs with reduced incidence of extrapyramidal side effects compared to the classical neuroleptics (see Chapter 16). Clozapine also has a high affinity for subtypes of DA receptors.

A common strategy for the design of atypical antipsychotic drugs is to combine 5HT₂A/2C and dopamine D₂ receptor–blocking actions in the same molecule. Risperidone (RISPERDAL, others) is a potent 5HT₂A and D₂ receptor antagonist. Low doses of risperidone have been reported to attenuate negative symptoms of schizophrenia with a low incidence of extrapyramidal side effects.

CYPROHEPTADINE. Cyproheptadine is an effective H₁-receptor antagonist. Cyproheptadine blocks 5HT activity on smooth muscle by binding to 5HT₂A receptors. In addition, it has weak anticholinergic activity and possesses mild CNS depressant properties.

Cyproheptadine shares the properties and uses of other H₁-receptor antagonists (see Chapter 32). The 5HT blocking actions of cyproheptadine explain its value
in the off-label uses for postgastrectomy dumping syndrome, intestinal hypermotility of carcinoid, and migraine prophylaxis. Cyproheptadine is not a preferred treatment for these conditions.

**METHYSERGIDE.** Methysergide has both agonist and antagonist activities at multiple 5HT receptors. See its section, above.

**CLINICAL MANIPULATION OF 5HT LEVELS: SEROTONIN SYNDROME**

Excessive elevation of 5HT levels in the body can cause *serotonin syndrome*, a constellation of symptoms sometimes observed in patients starting new or increased antidepressant therapy or combining an SSRI with an NE reuptake inhibitor or a triptan (for migraine). Symptoms may include restlessness, confusion, shivering, tachycardia, diarrhea, muscle twitches/rigidity, fever, seizures, loss of consciousness, and death.

**DOPAMINE**

The highest concentrations of DA are found in the brain; DA stores are also present peripherally in the adrenal medulla and the transmitter is detectable in the plexuses of the GI tract and in enteric nervous system. DA modulates peripheral vascular tone, renal perfusion, and heart rate.

DA consists of a catechol moiety linked to an ethyl amine, leading to its classification as a catecholamine. DA is closely related to melanin, a pigment that is formed by oxidation of DA, tyrosine, or L-dopa. Melanin exists in the skin and cuticle and gives the substantia nigra its namesake dark color. Both DA and L-dopa are readily oxidized by nonenzymatic pathways to form cytotoxic reactive oxygen species (ROS) and quinones. DA- and DOPA-quinones form adducts with α-synuclein, a major constituent of Lewy bodies in Parkinson disease (see Chapter 22). DA is a polar molecule that does not readily cross the blood-brain barrier.
SYNTHESIS AND METABOLISM OF DA. The biosynthesis and metabolism of DA are summarized by Figure 13–4.

Figure 13–4 Synthesis and inactivation of dopamine. Enzymes are identified in blue lettering, and cofactors are shown in black letters. See legend to Figure 13–5 for key to abbreviations.

Phenylalanine and tyrosine are the precursors of DA. For the most part, mammals convert dietary phenylalanine to tyrosine by phenylalanine hydroxylase. Tyrosine crosses readily into the brain through uptake; normal brain levels of tyrosine are typically saturating. Conversion of tyrosine to L-dopa (3,4-
dihydroxyphenylalanine) by the enzyme tyrosine hydroxylase is the rate-limiting step in the synthesis of DA (as in NE synthesis; see Chapter 8). Once generated, L-dopa is rapidly converted to DA by AADC, the same enzyme that generates 5HT from L-5-hydroxytryptophan. Unlike DA, L-dopa readily crosses the blood-brain barrier and is converted to DA in the brain, which explains its utility in therapy for Parkinson disease (see Chapter 22). Diminished levels of phenylalanine hydroxylase lead to high levels of phenylalanine, producing a condition known as phenylketonuria, which must be controlled by dietary restrictions in order to avoid intellectual impairment.

THE DOPAMINERGIC SYNAPSE. The neurochemical events that underlie DA neurotransmission are summarized in Figure 13–5.
Figure 13–5 Dopaminergic nerve terminal. Dopamine (DA) is synthesized from tyrosine in the nerve terminal by the sequential actions of tyrosine hydrolase (TH) and aromatic amino acid decarboxylase (AADC). DA is sequestered by vesicular monoamine transporter (VMAT2) in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D₁ and D₂ receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET), or removed by postsynaptic uptake via OCT3 transporters. Cytosolic DA is subject to degradation by monoamine oxidase (MAO) and aldehyde dehydrogenase (ALDH) in the neuron, and by catechol-O-methyltransferase (COMT) and MAO/ALDH in nonneuronal cells; the final metabolic product is homovanillic acid (HVA). PH, phenylalanine hydroxylase.
See structures in Figure 13–4.

In dopaminergic neurons, synthesized DA is packaged into secretory vesicles (or into granules within adrenal chromaffin cells) by the vesicular monoamine transporter, VMAT2. By contrast, in adrenergic or noradrenergic cells, the DA is not packaged; instead, it is converted to NE by DA β-hydroxylase and, in adrenergic cells, further altered to epinephrine in cells expressing phenylethanolamine N-methyltransferase (see Chapter 8). Synaptically released DA is subject to transporter clearance and metabolism. The DA transporter (DAT) is not selective for DA; moreover, DA can also be cleared from the synapse by the NE transporter, NET. Reuptake of DA by DAT is the primary mechanism for termination of DA action, and allows for either vesicular repackaging of transmitter or metabolism. The DA transporter is regulated by phosphorylation, offering the potential for DA to regulate its own uptake.

The DA transporter is predominantly localized perisynaptically so that DA is cleared at a distance from its release site. The DA transporter is a site of action for cocaine and methamphetamine. The DA transporter is also the molecular target for some neurotoxins, including 6-hydroxydopamine and 1-methyl-4-phenylpyridinium (MPPm), the neurotoxic metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Following uptake into dopaminergic neurons, MPP and 6-hydroxydopamine elicit intra- and extracellular DA release, ultimately resulting in neuronal death. This selective dopaminergic degeneration mimics Parkinson disease, and serves as an animal model for this disorder.

Metabolism of DA occurs primarily by MAO localized in both pre- and postsynaptic elements. MAO acts on DA to generate an inactive aldehyde derivative by oxidative deamination (see Figures 13–4 and 13–5), which is subsequently metabolized by aldehyde dehydrogenase to form 3,4-dihydroxyphenylacetic acid (DOPAC). DOPAC can be further metabolized by COMT to form homovanillic acid (HVA). COMT can convert DA to 3-methoxytyramine, which is subsequently converted to HVA by MAO. DOPAC, and HVA, as well as DA, are excreted in the urine.

COMT in the periphery also metabolizes L-dopa to 3-O-methyldopa, which then competes with L-dopa for uptake into the CNS. Consequently, L-dopa given in the treatment of Parkinson disease must be coadministered with peripheral COMT inhibitors to preserve L-dopa and allow sufficient entry into the CNS (see
Chapter 22).

PHYSIOLOGICAL FUNCTIONS OF DOPAMINE

MULTIPLE DA RECEPTORS

Five distinct GPCRs have been cloned and determined to mediate the actions of DA. The family of DA receptors is divided into the D1 and D2 subfamilies based on their effector-coupling profiles (Figure 13–6).

![D1 and D2 receptor families](image)

**Figure 13–6** Distribution and characterization of DA receptors in the CNS.

The **D1 subfamily** consists of the D1 and D5 receptor subtypes; both are GPCRs that couple to Gs to stimulate cellular cyclic AMP production couple, but they differ in their pharmacological profiles.

The D1 receptor is the most highly conserved and the most highly expressed of
the DA receptors. The highest levels of D₁ receptor protein are found within the CNS. The neostriatum expresses the highest levels of D₁ receptor but does not express any detectable Ga₅. In this region, the D₁ receptor appears to couple to G_olf to increase levels of cAMP and its downstream effectors. The D₁ receptor is also located in the kidney, retina, and cardiovascular system. The D₅ gene is polymorphic; several functional single nucleotide polymorphisms (SNPs) within the transmembrane domains alter binding properties of numerous ligands, including DA. The D₅ receptor is most highly expressed in the substantia nigra, hypothalamus, striatum, cerebral cortex, nucleus accumbens, and olfactory tubercle.

**The D2 subfamily** contains the D₂, D₃, and D₄ receptors. All reduce intracellular cyclic AMP production by coupling to G₁₀ proteins, but they diverge in amino acid sequence and pharmacology.

The D₂ receptor is expressed throughout the brain. D₂S and D₂L receptors have similar pharmacological properties and both function as autoreceptors, inhibiting cAMP formation. D₂ receptor signaling through ββγ also regulates a variety of cellular functions, including inwardly rectifying K⁺ channels, N-type Ca²⁺ channels, PLA₂, ERK, and L-type Ca²⁺ channels. The D₂ receptor can activate Gᵢ₀ proteins independent of agonist (constitutive activity). The D₃ receptor is less abundant than the D₂ receptor, and is only expressed in the limbic regions of the brain. The D₄ receptor is abundantly expressed in the retina, and is also found in the hypothalamus, prefrontal cortex, amygdala, hippocampus, and pituitary. D₄ is the most polymorphic of the DA receptors, containing a variable number of tandem repeats (VNTR) within the third intracellular loop. There are several SNPs in the D₄ receptor, 1 of which results in dramatic alterations in ligand binding. There are associations between a 7-repeat D₄ VNTR variant and attention deficit hyperactivity disorder (ADHD).

**ACTIONS OF DA ON PHYSIOLOGIC SYSTEMS**

**Heart and Vasculature.** At low concentrations, circulating DA primarily stimulates vascular D₁ receptors, causing vasodilation and reducing cardiac afterload. The net result is a decrease in blood
pressure and an increase in cardiac contractility. As circulating DA concentrations rise, DA is able to activate β adrenergic receptors to further increase cardiac contractility.

At very high concentrations, circulating DA activates A adrenergic receptors in the vasculature, thereby causing vasoconstriction; thus, high concentrations of DA increase blood pressure. Clinically, DA administration is used to treat severe congestive heart failure, sepsis, or cardiogenic shock. It is only administered intravenously and is not considered a long-term treatment.

**KIDNEY.** DA is a paracrine/autocrine transmitter in the kidney and binds to both receptors of both the D1 and D2 subfamily. Renal DA primarily serves to increase natriuresis, though it can also increase renal blood flow and glomerular filtration. Under basal sodium conditions, DA regulates Na⁺ excretion by inhibiting the activity of various Na⁺ transporters, including the apical Na⁺-H⁺ exchanger and the basolateral Na⁺, K⁺-ATPase. Activation of D₁ receptors increases renin secretion, whereas DA, acting on D₃ receptors, reduces renin secretion. Abnormalities in the DA system and its receptors have been implicated in human hypertension.

**PITUITARY GLAND.** DA is the primary regulator of prolactin secretion from the pituitary gland. DA released from the hypothalamus into the hypophyseal portal blood supply acts on lactotroph D₂S and D₂L receptors to decrease prolactin secretion (see Chapter 38).

**CATECHOLAMINE RELEASE.** Both D₁ and D₂ receptors modulate the release of NE and EPI. The D₂ receptor provides tonic inhibition of EPI release from chromaffin cells of the adrenal medulla, and of NE release from sympathetic nerve terminals. In contrast, the D₁ receptor promotes the release of catecholamines from the adrenal medulla.
CNS. There are 3 major groups of DA projections in the brain (Figure 13–7): mesocortico/-mesolimbic (originating in the ventral tegmental area), nigrostriatal (originating in the substantia nigra pars compacta) and tuberoinfundibular (originating in the hypothalamus). The physiological processes under dopaminergic control include reward, emotion, cognition, memory, and motor activity. Dysregulation of the dopaminergic system is critical in a number of disease states, including Parkinson disease, Tourette syndrome, bipolar depression, schizophrenia, ADHD, and addiction/substance abuse.

Figure 13–7 Major dopaminergic projections in the CNS.

- The nigrostriatal (or mesostriatal) pathway. Neurons in the substantia nigra pars compacta (SNc) project to the dorsal striatum (upward dashed blue arrows); this is the pathway that degenerates in Parkinson disease.
- The mesocortico/mesolimbic pathway. Neurons in the ventral tegmental area project to the ventral striatum (nucleus accumbens), olfactory bulb, amygdala, hippocampus, orbital and medial prefrontal cortex, and cingulate gyrus (solid blue arrows).
- The tuberoinfundibular pathway. Neurons in the arcuate nucleus of the hypothalamus project by the tuberoinfundibular pathway in the hypothalamus, from which DA is delivered to the anterior pituitary (red arrows).
The mesolimbic pathway is associated with reward and, less so, with learned behaviors. Dysfunction in this pathway is associated with addiction, schizophrenia, and psychoses (including bipolar depression), and learning deficits. The mesocortical projections are important for “higher-order” cognitive functions including motivation, reward, emotion, and impulse control; they are also implicated in psychoses, including schizophrenia, and in ADHD. The nigrostriatal pathway is a key regulator of movement (see Chapter 22). Impairments in this pathway are evident in Parkinson disease and underlie detrimental movement side effects associated with dopaminergic therapy, including tardive dyskinesia. DA released in the tuberoinfundibular pathway is carried by the hypophyseal blood supply to the pituitary, where it regulates prolactin secretion.

**ELECTROPHYSIOLOGY.** DA is not a classical excitatory or inhibitory neurotransmitter; rather, DA acts as a modulator of neurotransmission. D1-like receptor activation modulates Na+, as well as N-, P- and L-type Ca²⁺ currents, via a PKA-dependent pathway. D2 receptors regulate K⁺ currents. DA also modulates the activity of ligand-gated ion channels, including NMDA and AMPA receptors.

Dopaminergic neurons are strongly influenced by *excitatory glutamate and inhibitory GABA input*. In general, glutamate inputs enable burstlike firing of dopaminergic neurons, resulting in high concentrations of synaptic DA. GABA inhibition of DA neurons causes a tonic, basal level of DA release into the synapse. DA release also modulates GABA and glutamate neurons, thus providing an additional level of interaction between DA and other neurotransmitters. Strong phasic or slow tonic release of DA, and the subsequent activation of DA receptors, has differential effects on the induction of long-term potentiation (LTP) and long-term depression (LTD). In the striatum, phasic activation of DA neurons and stimulation of D₁ receptors favors LTP induction, while tonic DA release with concomitant activation of both D₁- and D₂-like receptors favors LTD.

**ROLES OF DA IN BEHAVIOR**

**LOCOMOTION: MODELS OF PARKINSON DISEASE (PD).** In the
early 1980s, several young people in California developed rapid-onset parkinsonism. All of the affected individuals had injected a synthetic analog of meperidine that was contaminated with MPTP. MPTP is metabolized by MAO-B to the neurotoxic MPP+. Because of the high specificity of MPP+ for the DA transporter, neuronal death is largely restricted to the substantia nigra and ventral tegmental area, resulting in a phenotype remarkably similar to Parkinson disease.

6-Hydroxydopamine (6-OHDA) is similar to MPTP in both mechanism of action and utility in animal models. Lesioning animals with MPTP or 6-OHDA results in tremor, grossly diminished locomotor activity, and rigidity. As with Parkinson disease, these motor deficits are alleviated with L-dopa therapy or dopaminergic agonists.

Other pharmacological agents are also known to alter locomotor activity via dopaminergic actions, including cocaine and amphetamine. These drugs bind to DAT and inhibit reuptake of synaptic DA.

Studies with D1 receptor knockout mice indicate that the D1 receptor, but not the D5 receptor, is primarily responsible for the increase in locomotor activity that occurs following administration of D1-family agonists. D2 receptor knockout mice display marked reductions in locomotor activity, initiation of movement, and rearing behaviors. This reduction in motor activity is also present in mice that are specifically lacking only the D2L receptor. The D3 and D4 receptor knockout animals display unique locomotor alterations in response to novel environments.

**REWARD: IMPLICATIONS IN ADDICTION.** In general, drugs of abuse cause increased DA levels in the nucleus accumbens, an area critical for rewarded behaviors. This role for mesolimbic DA in addiction has led to numerous studies on abused drugs in DA receptor knockout mice that suggest complex roles of D1, D2, and D3 receptors in addiction that are reviewed in the parent text.

**COGNITION, LEARNING, AND MEMORY.** Mice lacking the D1 receptor display deficits in multiple forms of memory. Other findings in animal models
imply an important role for the D₂ receptor in disorders with defects in sensorimotor gating, most notably schizophrenia. Indeed, many of the antipsychotic drugs used in the treatment of schizophrenia are high affinity antagonists for the D₂ receptor.

**DA RECEPTOR AGONISTS AND ANTAGONISTS**

**DA RECEPTOR AGONISTS.** DA receptor agonists are currently used in the treatment of Parkinson disease (PD), restless leg syndrome, and hyperprolactinemia.

One of the primary limitations to the therapeutic use of dopaminergic agonists is the lack of receptor subtype selectivity. Recent advances in receptor-ligand structure-function relationships have enabled the development of subtype-specific drugs, many of which have already proven to be useful experimental tools (Table 13–6). DA receptor activity can be modulated by drugs that bind to allosteric sites on the receptor, thereby enhancing or decreasing endogenous DA signaling in a receptor-specific manner.

**DA RECEPTOR AGONISTS AND PARKINSON DISEASE.** PD is characterized by extensive degeneration of dopaminergic neurons within the substantia nigra, resulting in tremor, rigidity, and bradykinesia. The principal pharmacotherapy for PD is L-dopa, but limitations to its therapeutic effects (see Chapter 22) have generated intense interest in developing alternative therapies for PD, with the intent of either delaying the usage of L-dopa or alleviating its side
effects. DA agonists can be used in conjunction with lower doses of L-dopa in a combined therapy approach. Two general classes of dopaminergic agonists are used in the treatment of PD: ergots and non-ergots. The use of these drugs in the management of PD is described in Chapter 22.

**D1/D2 RECEPTOR AGONISTS: ERGOT ALKALOIDS.** Ergot derivatives act on several different neurotransmitter systems, including DA, 5HT, and adrenergic receptors. *Bromocriptine* (PARLODEL) and pergolide (PERMAX) have been used for the treatment of PD; however, their use is associated with risk for serious cardiac complications.

Bromocriptine is a potent D2 receptor agonist and a weak D1 antagonist. Pergolide is a partial agonist of D1 receptors and a strong D2-family agonist with high affinity for both D2 and D3 receptor subtypes. Ergot derivatives are commonly reported to cause unpleasant side effects, including nausea, dizziness, and hallucinations. Pergolide was removed from the U.S. market as therapy for PD after as it was associated with an increased risk for valvular heart disease.

**ERGOT ALKALOIDS IN THE TREATMENT OF HYPERPROLACTINEMIA.** The ergot-based DA agonists bromocriptine and *cabergoline* (DOSTINEX) are used in the treatment of hyperprolactinemia. Both are strong agonists at D2 receptors, with lower affinity for D1, 5HT, and α adrenergic receptors; both activate D2 receptors in the pituitary to reduce prolactin secretion. The risk of valvular heart disease in ergot therapy is not associated with the lower doses used in treating hyperprolactinemia. The use of bromocriptine and cabergoline in the management of hyperprolactinemia is described in Chapter 38.

**D1/D2 RECEPTOR AGONISTS (NON-ERGOT ALKALOIDS).** *Apomorphine* (APOKYN) is approved for the treatment of PD. Apomorphine binds with the order of potency D4 > D2 > D3 > D5,
and with lower affinity to D₁, α adrenergic, 5HT₁₅A, and 5HT₂ receptors. Apomorphine is most commonly used in combination with L-dopa to surmount the sudden “off” periods that can occur after long-term L-dopa treatment.

*Rotigotine* is offered in a transdermal patch (*Neupro*) that is approved for the treatment of PD and restless leg syndrome (RLS). Rotigotine preferentially binds to D₂ and D₃ receptors and has much lower affinity for D₁ receptors. In addition, rotigotine is an agonist at 5HT₁₅A and 5HT₂ receptors, and an antagonist at α₂ adrenergic receptors.

**D₂ FAMILY RECEPTOR AGONISTS (NON-ERGOT ALKALOIDS).** Pramipexole (*MiraPex*) and ropinirole (*Requip*) are agonists at all D₂ family receptors and also bind with highest affinity to the D₃ receptor subtype. In addition to its utility in the treatment of PD, ropinirole has also been FDA-approved as pharmacotherapy for RLS. Mild dopaminergic hypofunction has been noted in patients with RLS.

**D₄ RECEPTOR AGONISTS AND ADHD.** The D₄ receptor is significant in ADHD; there is an association between the 7-repeat D₄ VNTR variant and patients with ADHD. D₄-selective agonists show significant promise for the next generation of ADHD therapy.

**DA RECEPTOR ANTAGONISTS**

As with the DA receptor agonists, a lack of subtype-specific antagonists has limited the therapeutic utility of this group of ligands. Selective antagonists are now available as experimental tools (see Table 13–6). Many subtype-selective antagonists are in early stages of preclinical testing for therapeutic utility.

**DA RECEPTOR ANTAGONISTS AND SCHIZOPHRENIA.** DA receptor antagonists are a mainstay in the pharmacotherapy of schizophrenia. While many neurotransmitter systems likely contribute to the complex pathology of
schizophrenia (see Chapter 16), DA dysfunction is considered the basis of this disorder. The DA hypothesis of schizophrenia has its origins in the characteristics of the drugs used to treat this disorder: All antipsychotic compounds used clinically have high affinity for DA receptors. The drugs used to treat schizophrenia are classified as either typical (first generation) antipsychotics or atypical antipsychotics (characterized by lack of extrapyramidal side effects). Most atypical antipsychotics are low affinity antagonists at the D₂ receptor and high affinity antagonists or inverse agonists at the 5HT₂A receptor. Some of the newer drugs in development do not fit into this classification scheme, including the D₁-selective agonist, dihydrexidine.

ANTIPSYCHOTIC AGENTS

Typical Antipsychotics. The first antipsychotic drug used to treat schizophrenia was chlorpromazine (Thorazine). Its antipsychotic properties were attributed to its antagonism of DA receptors, especially the D₂ receptor. More D₂-selective ligands were developed to improve the antipsychotic properties, including haloperidol (Haldol) and similar D₂-selective drugs (see Chapter 16).

Atypical Antipsychotics. This class of antipsychotic drugs originated with clozapine (Fazaclo). The lack of extrapyramidal side effects has been attributed to a much lower affinity for the D₂ receptor compared to the typical antipsychotics. Atypical agents are also less likely to stimulate prolactin production. Clozapine has higher affinity for the D₄ receptor. Most atypical antipsychotics are low affinity antagonists at the D₂ receptor and high affinity antagonists or inverse agonists at the 5HT₂A receptor.

Aripiprazole (Abilify) has fewer side effects than earlier atypical antipsychotics. Aripiprazole diverges from the traditional atypical profile in 2 ways: first, it has higher affinity for D₂ receptors than for 5HT₂A receptors; second, it is a partial agonist at D₂ receptors. As a partial agonist, aripiprazole may diminish the subcortical DA hyperfunction by competing with DA for receptor binding, while simultaneously enhancing dopaminergic neurotransmission in the prefrontal cortex by acting as an agonist. The dual mechanism afforded by a partial agonist may thus treat both the positive and negative symptoms associated with schizophrenia.

D₃ RECEPTOR ANTAGONISTS AND DRUG ADDICTION. D₃-selective
antagonists show promise in the treatment of addiction.
Neurotransmission and the Central Nervous System

ORGANIZATIONAL PRINCIPLES OF THE CNS

The brain is a complex assembly of interacting neurons and nuclei that regulate their own and each other’s activities in a dynamic fashion, generally through chemical neurotransmission. It is useful to examine the major anatomical regions of the CNS and their associations with specific neurotransmitter systems and the effect of pharmacological agents thereon.

CELLULAR ORGANIZATION OF THE BRAIN

Neurons. Neurons are classified according to function (sensory, motor, or interneuron), location, the identity of the transmitter they synthesize and release or the class or classes of receptor expressed on the cell surface. Neurons exhibit the cytological characteristics of highly active secretory cells with large nuclei: large amounts of smooth and rough endoplasmic reticulum; and frequent clusters of specialized smooth endoplasmic reticulum (Golgi complex), in which secretory products of the cell are packaged into membrane-bound organelles for transport from the perikaryon to the axon or dendrites. The sites of interneuronal communication in the CNS are termed synapses. Like peripheral “junctions,” central synapses are denoted by accumulations of tiny (50-150 nm) synaptic vesicles. The proteins of these vesicles have specific roles in transmitter storage, vesicle docking, and secretion and re-storage of transmitter.

Support Cells. Neurons in the CNS are outnumbered by support cells, including macroglia, microglia, vascular elements, the cerebrospinal fluid (CSF)-forming cells of the choroid plexus found within the intracerebral ventricular system, and the meninges, which cover the surface of the brain and comprise the CSF-containing envelope. Macroglia are the most abundant support cells; some are categorized as astrocytes (cells interposed between the vasculature and the neurons, often surrounding individual compartments of synaptic complexes). Astrocytes play a variety of metabolic support roles including furnishing energy intermediates and supplementary removal of neurotransmitters following release.
The oligodendroglia, a second prominent category of macroglia, are myelin-producing cells. Myelin, made up of multiple layers of compacted membranes, insulate segments of axons bioelectrically and permit nondecremental propagation of action potentials. Microglia are derived from mesoderm and are related to the macrophage/monocyte lineage. Some microglia reside within the brain, while additional cells of this class may be recruited to the brain during periods of inflammation following either microbial infection or brain injury.

**BLOOD-BRAIN BARRIER.** The blood-brain barrier (BBB) is an important boundary between the periphery and the CNS that forms a permeability barrier to the passive diffusion of substances from the bloodstream into the CNS. The BBB diminishes the rate of access of many chemicals from plasma to the brain and is the localization of several drug export systems in the cells that constitute the BBB (see Chapter 5). An exception exists for lipophilic molecules, which diffuse fairly freely across the BBB and accumulate in the brain.

This barrier, nonexistent in the peripheral nervous system, is much less prominent in the hypothalamus and in several small, specialized organs (the circumventricular organs) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ.

Selective barriers to permeation into and out of the brain also exist for small, charged molecules such as neurotransmitters, their precursors and metabolites, and some drugs. These diffusional barriers are viewed as a combination of the partition of solute across the vasculature (which governs passage by definable properties such as molecular weight, charge, and lipophilicity) and the presence or absence of energy-dependent transport systems (see Chapter 5). Important exceptions are the specific uptake transporters for amino acids, one of which contributes to the therapeutic utility of L-dopa in the treatment of Parkinson disease.

The brain clears metabolites of transmitters into the fluid-containing lateral ventricles by excretion via the acid transport system of the choroid plexus. Substances that rarely gain access to the brain from the bloodstream often can reach the brain when injected directly into the cerebrospinal fluid. Under certain
conditions, it may be possible to open the BBB, at least transiently, to permit the entry of chemotherapeutic agents. Cerebral ischemia and inflammation also modify the BBB, increasing access to substances that ordinarily would not affect the brain.

**CHEMICAL COMMUNICATION IN THE CNS**

A central concept of neuropsychopharmacology is that drugs that influence behavior and improve the functional status of patients with neurological or psychiatric diseases act by enhancing or blunting the effectiveness of specific transmitters and channels.

Identified targets for centrally acting drugs include ion channels that mediate change in excitability induced by neurotransmitters, neurotransmitter receptors, and transport proteins that reaccumulate released transmitter. The transport proteins include those selective for NE, dopamine, and serotonin (NET, DAT, and SERT) that accumulate released transmitter and those that package it for reuse (e.g., VMAT2). Inhibition of reuptake increases the concentration and dwell time of transmitter in the synaptic space (e.g., as do serotonin selective reuptake inhibitors and cocaine). Inhibition of vesicular storage leads to depletion of releasable neurotransmitter (e.g., inhibition of VMAT2 and NE storage by reserpine).

An understanding at the systems level is required to assemble the structural and functional properties of specific central transmitter systems, linking the neurons that make and release a given neurotransmitter to its behavioral effects. The entire concept of animal models of human psychiatric diseases rests on the assumption that scientists can appropriately infer from observations of behavior and physiology (heart rate, respiration, locomotion, etc.) that the states experienced by animals are equivalent to the emotional states experienced by human beings expressing similar physiological changes.

**IDENTIFICATION OF CENTRAL TRANSMITTERS.** The criteria for identification of central transmitters require the same data set used to establish the transmitters of the autonomic nervous system (see Chapter 8):

- *The transmitter must be shown to be present in the presynaptic terminals of the synapse and in the neurons from which those presynaptic terminals...*
arise.

• The transmitter must be released from the presynaptic nerve concomitantly with presynaptic nerve activity.
• When applied experimentally to target cells, the effects of the putative transmitter must be identical to the effects of stimulating the presynaptic pathway.
• Specific pharmacological agonists and antagonists should mimic and antagonize, respectively, the measured functions of the putative transmitter with appropriate affinities and order of potency.

Many brain and spinal cord terminals contain more than 1 transmitter substance. Coexisting substances (presumed to be released together) may either act jointly on the postsynaptic membrane, or may act presynaptically to affect release of transmitter from the presynaptic terminal. Clearly, if more than 1 substance transmits information, no single agonist or antagonist would be expected to faithfully mimic or fully antagonize activation of a given presynaptic element. Co-storage and co-release of ATP and NE are an example. In addition to being released as a cotransmitter with other biogenic amines, ATP and adenosine have been shown to mediate diverse effects through interactions with purinergic receptors.

MANY NEUROTRANSMITTERS AND DRUGS ACT ON IDENTIFIED NEURONAL MACROMOLECULES

A number of molecular mechanisms link receptor occupancy to biological responses (see Chapter 3). The most commonly seen post-receptor events are changes in ion flux through channels formed by a multi-subunit receptor complex and the alteration of intracellular signaling via transmembrane receptor systems.

ION CHANNELS. The electrical excitability of neurons is achieved through modification of ion channels in neuronal plasma membranes. Na⁺, K⁺, and Ca²⁺, as well as Cl⁻ anions, are regulated in their flow through highly discriminative ion channels. These channels are grouped structurally and termed voltage-dependent channels (Figure 14–1), and Cl⁻ channels (Figure 14–2). Ligand-gated ion channels,
regulated by the binding of neurotransmitters, form another distinct group of ion channels; a prominent example is the nicotinic acetylcholine receptor, a Na\(^+\) channel when activated (see Figures 11–1 and 11–2).

Figure 14–1 Structural similarities of voltage-dependent Na\(^+\), Ca\(^{2+}\), and K\(^+\) channels. A. The subunit in both Ca\(^{2+}\) and Na\(^+\) channels contains 4 subunits, each with 6 transmembrane hydrophobic domains. The hydrophobic regions that connect segments 5 and 6 in each domain form the pore of the channel. Segment 4 in each domain includes the voltage-sensor. (Adapted with permission from Catterall W. Neuron, 2000;26:13–25. © Elsevier.) B. The Ca\(^{2+}\) channel also
requires several auxiliary small proteins ($\alpha_2$, $\beta$, $\gamma$, and $\delta$); $\alpha_2$ and $\delta$ subunits are linked by a disulfide bond. Regulatory subunits also exist for Na$^+$ channels. C. Voltage-sensitive K$^+$ channels (K$_v$) and the rapidly activating K$^+$ channel (K$_A$) share a similar putative hexaspanning structure resembling in overall configuration 1 repeat unit within the Na$^+$ and Ca$^{2+}$ channel structure; the inwardly rectifying K$^+$ channel protein (K$_{ir}$) retains the general configuration of just loops 5 and 6. Regulatory t subunits (cytosolic) can alter K$_v$ channel functions. Voltage-dependent channels provide for rapid changes in ion permeability along axons and within dendrites and for excitation-secretion coupling that releases neurotransmitters from presynaptic sites. The transmembrane Na$^+$ gradient ($\sim$140 mM outside vs. $\sim$14 mM inside the cell) means that increases in permeability to Na$^+$ causes depolarization. In contrast, the K$^+$ gradient ($\sim$4 mM outside the cell vs. $\sim$120 mM inside) is such that increased permeability to K$^+$ results in hyperpolarization. Changes in the concentration of intracellular Ca$^{2+}$ (extracellular free Ca$^{2+}$: 1.25 mM; intracellular Ca$^{2+}$: resting $\sim$100 nM, rising to $\sim$1 $\mu$M when Ca$^{2+}$ entry is stimulated) affects multiple processes in the cell and are critical in the release of neurotransmitters.

![Figure 14–2 Three families of Cl– channel](image)

Figure 14–2 Three families of Cl– channel. Due to the Cl– gradient across the plasma membrane ($\sim$116 mM outside vs. 20 mM inside the cell), activation of Cl– channels causes an inhibitory postsynaptic potential (IPSP) that dampens neuronal excitability; inactivation of these channels can lead to hyperexcitability. There are 3 distinct types of Cl– channel:

- **Ligand-gated channels** are linked to inhibitory transmitters including GABA and glycine.
- **CLC channels**, of which 9 subtypes have been cloned, affect Cl-flux, membrane potential, and the pH of intracellular vesicles.
- **Cystic fibrosis transmembrane conductance regulated (CFTR) channels** bind ATP and are regulated by phosphorylation of serine residues.
Two other families of channels regulate ion fluxes: cyclic nucleotide–gated (CNG) channels, and transient receptor potential (TRP) channels. CNG channels consist of 2 groups:

- The CNG channels, which play important roles in sensory transduction for olfactory and photoreceptors
- The hyperpolarization-activated, cyclic nucleotide–gated (HCN) channels

HCN channels are cation channels that open with hyperpolarization and close with depolarization; upon direct binding of cyclic AMP or cyclic GMP, the activation curves for the channels are shifted to more hyperpolarized potentials. These channels play essential roles in cardiac pacemaker cells and presumably in rhythmically discharging neurons.

TRP channels are a family of hexaspanning receptors containing a cation-permeable pore. TRP channels respond to multiple stimuli and function in sensory physiology, including thermosensation, osmosensation, and taste. Members of the IRPV subfamily (vanilloid receptors) interact with ligands such as the endogenous cannabinoid anandamide and capsaicin, a “hot” or “irritant” component of chili peppers.

TRANSMEMBRANE RECEPTOR SYSTEMS. A variety of membrane receptors interact with neurotransmitters and neurohormones. These systems have been described in detail in Chapter 3.

CELL SIGNALING AND SYNAPTIC TRANSMISSION. Most cell-to-cell communication in the CNS involves chemical transmission that requires a series specializations for transmitter synthesis, storage, release, recognition, and termination of action (Figure 14–3; see also Figures 8–2, 8–3, and 8–5). In addition to primary neurotransmitters
(usually vesicular), there are neurohormones neuromodulators, and neurotrophic factors that influence CNS function:

Figure 14–3 Transmitter release, action, and inactivation. Depolarization opens voltage-dependent Ca\(^{2+}\) channels in the presynaptic nerve terminal. (1) The influx of Ca\(^{2+}\) during an action potential (AP) triggers (2) the exocytosis of small synaptic vesicles that store neurotransmitter (NT) involved in fast neurotransmission. Released neurotransmitter interacts with receptors in the postsynaptic membranes that either couple directly with ion channels (3) or act through second messengers, such as (4) GPCRs. Neurotransmitter receptors in the presynaptic nerve terminal membrane (5) can inhibit or enhance subsequent exocytosis. Released neurotransmitter is inactivated by reuptake into the nerve terminal by (6) a transport protein coupled to the Na\(^{+}\) gradient (e.g., for DA, NE, and GABA), or by (7) degradation (ACh, peptides), or by (8) uptake and metabolism by glial cells (Glu). The synaptic vesicle membrane is recycled by
(9) clathrin-mediated endocytosis. Neuropeptides and proteins are stored in (10) larger, dense core granules within the nerve terminal. These dense core granules are released from (11) sites distinct from active zones after repetitive stimulation.

**NEUROHORMONES.** The anterior and posterior pituitary secrete a variety of hormones and releasing factors. Hypothalamic neurons affecting the anterior pituitary release their hormones into the hypothalamic–adenohypophyseal portal blood system, which delivers them to the anterior pituitary, where they regulate the release of trophic hormones (i.e., ACTH, FSH, GH, LH, prolactin) into the blood. Other hypothalamic neurons project onto the posterior pituitary, where they release their peptide contents, oxytocin and arginine vasopressin (antidiuretic hormone) into the systemic circulation (see Chapters 25 and 38 and Figure 38–1).

**NEUROMODULATORS.** The distinctive feature of a modulator is that it originates from nonsynaptic sites, yet influences the excitability of nerve cells. Substances such as CO and ammonia, arising from active neurons or glia, are potential modulators acting through non-synaptic actions. Similarly, circulating steroid hormones, steroids produced in the nervous system (i.e., neurosteroids), locally released adenosine, and other purines, eicosanoids, and nitric oxide (NO) are regarded as modulators and/or neurotransmitters.

**NEUROTROPHIC FACTORS.** Neurotrophic factors are substances produced within the CNS by neurons, astrocytes, microglia, or inflammatory or immune cells that assist neurons in their attempts to repair damage. Seven categories of neurotrophic peptides are recognized:

- *Classic neurotrophins* (nerve growth factor, brain-derived neurotrophic factor, and the related neurotrophins)
- *Neuropoietic factors*, (e.g., cholinergic differentiation factor [also called leukemia inhibitory factor], ciliary neurotrophic factor, and some interleukins)
- Growth factor peptides, such as epidermal growth factor, transforming growth factors GG and A, glial cell–derived neurotrophic factor, and activin A
- Fibroblast growth factors
- Insulin-like growth factors
• Platelet-derived growth factors
• Axon guidance molecules, some of which also affect cells of the immune system

CENTRAL NEUROTRANSMITTERS

Neurotransmitters can be discussed by chemical categories: amino acids, amines, and neuropeptides. Other substances that may participate in central synaptic transmission include purines (such as adenosine and ATP), NO, and arachidonic acid derivatives.

AMINO ACIDS. The CNS contains uniquely high concentrations of certain amino acids, notably glutamate and β-aminobutyric acid (GABA) that potently alter neuronal firing. They are ubiquitously distributed within the brain and they produce prompt, powerful, and readily reversible but redundant effects on neurons. The dicarboxylic amino acids (e.g., glutamate and aspartate) produce excitation, while the monocarboxylic amino acids (e.g., GABA, glycine, -alanine, and taurine) cause inhibition. Following the emergence of selective antagonists, identification of selective receptors and receptor subtypes became possible. Figure 14–4 shows these amino acid transmitters and their drug congeners.
GABA. GABA receptors have been divided into 3 main types:
- The **GABA<sub>A</sub> receptor** (the most prominent GABA receptor subtype), a ligand-gated Cl-ion channel, or *ionotropic receptor*
- The **GABA<sub>B</sub> receptor**, a GPCR, or metabotropic receptor
- The **GABA<sub>C</sub> receptor**, a transmitter-gated Cl-channel

GABA<sub>A</sub> receptor has been extensively characterized as the site of action of many neuroactive drugs, notably benzodiazepines, barbiturates, ethanol,
anesthetic steroids, and volatile anesthetics (Figure 14–5). The GABA_A receptor is probably pentameric or tetrameric in structure, with subunits that assemble around a central pore. The major form of the GABA_A receptor contains at least 3 different subunits α, β, and γ, with likely stoichiometry of 2α, 2β, 1γ. All 3 subunits are required to interact with benzodiazepines with the profile expected of a native GABA_A receptor.

The GABA_B or metabotropic GABA receptors interact with G_i to inhibit adenylyl cyclase, activate K+ channels, and reduce Ca^{2+} conductance and with G_q to enhance PLC activity. Presynaptic GABA_B receptors function as autoreceptors, inhibiting GABA release, and may play the same role on neurons releasing other transmitters. The GABA_C receptor is less widely distributed than the A and B subtypes. GABA is more potent by an order of magnitude at GABA_C than at GABA_A receptors, and a number of GABA_B agonists (e.g., baclofen) and modulators (e.g., benzodiazepines and barbiturates) do not interact with GABA_C receptors. GABA_C receptors are found in the retina, spinal cord, superior colliculus, and pituitary.

GABA mediates the inhibitory actions of local interneurons in the brain and may also mediate presynaptic inhibition within the spinal cord. GABA-containing
neurons frequently coexpress 1 or more neuropeptides.

The most useful compounds for confirmation of GABA-mediated effects have been bicuculline and picrotoxin; however, many convulsants whose actions previously were unexplained (including penicillin and pentylentetrazol) are relatively selective antagonists of the action of GABA. Useful therapeutic effects have not yet been obtained through the use of agents that mimic GABA (such as muscimol), inhibit its active reuptake (such as 2,4-diaminobutyrate, nipecotic acid, and guvacine), or alter its turnover (such as aminooxyacetic acid).

**GLYCINE.** Many of the features described for the GABA<sub>A</sub> receptor family also apply to the inhibitory glycine receptor, which is prominent in the brainstem and spinal cord. Multiple subunits assemble into a variety of glycine receptor subtypes, the complete functional significance of which is not known.

**GLUTAMATE AND ASPARTATE.** Glutamate and aspartate have powerful excitatory effects on neurons in virtually every region of the CNS. Glutamate receptors are classed functionally either as ligand-gated ion channel (ionotropic) receptors or as metabotropic GPCRs (Table 14–1). The ligand-gated ion channels are further classified into N-methyl-D-aspartate (NMDA) receptors and non-NMDA receptors. The non-NMDA receptors include the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainic acid (KA) receptors.

NMDA receptor agonists include open-channel blockers such as phencyclidine (PCP or “angel dust”); antagonists include 5,7-dichlorokynurenic acid, which acts at an allosteric glycine-binding site, and ifenprodil, which may act as a closed-channel blocker. The activity of NMDA receptors is sensitive to pH and to modulation by a variety of endogenous agents including Zn$^{2+}$, some neurosteroids, arachidonic acid, redox reagents, and polyamines such as spermine. NMDA receptors are involved in normal synaptic transmission; activation of NMDA receptors is associated more closely with the induction of various forms of synaptic plasticity rather than with fast point-to-point signaling in the brain.
AMPA and kainate receptors mediate fast depolarization at glutamatergic synapses in the brain and spinal cord. AMPA or kainate receptors and NMDA receptors may be colocalized at many glutamatergic synapses. A well-characterized phenomenon involving NMDA receptors is the induction of long-term potentiation (LTP) and its converse, long-term depression (LTD) (Figure 14–6).

**Figure 14–6** *NMDA receptor-dependent LTP and LTD.* LTP refers to a prolonged (hours to days) increase in the size of a postsynaptic response to a presynaptic stimulus of given strength. Activation of NMDA receptors is obligatory for the induction of LTP that occurs in the hippocampus. NMDA receptors normally are blocked by Mg²⁺ at resting membrane potentials. Thus, activation of NMDA receptors requires glutamate binding and the simultaneous depolarization of the postsynaptic membrane. This is achieved by activation of AMPA/kainate receptors at nearby synapses involving inputs from different neurons. AMPA receptors also are dynamically regulated to affect their sensitivity to the synergism with NMDA. Thus, NMDA receptors may function as coincidence detectors, being activated only when there is simultaneous firing of 2 or more neurons. LTD is the converse of LTP. **A.** NMDA receptor-dependent LTP requires post synaptic NMDA receptor activation leading to a rise in Ca²⁺ and
activation of CaM kinase II (CaMKII). AMPA receptor insertion into the postsynaptic membrane is a major mechanism underlying LTP expression. B. NMDA receptor-dependent LTD is triggered by Ca$^{2+}$ entry through postsynaptic NMDA receptor channels, leading to increases in the activity of the protein phosphatases calcineurin and PP1. LTD occurs when postsynaptic AMPA receptors are internalized. (Redrawn with permission from Nestler EJ, Hyman SE, Malenka RC, eds. Molecular Neuropharmacology. New York: McGraw-Hill, 2009, p 132. © 2009 by The McGraw-Hill Companies, Inc.)

**GLUTAMATE EXCITOTOXICITY.** High concentrations of glutamate lead to neuronal cell death (Figure 14–7). The cascade of events leading to neuronal death is thought to be triggered by excessive activation of NMDA or AMPA/kainate receptors, allowing significant influx of Ca$^{2+}$ into neurons. Glutamate-mediated excitotoxicity may underlie the damage that occurs after ischemia or hypoglycemia in the brain, during which a massive release and impaired reuptake of glutamate in the synapse leads to excess stimulation of glutamate receptors and subsequent cell death. NMDA receptor antagonists can attenuate neuronal cell death induced by activation of these receptors.
Mechanisms contributing to neuronal injury during ischemia-reperfusion-induced glutamate release. Several pathways contribute to excitotoxic neuronal injury in ischemia, with excess cytosolic Ca\(^{2+}\) playing a precipitating role. DAG, diacylglycerol; GluR, AMPA/kainate type of glutamate receptors; IP\(_3\), inositol trisphosphate; mGluR, metabotropic glutamate receptor; NMDA-R, N—methyl-D-aspartate receptor; O\(_2^-\), superoxide radical; PIP\(_2\), phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PL, phospholipids, PLA\(_2\)/C phospholipases, VSCC, voltage-sensitive Ca\(^{2+}\) channel. COX, cyclooxygenase; LOX, lipoxygenase; NCX, Na\(^+\)/Ca\(^{2+}\) exchanger; mtPTP, mitochondrial permeability transition pore. (Reproduced with permission from Dugan LL, Kim-Han JS: Hypoxic-ischemic brain injury and oxidative stress, in Siegel GS, Albers RW, Brady S, Price D, eds. ACETYLCHOLINE. The effects of ACh result from interaction with
a mixture of nicotinic and muscarinic receptors. Nicotinic ACh receptors (see Figures 11–1 and 11–2) are found in autonomic ganglia, the adrenal gland, and in the CNS. Their activation by ACh results in a rapid increase in the influx of Na\(^+\), depolarization, and the activation of voltage-sensitive Ca\(^{2+}\) influx. There are 5 subtypes of muscarinic receptors, all of which are expressed in the brain. M\(_1\), M\(_3\), and M\(_5\) couple to G\(_q\) while the M\(_2\) and M\(_4\) receptors couple to G\(_i\) (Table 14–2).

**CATECHOLAMINES.** The brain contains separate neuronal systems that use 3 different catecholamines—dopamine (DA), NE, and epinephrine (EPI). Each system is anatomically distinct and serves separate, functional roles within its field of innervation.

**DOPAMINE.** More than half the CNS content of catecholamine is DA. The 5 receptors for DA are GPCRs that regulate adenylyl cyclase activity via coupling to G\(_s\) (D\(_1\) and D\(_5\)) and G\(_i\) (D\(_2-4\)) (Table 14–3). DA-containing pathways and receptors have been implicated in the pathophysiology of schizophrenia and Parkinson disease and in the side effects seen following pharmacotherapy of these disorders (see Chapters 16 and 22).

**Table 14–3**
Dopamine Receptors in the CNS

Large amounts of DA are found in the basal ganglia. There are 3 major DA-containing pathways in the CNS: the nigrostriatal, the mesocortical/mesolimbic, and the tuberoinfundibular, as described in Chapter 13 and depicted in Figure 13–7.

**NOREPINEPHRINE.** Both B and adrenergic receptors subtypes are present in the CNS; all are GPCRs (Table 14–4; see also Chapter 8).

Table 14–4

Adrenergic Receptors in the CNS
β receptors couple to Gs and thence to adenylyl cyclase. α1 Adrenergic receptors are coupled to Gq, resulting in stimulation of the PLC-IP3/DAG-Ca2+-PKC pathway, and are associated predominantly with neurons. d1 Receptors on noradrenergic target neurons respond to NE with depolarizing responses because of decreases in K+ conductance. α2 Adrenergic receptors are found on glial and vascular elements, as well as on neurons. They are prominent on noradrenergic neurons, where they presumably couple to Gi, inhibit adenylyl cyclase, and mediate a hyperpolarizing response due to enhancement of an inwardly rectifying K+ channel (via heterodimer). e2 Receptors are located presynaptically where they function as inhibitory autoreceptors. The antihypertensive effects of clonidine may result from stimulation of such autoreceptors.

There are relatively large amounts of NE within the hypothalamus and in certain parts of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the hippocampus. NE also is present in significant amounts in most brain regions. Mapping studies indicate that noradrenergic neurons of the locus ceruleus innervate specific target cells in a large number of cortical, subcortical, and spinomedullary fields.
**EPINEPHRINE.** EPI-containing neurons are found in the medullary reticular formation. Their physiological properties have not been identified.

**5-HYDROXYTRYPTAMINE (SEROTONIN; 5HT).** There are 5 types of 5HT receptors, with 14 distinct subtypes (*Table 14–5*). These subtypes exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, exhibit subtype-specific distributions within the CNS, and mediate distinct behavioral effects of 5HT. All 5HT receptors are GPCRs coupling to a variety of G-protein subunits *except* the 5HT₃ receptor, which is a ligand-gated ion channel. The localizations and properties of 5HT receptors are summarized in *Table 13–1*, their physiological roles in various CNS activities in *Table 13–2*, the electrophysiological events associated with receptor activation in *Table 13–4*, and aspects of their clinical pharmacology in *Table 13–5*.

---

**Table 14–5**

5HT Receptors in the CNS
In mammalian CNS, neurons containing 5HT are found in 9 nuclei lying in or adjacent to the midline (raphe) regions of the pons and upper brainstem. Cells receiving cytochemically demonstrable 5HT input, such as the suprachiasmatic nucleus, ventrolateral geniculate body, amygdala, and hippocampus, exhibit a uniform and dense investment of serotonergic terminals.

**HISTAMINE.** Four subtypes of histamine receptors have been described; all are GPCRs coupling to regulate adenylyl cyclase and PLC as described in Figure 14–8. \(H_1\) receptors, the most prominent, are located on glia and vessels as well as on neurons. \(H_3\) receptors,
which have the greatest sensitivity to histamine, are localized primarily in basal ganglia and olfactory regions in rat brain. *H₄* receptors are expressed on cells of hematopoietic origin: eosinophils, T cells, mast cells, basophils, and dendritic cells. H₄ receptors are postulated to play a role in inflammation and chemotaxis. For details, consult Chapter 32.

**Figure 14–8** *Main signaling pathways for histamine receptors.* Histamine can couple to a variety of G protein-linked signal transduction pathways via 4 different receptors. The H₁ receptor and some H₄ receptors activate phosphatidylinositol turnover via G₉/₁₁. The other receptors couple either positively (H₂ receptor) or negatively (H₃ and H₄ receptor) to adenylyl cyclase activity via G₅ and Gᵢ/ₒ.

Histaminergic neurons are located in the ventral posterior hypothalamus; they give rise to long ascending and descending tracts that are typical of the patterns characteristic of other aminergic systems. The histaminergic system is thought to affect arousal, body temperature, and vascular dynamics.

**PEPTIDES.** A remarkable array of neurotransmitters and neuromodulators have been described (Table 14–6). While some CNS peptides (see Table 14–6) may function on their own, most are now thought to act primarily in concert with coexisting transmitters
(biogenic amines and amino acids), but their release can be independently regulated (see Figure 14–3). Many neuropeptides act via GPCRs (Table 14–7).

### Table 14–7

**Peptide Transmitters and Receptors**
Peptide synthesis takes place primarily in perikarya and the resulting peptide is then transported to nerve terminals. Single genes can, through posttranslational modifications, give rise to multiple neuropeptides. For example, proteolytic processing of proopiomelanocortin (POMC) gives rise to ACTH, α-, γ-, and β-MSH, and β-endorphin (Figure 14–9). In addition, alternative splicing of RNA transcripts may result in distinct mRNA species (e.g., calcitonin and calcitonin gene-related peptide [CGRP]).
Figure 14–9 **Proteolytic processing of proopiomelanocortin (POMC).** After removal of the signal peptide from pre-POMC, the remaining propeptide undergoes endoproteolysis by prohormone convertases 1 and 2 (PC1 and PC2) at dibasic residues. PC1 liberates the bioactive peptides adrenocorticotropic hormone (ACTH), t-endorphin (β end), and γ-lipotrophic hormone (γ-LPH). PC2 cleaves ACTH into corticotrophin-like intermediate lobe peptide (CLIP) and c-melanocyte stimulating hormone (α-MSH) and also releases γ-MSH from the N-terminal portion of the propeptide. The joining peptide (JP) is the region between ACTH and γ-MSH. β-MSH is formed by cleavage of γ-LPH. Some of the resulting peptides are amidated or acetylated before they become fully active.

**Cannabinoids.** Delta-9-tetrahydrocannabinol (THC) is 1 of several active substances in marijuana (Figure 14–10). The primary
pharmacologic effects of THC follow its interaction with \textit{CB}_1\textit{receptors} in the CNS and \textit{CB}_2\textit{receptors} in the periphery. Both \textit{CB}_1 and \textit{CB}_2 receptors are linked to \textit{G}_i and thence to inhibition of adenylyl cyclase activity. The natural endogenous ligands for these receptors are arachidonic acid derivatives including \textit{anandamide} and \textit{2-arachidonoyl glycerol} (see Figure 14–10).

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{cannabinoid_receptor_ligands.png}
\caption{Cannabinoid receptor ligands. Anandamide and 2-arachidonoyl glycerol are endogenous agonists. Rimonabrant is a synthetic \textit{CB} receptor antagonist. \textit{\@del}_9\text{-tetrahydrocannabinol} is a \textit{CB} agonist derived from marijuana.}
\end{figure}

THC has dramatic short-term effects, including causing feelings of euphoria and altered sensory perception. \textit{CB}_1 receptors are found primarily in the basal ganglia, hippocampus, cerebellum, and cerebral cortex; activation of \textit{CB}_1 receptors results in inhibition of glutamate release. Some nonneuronal cells and tissues also express \textit{CB}_1 receptors, including leukocytes and testis. \textit{CB}_2 receptors are expressed in the spleen, tonsils, bone marrow, and on peripheral blood leukocytes.

Efforts to develop \textit{CB}_1 antagonists like rimonabrant (see Figure 14–10) have focused on possible treatments for drug addiction and obesity. Efforts are also
underway to develop agonists that interact with CB₁ and CB₂ receptors for the relief of pain. THC (dronabinol [MARINOL]) is sometimes used in the control of nausea and moderate pain (see Chapter 46).

**PURINES.** Adenosine, ATP, UDP, and UTP have roles as extracellular signaling molecules. ATP is a component of the adrenergic storage vesicles and is released along with catecholamines. Intracellular nucleotides may also reach the cell surface by other means, and extracellular adenosine can result from cellular release and metabolism of ATP.

Extracellular nucleotides and adenosine act on a family of purinergic receptors that is divided into 2 classes, P1 and P2 (Table 14–8). P1 receptors are GPCRs that interact with adenosine; 2 of these receptors (A₁ and A₃) couple to Gᵢ and 2 (A₂ₐ and A₂₆) couple to Gₛ; methylxanthines antagonize A₁ and A₃ receptors. Activation of A₁ receptors is associated with inhibition of adenylyl cyclase, activation of K⁺ currents, and in some instances, with activation of PLC; stimulation of A₂ receptors activates adenylyl cyclase. The P2 class includes a large number of P₂X receptors that are ligand-gated ion channels and the P₂Y receptors, a large subclass of GPCRs that couple to Gᵢ or Gₛ. The P₂Y₁₄ receptor is expressed in the CNS; it interacts with UDP-glucose and may couple to Gᵢ. The P₂Y₁₂ receptor is important clinically: inhibition of this receptor in platelets inhibits platelet aggregation.

*P₂Y₁₂, binds UDP-glucose, UDP-glucuronic, and/or UDP-acetylgalactosamine.*

*NECA is a non-selective agonist of P₂₁ receptor.*

*CP, N6-cyclopentyladenosine; Cnk, 5′-cyclopentyl-3′-deoxyadenosine; 1B-MECA, 1-(1-aminoethyl)adenosine-N-methylcarbamoyl; NECA, 1-(6-amino-3-hydroxy-9H-purin-2-yl)-5-hydroxy-N-ethyl-3H-1H-pyrazolo[3,4-b]-pyridazin-4-one; PPADS, Pyridoxalphosphate-6-azophenyl-2′,4′-disulfonic acid; TNP-ATP, 7-0-(2,3-dideoxy-β-D-mannopyranosyluridylyl)adenosine 5′-triphosphate.*
Although many of these receptors have been detected in brain, most of the current interest stems from pharmacological rather than physiological observations. Adenosine can act presynaptically throughout the cortex and hippocampal formation to inhibit the release of amine and amino acid transmitters. ATP-regulated responses have been linked pharmacologically to a variety of pathophysiological functions, including anxiety, stroke, and epilepsy. A<sub>2</sub> receptors and dopamine D<sub>2</sub> receptors appear to be functionally antagonistic, leading to investigation of A<sub>2a</sub> antagonists as adjunctive therapy for Parkinson disease.

**LIPID MEDIATORS.** *Arachidonic acid,* normally stored within the cell membrane as a glycerol ester, can be liberated during phospholipid hydrolysis (by pathways involving phospholipases A<sub>2</sub>, C, and D). Arachidonic acid can be converted to highly reactive regulators by 3 major enzymatic pathways (see Chapter 33): **cyclooxygenases** (leading to prostaglandins and thromboxane), **lipoxygenases** (leading to the leukotrienes and other transient catabolites of eicosatetraenoic acid), and **CYPs** (which are inducible and also expressed at low levels in brain). Arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, possibly involved with the formation of LTP and other forms of neuronal plasticity.

**NITRIC OXIDE (NO) AND CARBON MONOXIDE (CO).** Both constitutive and inducible forms of NOS are expressed in the brain. The application of inhibitors of NOS (e.g., methylarginine) and of NO donors (such as nitroprusside) suggests the involvement of NO in a host of CNS phenomena, including LTP, activation of soluble guanylyl cyclase, neurotransmitter release, and enhancement of glutamate (NMDA)-mediated neurotoxicity. CO, generated in neurons, is another diffusible gas that may act as intracellular messenger stimulating soluble guanylyl cyclase.

**CYTOKINES.** Cytokines are a family of polypeptide regulators. The effects of cytokines are regulated by the conditions imposed by other cytokines, interacting as a network with variable effects leading to synergistic, additive, or opposing actions. Tissue-produced peptides, termed *chemokines,* serve to attract immune and inflammatory cells into interstitial spaces. These special cytokines have received attention as potential regulators of nervous system inflammation (as in early stages of dementia, following infection with human immunodeficiency
virus, and during recovery from traumatic injury). Neurons and astrocytes may be induced under some pathophysiological conditions to express cytokines or other growth factors.

**ACTIONS OF DRUGS IN THE CNS**

**SPECIFICITY AND NONSPECIFICITY OF CNS DRUG ACTIONS.** The effect of a drug in the CNS is termed specific when it affects an identifiable molecular mechanism unique to target cells that bear receptors for that drug. Even a drug that is highly specific when tested at low concentrations may exhibit nonspecific actions at higher doses. In general, the more potent a drug at its desired target, the lower the probability that it will have off-target effects. Conversely, even drugs that have a broad spectrum of activity may not act identically at all levels of the CNS. For example, sedatives, hypnotics, and general anesthetics would have very limited utility if central neurons that control the respiratory and cardiovascular systems were especially sensitive to their actions. *The specificity of a drug’s action is frequently overestimated. This is partly due to the fact that drugs are often identified with the effect that is implied by the class name.*

**GENERAL (NONSPECIFIC) CNS DEPRESSANTS.** This category includes the anesthetic gases and vapors, the aliphatic alcohols, and some hypnotic-sedative drugs. These agents share the capacity to depress excitable tissue at all levels of the CNS, leading to a decrease in the amount of transmitter released by the nerve impulse, as well as to general depression of postsynaptic responsiveness and ion flux. At sub-anesthetic concentrations, these agents (e.g., ethanol) can exert relatively specific effects on certain groups of neurons, which may account for differences in their behavioral effects, especially the propensity to produce dependence.

**GENERAL (NONSPECIFIC) CNS STIMULANTS.** This category includes pentylenetetrazol and related agents that are capable of powerful excitation of the CNS, and the methylxanthines, which have a much weaker stimulant action. Stimulation may be accomplished by 1 of 2 general mechanisms: (1) blockade of inhibition or (2) direct neuronal excitation that may involve increased transmitter release or more prolonged transmitter action, as occurs when the reuptake of a released transmitter is inhibited.
DRUGS THAT SELECTIVELY MODIFY CNS FUNCTION. The agents in this group may cause either depression or excitation. In some instances, a drug may produce both effects simultaneously on different systems. The principal classes of these CNS drugs are anticonvulsants, drugs used in treating Parkinson disease, opioid and nonopioid analgesics, appetite suppressants, antiemetics, analgesic-antipyretics, certain stimulants, antidepressants, antimanic and antipsychotic agents, tranquilizers, sedatives and hypnotics, and medications employed in the treatment of Alzheimer disease (cholinesterase inhibitors and anti-glutamate neuroprotectants). Even if selectivity of action is remarkable, a drug usually affects several CNS functions to varying degrees.

GENERAL CHARACTERISTICS OF CNS DRUGS. Combinations of centrally acting drugs frequently are administered to therapeutic advantage (e.g., an anticholinergic drug and levodopa for Parkinson disease). However, other combinations of drugs may be detrimental because of potentially dangerous additive or mutually antagonistic effects. The effects of a CNS drug may be additive with the physiological state and the effects of other depressant and stimulant drugs. For example, anesthetics are less effective in a hyperexcitable subject than in a normal patient; the converse is true for stimulants. In general, the depressant effects of drugs from different categories are additive (e.g., the potentially fatal combination of barbiturates or benzodiazepines with ethanol), as are the effects of stimulants. Therefore, respiration depressed by morphine is further impaired by depressant drugs, while stimulant drugs can augment the excitatory effects of morphine to produce vomiting and convulsions.

Antagonism between depressants and stimulants is variable. Some instances of true pharmacological antagonism among CNS drugs are known; for example, opioid antagonists can selectively antagonize the effects of opioid analgesics. However, the antagonism exhibited between 2 CNS drugs is most often physiological in nature. For example, an individual whose CNS is depressed by an opiate cannot be returned entirely to normal by stimulation with caffeine.

The selective effects of drugs on specific neurotransmitter systems may be additive or competitive. The potential for drug interactions must be considered whenever such drugs are concurrently administered. To minimize such interactions, a drug-free period may be required when modifying therapy; in fact, development of desensitized and supersensitive states with prolonged therapy may limit the speed with which 1 drug may be halted and another
started. An excitatory effect is commonly observed with low concentrations of certain depressant drugs due either to depression of inhibitory systems or to a transient increase in the release of excitatory transmitters. Examples include the stage of excitement seen during induction of general anesthesia. The excitatory phase typically occurs with low concentrations of the depressant; uniform depression ensues with increasing drug concentration. The excitatory effects can be minimized, when appropriate, by pretreatment with a depressant drug that is devoid of such effects (e.g., benzodiazepines in preanesthetic medication). Acute, excessive stimulation of the cerebrospinal axis normally is followed by depression, which is in part a consequence of neuronal fatigue and exhaustion of stores of transmitters. Postictal depression is additive with the effects of depressant drugs. Acute, drug-induced depression generally is not followed by stimulation. However, chronic drug-induced sedation or depression may be followed by prolonged hyperexcitability on abrupt withdrawal of the medication (barbiturates or alcohol). This type of hyperexcitability can be controlled effectively by the same or another depressant drug (see Chapters 17, 23, and 24).
Depression and anxiety disorders are the most common mental illnesses, each affecting in excess of 10-15% of the population at some time in their lives. With the advent of more selective and safer drugs, the use of antidepressants and anxiolytics has moved from the domain of psychiatry to other medical specialties, including primary care. The relative safety of the majority of commonly used antidepressants and anxiolytics notwithstanding, their optimal use requires a clear understanding of their mechanisms of action, pharmacokinetics, potential drug interactions, and the differential diagnosis of psychiatric illnesses.

A confluence of symptoms of depression and anxiety may affect an individual patient; some of the drugs discussed here are effective in treating both disorders, suggesting common underlying mechanisms of pathophysiology and response to pharmacotherapy. In large measure, our current understanding of pathophysiological mechanisms underlying depression and anxiety has been inferred from the mechanisms of action of psychopharmacological compounds (see Chapter 14). While depression and anxiety disorders comprise a wide range of symptoms, including changes in mood, behavior, somatic function, and cognition, some progress has been made in developing animal models that respond with some sensitivity and selectivity to antidepressant or anxiolytic drugs. The last half century has seen notable advances in the discovery and development of drugs for treating depression and anxiety.

**CHARACTERIZATION OF DEPRESSIVE AND ANXIETY DISORDER**

**SYMPTOMS OF DEPRESSION**
Depression is classified as major depression (i.e., unipolar depression) or bipolar depression (i.e., manic depressive illness); bipolar depression and its treatment are discussed in Chapter 16. Lifetime risk of unipolar depression is ~15%. Females are affected twice as frequently as males. Depressive episodes are characterized by sad mood, pessimistic worry, diminished interest in normal activities, mental slowing and poor concentration, insomnia or increased sleep, significant weight loss or gain due to altered eating and activity patterns, psychomotor agitation or retardation, feelings of guilt and worthlessness, decreased energy and libido, and suicidal ideation, occurring most days for a period of at least 2 weeks. In some cases, the primary complaint of patients involves somatic pain or other physical symptoms and can present a diagnostic challenge for primary care physicians. Depressive symptoms also can occur secondary to other illnesses such as hypothyroidism, Parkinson disease, and inflammatory conditions. Further, depression often complicates the management of other medical conditions (e.g., severe trauma, cancer, diabetes, and cardiovascular disease, especially myocardial infarction).

Depression is underdiagnosed and undertreated. Approximately 10-15% of those with severe depression attempt suicide at some time. Thus, it is important that symptoms of depression be recognized and treated in a timely manner. Furthermore, the response to treatment must be assessed and decisions made regarding continued treatment with the initial drug, dose adjustment, adjunctive therapy, or alternative medication.

SYMPTOMS OF ANXIETY. Anxiety disorder symptoms include generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, posttraumatic stress disorder (PTSD), separation anxiety disorder, social phobia, specific phobias, and acute stress. In general, symptoms of anxiety that lead to pharmacological treatment are those that interfere significantly with normal function. Symptoms of anxiety also are often associated with depression and
other medical conditions.

Anxiety is a normal human emotion that serves an adaptive function from a psychobiological perspective. However, in the psychiatric setting, feelings of fear or dread that are unfocused (e.g., generalized anxiety disorder) or out of scale with the perceived threat (e.g., specific phobias) often require treatment. Drug treatment includes acute drug administration to manage episodes of anxiety, and chronic or repeated treatment to manage unrelieved and continuing anxiety disorders.

**ANTIDEPRESSANT DRUGS**

In general, antidepressants enhance serotonergic or noradrenergic transmission. Sites of interaction of antidepressant drugs with noradrenergic and serotonergic neurons are depicted in Figure 15–1. Table 15–1 summarizes the actions of the most widely used antidepressants. The most commonly used medications, often referred to as second-generation antidepressants, are the selective serotonin reuptake inhibitors (SSRIs) and the serotonin-norepinephrine reuptake inhibitors (SNRIs), which have greater efficacy and safety compared to the first-generation drugs, which include monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs).
Figure 15–1 Sites of action of antidepressants at noradrenergic (top) and serotonergic (bottom) nerve terminals. SSRIs, SNRIs, and TCAs increase noradrenergic or serotonergic neurotransmission by blocking the NE or 5HT transporter at presynaptic terminals (NET, SERT). MAOIs inhibit the catabolism of NE and 5HT. Trazodone and related drugs have direct effects on 5HT receptors that contribute to their clinical effects. Chronic treatment with a number of antidepressants desensitizes presynaptic autoreceptors and heteroreceptors, producing long-lasting changes in monoaminergic neurotransmission. Post-receptor effects of antidepressant treatment, including modulation of GPCR signaling and activation of protein kinases and ion channels, are involved in the mediation of the long-term effects of antidepressant
drugs. Note that NE and 5HT also affect each other’s neurons.

Note: Sansifoline is approved for only Periame disease, but may have antidepressant effects, especially at daily doses 20 mg, and is under investigation for administration by transdermal patch.

*Children, 0.5–1 mg/kg, up to 70 kg; see black box warning.

*G, oral tablet or capsule; I, injectable; NE, norepinephrine; 5HT, serotonin; DA, dopamine; L, ropifilide; 0/+, mild; 0/0+, moderate; 0/+, moderately severe; 0/0/+, severe.

Other significant side effects for individual drugs are described in the text.

In monoamine systems, inhibition of reuptake can enhance neurotransmission, presumably by slowing clearance of the transmitter from the synapse and prolonging the dwell-time of the transmitter in the synapse. Reuptake inhibitors inhibit either SERT, the neuronal serotonin (5-hydroxytryptamine [5HT]) transporter; NET, the neuronal norepinephrine (NE) transporter; or both. Similarly, MAOIs and TCAs enhance monoaminergic neurotransmission: the MAOIs by inhibiting monoamine metabolism and thereby enhancing neurotransmitter storage in secretory granules, the TCAs by inhibiting 5HT and NE reuptake.
Long-term effects of antidepressant drugs evoke regulatory mechanisms that enhance the effectiveness of therapy. These responses include increased adrenergic or serotonergic receptor density or sensitivity, increased receptor-G protein coupling and cyclic nucleotide signaling, induction of neurotrophic factors, and increased neurogenesis in the hippocampus. Persistent antidepressant effects depend on the continued inhibition of 5HT or NE transporters, or enhanced serotonergic or noradrenergic neurotransmission achieved by an alternative pharmacological mechanism. Compelling evidence suggests that sustained signaling via NE or 5HT increases the expression of specific downstream gene products, particularly brain-derived neurotrophic factor (BDNF), which appears to be related to the ultimate mechanism of action of these drugs.

**CLINICAL CONSIDERATIONS WITH ANTIDEPRESSANT DRUGS**

Antidepressant drug treatment has generally a “therapeutic lag” lasting 3-4 weeks before a measurable therapeutic response becomes evident. After the successful initial treatment phase, a 6-12–month maintenance treatment phase is typical, after which the drug is gradually withdrawn. If a patient is chronically depressed (i.e., >2 years), lifelong treatment with an antidepressant is advisable.

A controversial issue regarding the use of all antidepressants is their relationship to suicide. Data establishing a clear link between antidepressant treatment and suicide are lacking. However, the FDA has issued a “black box” warning regarding the use of SSRIs and a number of other antidepressants in children and adolescents due to the possibility of an association between antidepressant treatment and suicide. For seriously depressed patients, the risk of not being on an effective antidepressant drug outweighs the risk of being treated with one.

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

The SSRIs are effective in treating major depression. SSRIs also are anxiolytics with demonstrated efficacy in the treatment of generalized anxiety, panic, social anxiety, and obsessive-compulsive disorders.
Sertraline and paroxetine are approved for the treatment of PTSD. SSRIs also are used for treatment of premenstrual dysphoric syndrome and for preventing vasovagal symptoms in postmenopausal women.

SERT mediates the reuptake of serotonin into the presynaptic terminal; neuronal uptake is the primary process by which neurotransmission via 5HT is terminated (see Figure 15–1). SSRIs block reuptake and prolong serotonergic neurotransmission. SSRIs used clinically are relatively selective for inhibition of SERT relative to NET (Table 15–2; not shown is vilazodone [VIIBRYD], an SSRI and partial 5HT$_{1A}$ agonist, recently approved by the FDA for treatment of major depression).

| Table 15–2 |
| Selectivity of Antidepressants at the Human Biogenic Amine Transporters |
SSRI treatment causes stimulation of 5HT_{1A} and 5HT_{7} autoreceptors on cell bodies in the raphe nucleus and of 5HT_{1D} autoreceptors on serotonergic terminals, and this reduces serotonin synthesis and release toward predrug levels. With repeated treatment with SSRIs, there is a gradual downregulation and desensitization of these autoreceptor mechanisms. In addition, downregulation of postsynaptic 5HT_{2A} receptors may contribute to antidepressant efficacy directly or by influencing the function of noradrenergic and other neurons via serotonergic heteroreceptors. Other postsynaptic 5HT receptors likely remain responsive to increased synaptic concentrations of 5HT and contribute to the therapeutic effects of the SSRIs.

Later-developing effects of SSRI treatment also may be important in mediating ultimate therapeutic responses. These include sustained increases in cyclic AMP signaling and phosphorylation of the nuclear transcription factor CREB, as well as increases in the expression of trophic factors such as BDNF, and increases of neurogenesis from progenitor cells in the hippocampus and subventricular zone.
Repeated treatment with SSRIs reduces the expression of SERT, resulting in reduced clearance of released 5HT and increased serotonergic neurotransmission.

**SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS**

Four medications with a nontricyclic structure that inhibit the reuptake of both 5HT and NE have been approved for use in the U.S. for treatment of depression, anxiety disorders, and pain: venlafaxine and its demethylated metabolite, desvenlafaxine; duloxetine; and milnacipran.

SNRIs inhibit both SERT and NET (see Table 15–2) and cause enhanced serotonergic and/or noradrenergic neurotransmission. Similar to the action of SSRIs, the initial inhibition of SERT induces activation of 5HT$_{1A}$ and 5HT$_{1D}$ autoreceptors. This action decreases serotonergic neurotransmission by a negative feedback mechanism until these serotonergic autoreceptors are desensitized. Then, the enhanced serotonin concentration in the synapse can interact with postsynaptic 5HT receptors. SNRIs were developed with the rationale that they might improve overall treatment response compared to SSRIs. Specifically, the remission rate for venlafaxine appears slightly better than for SSRIs in head-to-head trials. Duloxetine, in addition to being approved for use in the treatment of depression and anxiety, also is used for treatment of fibromyalgia and neuropathic pain associated with peripheral neuropathy. Off-label uses include stress urinary incontinence (duloxetine), autism, binge eating disorders, hot flashes, pain syndromes, premenstrual dysphoric disorders, and PTSDs (venlafaxine).

**SEROTONIN RECEPTOR ANTAGONISTS**

Several antagonists of the 5HT$_2$ family of receptors are effective antidepressants. These includes 2 close structural analogues, trazodone and nefazodone, as well as mirtazapine (REMERON, others) and mianserin (not marketed in the U.S.).

The efficacy of trazodone may be somewhat more limited than the SSRIs; however, low doses of trazodone (50-100 mg) have been used widely both alone
and concurrently with SSRIs or SNRIs to treat insomnia. Both mianserin and mirtazapine are quite sedating and are treatments of choice for some depressed patients with insomnia. Trazodone blocks the 5HT2 and α1-adrenergic receptors. Trazodone also inhibits the serotonin transporter, but is markedly less potent for this action relative to its blockade of 5HT2A receptors. Similarly, the most potent pharmacological action of nefazodone also is the blockade of the 5HT2 receptors. Both mirtazapine and mianserin potently block histamine H1 receptors. They also have some affinity for α2-adrenergic receptors. Their affinities for 5HT2A, 5HT2C, and 5HT3 receptors are high, though less so than for histamine H1 receptors. Both of these drugs have been shown to increase the antidepressant response when combined with SSRIs compared to the action of the SSRIs alone.

**BUPROPION**

Bupropion (WELLBUTRIN, others) is discussed separately because it appears to act via multiple mechanisms. It enhances both noradrenergic and dopaminergic neurotransmission via inhibition of reuptake (by NET and also by DAT, although effects on this transporter are not potent in animal studies) (see Table 15–2). Its mechanism of action may also involve the presynaptic release of NE and DA and effects on VMAT2, the vesicular monoamine transporter (see Figure 8–6). The hydroxybupropion metabolite may contribute to the therapeutic effects of bupropion: This metabolite appears to have a similar pharmacology and is present in substantial levels. Bupropion is indicated for the treatment of depression, prevention of seasonal depressive disorder, and as a smoking cessation treatment (under the ZYBAN brand). Bupropion has effects on sleep EEG that are opposite those of most antidepressant drugs. Bupropion may improve symptoms of attention deficit hyperactivity disorder (ADHD) and has been used off-label for neuropathic pain and weight loss. Clinically, bupropion is widely used in combination with SSRIs to obtain a greater antidepressant response; however, there are very limited clinical data providing strong support for this practice.
ATYPICAL ANTIPSYCHOTICS

In addition to their use in schizophrenia, bipolar depression, and major depression with psychotic disorders, atypical antipsychotics have gained further, off-label use for major depression without psychotic features. The combination of aripiprazole (ABILIFY) with SSRIs and SNRIs and a combination of olanzapine and the SSRI fluoxetine (SYMBYAX) have been approved by the FDA for treatment-resistant major depression (i.e., following an inadequate response to at least 2 different antidepressants).

The initial recommended dose of aripiprazole is 2-5 mg/day with a recommended maximal dose of 15 mg/day following increments of no more than 5 mg/day every week. The olanzapine-fluoxetine combination is available in fixed-dose combinations of either 6 or 12 mg of olanzapine and 25 or 50 mg of fluoxetine. Quetiapine (SEROQUEL) may have either primary antidepressant actions on its own or adjunctive benefit for treatment-resistant depression; it is used off-label for insomnia. The mechanism of action and adverse effects of the atypical antipsychotics are described in detail in Chapter 16. The major risks of these agents are weight gain and metabolic syndrome, a greater problem for quetiapine and olanzapine than for aripiprazole.

TRICYCLIC ANTIDEPRESSANTS

TCAs may cause serious side effects and generally are not used as first-line drugs for the treatment of depression. TCAs and first-generation antipsychotics are synergistic for the treatment of psychotic depression. Tertiary amine TCAs (e.g., doxepin, amitriptyline) have been used for many years in relatively low doses for treating insomnia. In addition, because of the role of norepinephrine and serotonin in pain transmission, these drugs are commonly used to treat a variety of pain conditions.

The pharmacological action of TCAs is antagonism of serotonin and norepinephrine transporters (see Table 15–2). In addition to inhibiting NET somewhat selectively (desipramine, nortriptyline, protriptyline, amoxapine) or
both SERT and NET (imipramine, amitriptyline), these drugs also block other receptors (H₁, 5HT₂, α₁, and muscarinic). Given the superior activity of clomipramine over SSRIs, some combination of these additional pharmacological actions may contribute to the therapeutic effects of TCAs. One TCA, amoxapine, also is a dopamine-receptor antagonist; its use, unlike that of other TCAs, poses some risk for the development of extrapyramidal side effects such as tardive dyskinesia.

**MONOAMINE OXIDASE INHIBITORS**

MAOIs have efficacy equivalent to that of the TCAs but are rarely used because of their toxicity and major drug and food interactions. The MAOIs approved for treatment of depression include tranylcypromine (PARNATE, others), phenelzine (NARDIL), and isocarboxazid (MARPLAN). Selegiline (EMSAM) is available as a transdermal patch; transdermal delivery may reduce the risk for diet-associated hypertensive reactions.

The MAOIs nonselectively and irreversibly inhibit both MAO-A and MAO-B, which are located in the mitochondria and metabolize monoamines, including 5HT and NE (see Chapter 8). Selegiline inhibits MAO-B at lower doses, with effects on MAO-A at higher doses. Selegiline also is a reversible inhibitor of MAO, which may reduce the potential for serious adverse drug and food interactions. While both MAO-A and MAO-B are involved in metabolizing 5HT, only MAO-B is found in serotonergic neurons (see Chapter 13).

**PHARMACOKINETICS**

The metabolism of most antidepressants is mediated by hepatic CYPs (Table 15–3). Some antidepressants inhibit the clearance of other drugs by the CYP system, and this possibility of drug interactions should be a significant factor in considering the choice of agents.

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS.** All of the SSRIs are orally active and possess elimination half-lives consistent with once-daily dosing. In the case of fluoxetine, the combined action of the parent and the desmethyl metabolite norfluoxetine allows for a once-weekly formulation (**PROZAC WEEKLY**). CYP2D6 is involved in the metabolism of most SSRIs and the SSRIs are at least moderately potent inhibitors of this isoenzyme. This creates a significant potential for drug interaction for postmenopausal women taking the breast cancer drug and estrogen antagonist, tamoxifen (see Chapter 63). Because venlafaxine and desvenlafaxine are weak inhibitors of CYP2D6, these antidepressants are not contraindicated in this clinical situation. However, care should be used in combining SSRIs with drugs that are metabolized by

Values shown are elimination $t_{1/2}$ values for a number of clinically used antidepressant drugs; numbers in parentheses are $t_{1/2}$ values of active metabolites. Fluoxetine (2D6), fluvoxamine (1A2, 2C8, 3A3/4), paroxetine (2D6), and nefazodone (3A3/4) are potent inhibitors of CYP450; sertraline (2D6), citalopram (2C19), and venlafaxine are less potent inhibitors. Plasma concentrations are those observed at typical clinical doses. Information was obtained from manufacturers’ summaries and Appendix 2 of the parent text, which the reader should consult for important details.
CYPs.

**SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS.** Both immediate-release and extended-release (tablet or capsule) preparations of venlafaxine (Effexor XR, others) produces steady state-levels of drug in plasma within 3 days. The elimination half-lives for the parent venlafaxine and its active and major metabolite desmethyl venlafaxine are 5 and 11 h, respectively. Desmethyl venlafaxine is eliminated by hepatic metabolism and by renal excretion. Venlafaxine dose reductions are suggested for patients with renal or hepatic impairment. Duloxetine has a $t_{1/2}$ of 12 h. Duloxetine is not recommended for those with end-stage renal disease or hepatic insufficiency.

**SEROTONIN RECEPTOR ANTAGONISTS.** Mirtazapine has an elimination $t_{1/2}$ of 16-30 h. Thus, dose changes are suggested no more often than 1-2 weeks. The recommended initial dosing of mirtazapine is 15 mg/day with a maximal recommended dose of 45 mg/day. Clearance of mirtazapine is decreased in the elderly and in patients with moderate to severe renal or hepatic impairment. Pharmacokinetics and adverse effects of mirtazapine may have an enantiomer-selective component. Steady-state trazodone is observed within 3 days following dosing regimen. Trazodone typically is started at 150 mg/day in divided doses with 50 mg increments every 3-4 days. The maximally recommended dose is 400 mg/day for outpatients and 600 mg/day for inpatients. Nefazodone has a $t_{1/2}$ of only 2-4 h; its major metabolite hydroxynefazodone has a $t_{1/2}$ of 1.5-4 h.

**BUPROPION.** Bupropion elimination has a $t_{1/2}$ of 21 h and involves both hepatic and renal routes. Patients with severe hepatic cirrhosis should receive a maximum dose of 150 mg every other day while consideration for a decreased dose should also be made in cases of renal impairment.

**TRICYCLIC ANTIDEPRESSANTS.** The TCAs, or their active metabolites, have plasma half-lives of 8-80 h; this makes once-daily dosing possible for most of the compounds. Steady-state concentrations occur within several days to several weeks of beginning treatment. TCAs are largely eliminated by hepatic CYPs (see Table 15–3). Dosage adjustments of TCAs are typically made according to patient’s clinical response, not based on plasma levels. Nonetheless, monitoring the plasma exposure has an important relationship to treatment response: there is a relatively narrow therapeutic window. About 7% of patients...
metabolize TCAs slowly due to a variant CYP2D6 isoenzyme, causing a 30-fold difference in plasma concentrations among different patients given the same TCA dose. To avoid toxicity in “slow metabolizers,” plasma levels should be monitored and doses adjusted downward.

**MONOAMINE OXIDASE INHIBITORS.** MAOIs are metabolized by acetylation. A significant portion of the population (50% of the Caucasian population and an even higher percentage among Asians) are “slow acetylators” and will exhibit elevated plasma levels. The nonselective MAOIs used in the treatment of depression are irreversible inhibitors; thus, it takes up to 2 weeks for MAO activity to recover, even though the parent drug is excreted within 24 h. Recovery of normal enzyme function is dependent on synthesis and transport of new MAO to monoaminergic nerve terminals. Despite this irreversible enzyme inhibition, MAOIs require daily dosing.

**ADVERSE EFFECTS**

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS.** The SSRIs have no major cardiovascular side effects. The SSRIs are generally free of antimuscarinic side effects (dry mouth, urinary retention, confusion), do not block histamine or α-adrenergic receptors, and are not sedating (Table 15–4).

**Table 15–4**

Potencies of Selected Antidepressants at Muscarinic, Histamine H₁, and Alpha₁ Adrenergic Receptors
Adverse side effects of SSRIs from excessive stimulation of brain 5HT₂ receptors may result in insomnia, increased anxiety, irritability, and decreased libido, effectively worsening prominent depressive symptoms. Excess activity at spinal 5HT₂ receptors causes sexual side effects including erectile dysfunction, anorgasmia, and ejaculatory delay; these effects may be more prominent with paroxetine. Stimulation of 5HT₃ receptors in the CNS and periphery contributes to GI effects, which are usually limited to nausea but may include diarrhea and emesis. Some patients experience an increase in anxiety, especially with the initial dosing of SSRIs. With continued treatment, some patients also report a dullness of intellectual abilities and concentration. In general, there is not a strong relationship between SSRI serum concentrations and therapeutic efficacy.
Thus, dosage adjustments are based more on evaluation of clinical response and management of side effects.

Sudden withdrawal of antidepressants can precipitate a withdrawal syndrome. For SSRIs or SNRIs, the symptoms of withdrawal may include dizziness, headache, nervousness, nausea, and insomnia. This withdrawal syndrome appears most intense for paroxetine and venlafaxine compared to other antidepressants due to their relatively short half-lives and, in the case of paroxetine, lack of active metabolites. Conversely, the active metabolite of fluoxetine, norfluoxetine, has such a long $t_{1/2}$ (1-2 weeks) that few patients experience any withdrawal symptoms when discontinuing fluoxetine.

Unlike the other SSRIs, paroxetine is associated with an increased risk of congenital cardiac malformations when administered in the first trimester of pregnancy. Venlafaxine also is associated with an increased risk of perinatal complications.

**SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS.** SNRIs have a side effect profile similar to that of the SSRIs, including nausea, constipation, insomnia, headaches, and sexual dysfunction. The immediate release formulation of venlafaxine can induce sustained diastolic hypertension (diastolic blood pressure $>90$ mm Hg at consecutive weekly visits) in 10-15% of patients at higher doses; this risk is reduced with the extended-release form. This effect of venlafaxine may not be associated simply with inhibition of NET, since duloxetine does not share this side effect.

**SEROTONIN RECEPTOR ANTAGONISTS.** The main side effects of mirtazapine, seen in $>10\%$ of the patients, are somnolence, increased appetite, and weight gain. A rare side effect of mirtazapine is agranulocytosis. Trazodone use is associated with priapism in rare instances. Nefazodone was voluntarily withdrawn from the market after rare cases of liver failure were associated with its use. Generic nefazodone is still available in the U.S.

**BUPROPION.** At doses higher than that recommended for depression (450 mg/day), the risk of seizures increases significantly. The use of extended-release formulations often blunts the maximum concentration observed after dosing and minimizes the chance of reaching drug levels associated with an increased risk of seizures.
TRICYCLIC ANTIDEPRESSANTS. TCAs are potent antagonists at histamine H₁ receptors; H₁-receptor antagonism contributes to the sedative effects of TCAs (see Table 15–4). Antagonism of muscarinic acetylcholine receptors contributes to cognitive dulling as well as a range of adverse effects mediated by the parasympathetic nervous system (blurred vision, dry mouth, tachycardia, constipation, difficulty urinating). Some tolerance does occur for these anticholinergic effects. Antagonism of α₁ adrenergic receptors contributes to orthostatic hypotension and sedation. Weight gain is another side effect of this class of antidepressants.

TCAs also have quinidine-like effects on cardiac conduction that can be life threatening with overdose and limit the use of TCAs in patients with coronary heart disease. This is the primary reason that only a very limited supply should be available to the patient at any given time. Like other antidepressant drugs, TCAs also lower the seizure threshold.

MONOAMINE OXIDASE INHIBITORS. Hypertensive crisis resulting from food or drug interactions is one of the life-threatening toxicities associated with use of the MAOIs. Foods containing tyramine are a contributing factor. MAO-A within the intestinal wall and MAO-A and MAO-B in the liver normally degrade dietary tyramine. When MAO-A is inhibited, the ingestion of tyramine-containing foods leads to accumulation of tyramine in adrenergic nerve endings and neurotransmitter vesicles and induces norepinephrine and epinephrine release. The released catecholamines stimulate postsynaptic receptors in the periphery, increasing blood pressure to dangerous levels. The use of prescription or over-the-counter medications that contain sympathomimetic compounds also result in a potentially life-threatening elevation of blood pressure. In comparison to tranylcypromine and isocarboxazid, the selegiline transdermal patch is better tolerated and safer. Another serious, life-threatening issue with chronic administration of MAOIs is hepatotoxicity.

MAO-A inhibitors are efficacious in treating depression. However, MAO-B inhibitors such as selegiline (with oral formulations) are effective in treating depression only when given at doses that block both MAO-A and MAO-B. While not available in the U.S., reversible inhibitors of MAO-A (RIMAs, such as moclobemide) have been developed. Because these drugs are selective for MAO-A, significant MAO-B activity remains. Further, since the inhibition of
MAO-A by RIMAs is reversible and competitive, as concentrations of tyramine rise, enzyme inhibition is surmounted. Thus, RIMAs produce antidepressant effects with reduced risk of tyramine-induced hypertensive crisis.

**DRUG INTERACTIONS**

Many of these drugs are metabolized by hepatic CYPs, especially CYP2D6. Thus, other agents that are substrates or inhibitors of CYP2D6 can increase plasma concentrations of the primary drug. The combination of other classes of antidepressant agents with MAOIs is inadvisable and can lead to serotonin syndrome.

**SELECTIVE SEROTONIN REUPTAKE INHIBITORS.** Paroxetine and, to a lesser degree, fluoxetine are potent inhibitors of CYP2D6. The other SSRI s, outside of fluvoxamine, are at least moderate inhibitors of CYP2D6. This inhibition can result in disproportionate increases in plasma concentrations of drugs metabolized by CYP2D6 when doses of these drugs are increased. Fluvoxamine directly inhibits CYP1A2 and CYP2C19; fluoxetine and fluvoxamine also inhibit CYP3A4. A prominent interaction is the increase in TCA exposure that may be observed during coadministration of TCAs and SSRIs.

MAOIs enhance the effects of SSRIs due to inhibition of serotonin metabolism. Administration of these drugs together can produce synergistic increases in extracellular brain serotonin, leading to the serotonin syndrome. Symptoms of the serotonin syndrome include hyperthermia, muscle rigidity, myoclonus, tremors, autonomic instability, confusion, irritability, and agitation; this can progress toward coma and death. Other drugs that may induce the serotonin syndrome include substituted amphetamines such as methylenedioxymethamphetamine (Ecstasy), which directly releases serotonin from nerve terminals.

SSRIs should not be started until at least 14 days following discontinuation of treatment with an MAOI; this allows for synthesis of new MAO. For all SSRIs but fluoxetine, at least 14 days should pass prior to beginning treatment with an MAOI following the end of treatment with an SSRI. Because the active metabolite norfluoxetine has a $t_{1/2}$ of 1-2 weeks, at least 5 weeks should pass
between stopping fluoxetine and beginning an MAOI.

**SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS.** While 14 days are suggested to elapse from ending MAOI therapy and starting venlafaxine treatment, an interval of only 7 days is considered safe. Duloxetine has a similar interval to initiation following MAOI therapy, but requires only a 5-day waiting period to begin MAOI treatment after ending duloxetine. Failure to observe these required waiting periods can result in the serotonin syndrome.

**SEROTONIN RECEPTOR ANTAGONISTS.** Trazodone dosing may need to be lowered when given together with drugs that inhibit CYP3A4. Mirtazapine is metabolized by CYPs 2D6, 1A2, and 3A4. Trazodone and nefazodone are weak inhibitors of serotonin uptake and should not be administered with MAOIs due to concerns about the serotonin syndrome.

**BUPROPION.** The major route of metabolism for bupropion is CYP2B6. While there does not appear to be any evidence for metabolism by CYP2D6 and this drug is frequently administered with SSRIs, the potential for interactions with drugs metabolized by CYP2D6 should be kept in mind until the safety of the combination is firmly established.

**TRICYCLIC ANTIDEPRESSANTS.** Drugs that inhibit CYP2D6, such as SSRIs, may increase plasma exposures of TCAs. Other drugs that may act similarly are phenothiazine antipsychotic agents, type 1C anti-arrhythmic drugs, and other drugs with antimuscarinic, antihistaminic, and α-adrenergic antagonistic effects. TCAs can potentiate the actions of sympathomimetic amines and should not be used concurrently with MAOIs or within 14 days of stopping MAOIs.

**MONOAMINE OXIDASE INHIBITORS.** CNS depressants including meperidine and other narcotics, alcohol, and anesthetic agents should not be used with MAOIs. Meperidine and other opioid agonists in combination with MAOIs also induce the serotonin syndrome. SSRIs and SNRIs are contraindicated in patients on MAOIs to avoid the serotonin syndrome. In general, other antidepressants such as TCAs and bupropion also should be avoided in patients taking an MAOI.

**ANXIOLYTIC DRUGS**
Primary treatments for anxiety-related disorders include the SSRIs, SNRIs, benzodiazepines, buspirone, and \( \beta \) adrenergic antagonists. The SSRIs and the SNRI venlafaxine have anxiolytic activity with chronic treatment. The benzodiazepines are effective anxiolytics as both acute and chronic treatment. Buspirone, like the SSRIs, is effective following chronic treatment. It acts, at least in part, via the serotonergic system, where it is a partial agonist at 5HT\(_{1A}\) receptors. Buspirone also has antagonistic effects at dopamine D\(_2\) receptors, but the relationship between this effect and its clinical actions is uncertain. \( \beta \) adrenergic antagonists (e.g., propranolol and nadolol) are occasionally used for performance anxiety such as fear of public speaking; their use is limited due to significant side effects such as hypotension.

The antihistamine hydroxyzine and various sedative-hypnotic agents have been used as anxiolytics, but are generally not recommended because of their side effect profiles. Hydroxyzine, which produces short-term sedation, is used in patients who cannot use other types of anxiolytics (e.g., those with a history of drug or alcohol abuse where benzodiazepines would be avoided). Chloral hydrate has been used for situational anxiety, but there is a narrow dose range where anxiolytic effects are observed in the absence of significant sedation, and, therefore, the use of chloral hydrate is not recommended.

**CLINICAL CONSIDERATIONS WITH ANXIOLYTIC DRUGS.**

The choice of pharmacological treatment for anxiety is dictated by the specific anxiety-related disorders and the clinical need for acute anxiolytic effects. The benzodiazepines and \( \beta \) adrenergic antagonists are effective acutely. Chronic treatment with SSRIs, SNRIs, and buspirone is required to produce and sustain anxiolytic effects.

Benzodiazepines, such as alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, lorazepam, and oxazepam, are effective in the treatment of generalized anxiety disorder, panic disorder, and situational anxiety. In addition to their anxiolytic effects, benzodiazepines produce sedative, hypnotic, anesthetic, anticonvulsant, and muscle relaxant effects. The benzodiazepines also
impair cognitive performance and memory, adversely affect motor control, and potentiate the effects of other sedatives including alcohol. The anxiolytic effects of this class of drugs are mediated by allosteric interactions with the pentameric benzodiazepine-GABA_A receptor complex, in particular those GABA_A receptors comprised of α2, α3, and α5 subunits (see Chapters 14 and 17). The primary effect of the anxiolytic benzodiazepines is to enhance the inhibitory effects of the neurotransmitter GABA. The use of benzodiazepines in the treatment of anxiety has the potential for habituation, dependence, and abuse. Withdrawal of benzodiazepines after chronic treatment, particularly those with short durations of action, can include increased anxiety and seizures. For this reason, it is important that discontinuation be carried out in a gradual manner.

Benzodiazepines cause many adverse effects, including sedation, mild memory impairments, decreased alertness, and slowed reaction time. Occasionally, paradoxical reactions can occur with benzodiazepines such as increases in anxiety, sometimes reaching panic attack proportions. Other pathological reactions can include irritability, aggression, or behavioral disinhibition. Amnesic reactions (i.e., loss of memory for particular periods) can also occur. Benzodiazepines should not be used in pregnant women; there have been rare reports of craniofacial defects. In addition, benzodiazepines taken prior to delivery may result in sedated, under-responsive newborns and prolonged withdrawal reactions. In the elderly, benzodiazepines increase the risk for falls and must be used cautiously. These drugs are safer than classical sedative-hypnotics in overdosage and typically are fatal only if combined with other CNS depressants.

Benzodiazepines have some abuse potential. When these agents are abused, it is generally in a multidrug abuse pattern. In fact, the primary reason for misuse of these agents often is failed attempts to control anxiety. Tolerance to the anxiolytic effects develops with chronic administration, with the result that some patients escalate the dose of benzodiazepines over time. Ideally, benzodiazepines should be used for short periods of time and in conjunction with other medications (e.g., SSRIs) or evidence-based psychotherapies (e.g., cognitive behavioral therapy for anxiety disorders).

SSRIs and the SNRI venlafaxine are first-line treatments for most types of anxiety disorders, except when an acute drug effect is desired; fluvoxamine is
approved only for obsessive-compulsive disorder. As for their antidepressant actions, the anxiolytic effects of these drugs become manifest following chronic treatment. Other drugs with actions on serotonergic neurotransmission, including trazodone, nefazodone, and mirtazapine, also are used in the treatment of anxiety disorders. Details regarding the pharmacology of these classes of were presented earlier. Both SSRIs and SNRIs are beneficial in specific anxiety conditions such as generalized anxiety disorder, social phobias, obsessive-compulsive disorder, and panic disorder. These effects appear to be related to the capacity of serotonin to regulate the activity of brain structures such as amygdala and locus coeruleus that are thought to be involved in the genesis of anxiety. Anxious patients appear to be particularly prone to severe discontinuation reactions with certain medications such as venlafaxine and paroxetine; therefore, slow off-tapering is required.

Buspirone requires chronic treatment for effectiveness. Buspirone is primarily effective in the treatment of generalized anxiety disorder, but not for other anxiety disorders.
Psychosis is a symptom of mental illnesses characterized by a distorted or nonexistent sense of reality. Common psychotic disorders include mood disorders (major depression or mania) with psychotic features, substance-induced psychosis, dementia with psychotic features, delirium with psychotic features, brief psychotic disorder, delusional disorder, schizoaffective disorder, and schizophrenia. Schizophrenia has a worldwide prevalence of 1%, but patients with schizophrenia exhibit features that extend beyond those seen in other psychotic illnesses. The positive symptoms of psychotic disorders include: hallucinations, delusions, disorganized speech, and disorganized or agitated behavior. Schizophrenia patients also suffer from negative symptoms (apathy, avolition, alogia), and cognitive deficits, particularly deficits in working memory, processing speed, and social cognition.

The dopamine (DA) hypothesis of psychosis was derived from the discovery that chlorpromazine and reserpin exhibited therapeutic antipsychotic properties in schizophrenia by decreasing dopaminergic neurotransmission. The DA overactivity hypothesis led to the development of the first therapeutic class of antipsychotic agents, now referred to as typical or first-generation antipsychotic drugs. The term “neuroleptic” refers to typical antipsychotic drugs that act through D$_2$ receptor blockade but are associated with extrapyramidal side effects.

The DA hypothesis has its limitations: it does not account for the cognitive deficits associated with schizophrenia and does not explain the psychotomimetic effects of LSD (e.g., d-lysergic acid, a potent serotonin 5HT$_2$ receptor agonist) or the effects of phencyclidine and ketamine, antagonists of the N-methyl-D-aspartate (NMDA) glutamate receptor. Advances in treatment have emerged
from exploration of alternative (non-dopaminergic) mechanisms for psychosis and from experience with atypical antipsychotic agents such as clozapine. The newer atypical antipsychotics potently antagonize the 5HT₂ receptor, while blocking D₂ receptors less potently than older typical antipsychotic agents, resulting in antipsychotic efficacy with limited extrapyramidal side effects. Promising medications target glutamate and 5HT₇ receptor subtypes, receptors for γ-aminobutyric acid (GABA) and acetylcholine (both muscarinic and nicotinic), and peptide hormone receptors (e.g., oxytocin).

**PHARMACOTHERAPY**

The 12th edition of the parent text reviews the relevant pathophysiology and the general goals of pharmacotherapy of psychosis and mania. Regardless of the underlying pathology, the immediate goal of antipsychotic treatment is a decrease in the acute symptoms that induce patient distress, particularly behavioral symptoms (e.g., hostility, agitation) that may present a danger to the patient or others. The dosing, route of administration, and choice of antipsychotic depend on the underlying disease state, clinical acuity, drug-drug interactions with concomitant medications, and patient sensitivity to short- or long-term adverse effects. With the exception of clozapine’s superior efficacy in treatment-refractory schizophrenia, neither the clinical presentation nor biomarkers predict the likelihood of response to a specific antipsychotic class or agent. As a result, avoidance of adverse effects based upon patient and drug characteristics and exploitation of certain medication properties (e.g., sedation related to histamine H₁ or muscarinic antagonism) are the principal determinants for choosing initial antipsychotic therapy.

All commercially available antipsychotic drugs reduce dopaminergic neurotransmission (Figure 16–1). Chlorpromazine and other early low-potency typical antipsychotic agents are also profoundly sedating, a feature that used to be considered relevant to their therapeutic pharmacology. The development of the high-potency typical antipsychotic agent haloperidol, a drug with limited H₁ and M₁ affinity and significantly less sedative effect, demonstrate that sedation is
not necessary for antipsychotic activity, although at times desirable.

Figure 16–1 Sites of action of antipsychotic agents and Li⁺. Following exocytotic release, DA interacts with both postsynaptic receptors and presynaptic autoreceptors. Termination of DA action occurs primarily by reuptake into presynaptic terminals via the DA transporter DAT, with secondary deamination by mitochondrial monoamine oxidase (MAO). Stimulation of postsynaptic D₁ receptors activates the Gₛ-adenylyl cyclase-cAMP pathway. D₂ receptors couple through Gᵢ to inhibit adenylyl cyclase and through G₉ to activate the PLC-IP₃-Ca²⁺ pathway. Activation of the G₁ pathway can also activate K⁺ channels, leading to hyperpolarization. Li⁺ inhibits the phosphatase that liberates inositol (I) from inositol phosphate (IP). Li⁺ can also inhibit depolarization-evoked release of DA and NE, but not 5HT. D₂-like autoreceptors suppress synthesis of DA by diminishing phosphorylation of rate-limiting tyrosine hydroxylase (TH), and by limiting DA release. In contrast, presynaptic A₂ adenosine receptors (A₂R) activate the AC-cAMP-PKA pathway, thereby enhancing TH activity. All antipsychotic agents act at D₂ receptors and autoreceptors; some also block D₁ receptors (see Table 16–2). Stimulant agents inhibit DA reuptake by DAT, thereby prolonging the dwell time of synaptic DA. Initially in antipsychotic treatment, DA neurons release more DA, but following repeated treatment, they enter a state of physiological depolarization inactivation, with diminished production and release of DA, in addition to continued receptor blockade. —, inhibition or blockade; +, elevation of activity; −, reduction of activity.
SHORT-TERM TREATMENT

DELIRIUM AND DEMENTIA. Disease variables have considerable influence on selection of antipsychotic agents. Psychotic symptoms of delirium or dementia are generally treated with low medication doses, although doses may have to be repeated at frequent intervals initially to achieve adequate behavioral control. Despite widespread clinical use, not a single antipsychotic drug has received approval for dementia-related psychosis. Moreover, all antipsychotic drugs carry warnings that they may increase mortality in this setting. Because anticholinergic drug effects may worsen delirium and dementia, high-potency typical antipsychotic drugs (e.g., haloperidol) or atypical antipsychotic agents with limited antimuscarinic properties (e.g., risperidone) are often the drugs of choice.

The best tolerated doses in dementia patients are one-fourth of adult schizophrenia doses. Extrapyramidal neurological symptoms (EPSs), orthostasis, and sedation are particularly problematic in this patient population (see Chapter 22). Significant antipsychotic benefits are usually seen in acute psychosis within 60-120 min after drug administration. Oral dissolving tablet (ODT) preparations for risperidone, aripiprazole, and olanzapine, or liquid concentrate forms of risperidone or aripiprazole, are options for some patients. The dissolving tablets adhere to any moist tongue or oral surface, cannot be spit out, and are then swallowed along with oral secretions. Intramuscular (IM) administration of ziprasidone, aripiprazole, or olanzapine represents an option for treating agitated and minimally cooperative patients, and presents less risk for drug-induced parkinsonism than haloperidol. QTc prolongation associated with intramuscular droperidol and intravenous administration of haloperidol have curtailed use of those particular formulations.

MANIA. All atypical antipsychotic agents with the exception of clozapine and iloperidone have indications for acute mania, and doses are titrated rapidly to the maximum recommended dose over the first 24-72 h of treatment. Acute mania patients with psychosis require very high daily doses. Clinical response (decreased psychomotor agitation and irritability, increased sleep, and reduced or absent...
delusions and hallucinations) usually occurs within 7 days. Patients with mania may need to continue on antipsychotic treatment for many months after the resolution of psychotic and manic symptoms, typically in combination with a mood stabilizer such as lithium or valproic acid preparations. Combining an antipsychotic agent with a mood stabilizer often improves control of manic symptoms, and further reduces the risk of relapse. Weight gain from the additive effects of antipsychotic agents and mood stabilizers (lithium, valproic acid) presents a significant clinical problem.

**MAJOR DEPRESSION.** Patients with major depressive disorder with psychotic features require lower than average doses of antipsychotic drugs, given in combination with an antidepressant. Most antipsychotic drugs show limited antidepressant benefit as monotherapy agents. However, atypical antipsychotic agents are efficacious as adjunct therapy in treatment-resistant depression. Their clinical efficacy may be related to the fact that almost all atypical antipsychotic medications are potent 5HT$_2$A antagonists (Figure 16–2).

![Figure 16–2](image)

**Figure 16–2** Receptor occupancy and clinical response for antipsychotic agents. Typically, D$_2$ receptor occupancy by the drug >60% provides antipsychotic effects; receptor occupancy >80% causes extrapyramidal symptoms (EPS).
Atypical agents combine weak D₂ receptor blockade with more potent 5HT₂A antagonism/inverse agonism. Inverse agonism at 5HT₂ receptor subtypes may contribute to the reduced EPS risk of olanzapine (Panel A) and risperidone (Panel B) and efficacy at lower D₂ receptor occupancy (olanzapine, Panel A). Aripiprazole is a partial D₂ agonist that can achieve only 75% functional blockade.

5HT₂A and 5HT₂C antagonism facilitates DA release and increases noradrenergic outflow from the locus coeruleus. Administration of 5HT₂A and 5HT₂C antagonists in the form of low doses of atypical antipsychotic agents, along with selective serotonin reuptake inhibitors (SSRIs), increases responses rates in SSRI nonresponders. A combination preparation of low-dose olanzapine and fluoxetine is approved for bipolar depression, and low-dose risperidone (i.e., 1 mg) increases clinical response rates when added to existing SSRI treatment in SSRI nonresponders. Aripiprazole is FDA-approved for adjunctive use in antidepressant nonresponders, again at low doses (2-15 mg). Aripiprazole and most other antipsychotic drugs are ineffective as monotherapy for bipolar depression, with quetiapine being the sole exception.

**SCHIZOPHRENIA.** Newer, atypical antipsychotic agents offer a better neurological side-effect profile than typical antipsychotic drugs. Atypical agents show markedly reduced EPS risk compared to typical antipsychotic agents. Excessive D₂ blockade increases risk for motor neurological effects (e.g., muscular rigidity, bradykinesia, tremor, akathisia), slows mentation (bradyphrenia), and interferes with central reward pathways, resulting in patient complaints of anhedonia. In acute psychosis, sedation may be desirable, but the use of a sedating antipsychotic drug may interfere with a patient’s cognitive function and social reintegration.

Schizophrenia patients have a 2-fold higher prevalence of metabolic syndrome and type 2 diabetes mellitus (DM) and twice the rate of cardiovascular (CV) related mortality than the general population. Consensus guidelines recommend baseline determination of serum glucose, lipids, weight, blood pressure, and when possible, waist circumference and personal and family histories of metabolic and CV disease. Drug-induced parkinsonism can also occur,
especially among elderly patients exposed to antipsychotic agents that have high D2 affinity (e.g., typical antipsychotic drugs); recommended doses are ~50% of those used in younger schizophrenia patients.

**LONG-TERM TREATMENT**

The choice of antipsychotic agents for long-term schizophrenia treatment is based primarily on avoidance of adverse effects and, when available, prior history of patient response. Because schizophrenia spectrum disorders are lifelong diseases, treatment acceptability is paramount to effective illness management. Atypical antipsychotic agents offer significant advantages related to reduced neurological risk, with long-term tardive dyskinesia rates <1%, or approximately one-fifth to one-tenth of that seen with typical antipsychotic drugs.

Antipsychotic treatments are associated with metabolic risks that include: weight gain, dyslipidemia (particularly hypertriglyceridemia), an adverse impact on glucose-insulin homeostasis, including new-onset type 2 DM, and diabetic ketoacidosis (DKA), with reported fatalities from the latter. Clozapine and olanzapine have the highest metabolic risk and are only used as last resort.

Acutely psychotic patients usually respond within hours after drug administration, but weeks may be required to achieve maximal drug response, especially for negative symptoms. Usual dosages for acute and maintenance treatment are noted in Table 16–1. Treatment-limiting adverse effects may include weight gain, sedation, orthostasis, and EPS, which to some degree can be predicted based on the potencies of the selected agent to inhibit neurotransmitter receptors (Table 16–2). The detection of dyslipidemia or hyperglycemia is based on laboratory monitoring (see Table 16–1). Certain adverse effects such as hyperprolactinemia, EPS, orthostasis, and sedation may respond to dose reduction, but metabolic abnormalities improve only with discontinuation of the drug and switching to a more metabolically benign medication. Patients with refractory schizophrenia on clozapine are not good candidates for switching because they are resistant to other medications (see the definition of refractory schizophrenia below).

*Dose Forms: O, tablet; S, solution; IM, intramuscular; ODT, orally dissolving tablet.

*bDoses in first episode, younger, or antipsychotic-naive patients are lower than for chronic schizophrenia patients. Dose in elderly patients is ~50% of that used in younger adults: dosing for dementiainduced psychosis is ~25%.

*cDue to orthostasis risk, dose titration of ilipendone is 1 mg 2x/daily on day 1, increasing to 2, 4, 6, 8, 10, and 12 mg 2x/daily on days 2-7 (as needed).

*dIn acute schizophrenia, delirium IM loading doses of 224 mg at day 1 and 156 mg at day 2 provide paliperidone levels equivalent to 6 mg oral paliperidone during the first week and peaking on day 5 at a level comparable to 12 mg oral paliperidone. No oral antipsychotic needed in first week. Maintenance IM doses can be given every 4 weeks after day 8. Maintenance dose options: 39 to 234 mg every 4 weeks. Failure to give initiation doses (except for those switching from depot) will result in subtherapeutic levels for months.

*eNot available in the U.S.

fOral dose must be given with food to facilitate absorption.

</table>
The common problem of medication nonadherence among schizophrenia patients has led to the development of long-acting injectable (LAI) antipsychotic medications, often referred to as *depot antipsychotics*. There are currently 4 available LAI forms in the U.S.: decanoate esters of fluphenazine and haloperidol, risperidone-impregnated microspheres, and paliperidone palmitate. Patients receiving LAI antipsychotic medications show consistently lower relapse rates compared to patients receiving comparable oral forms and may suffer fewer adverse effects.

Lack of response to adequate antipsychotic drug doses for adequate periods of time may indicate treatment-refractory illness. Refractory schizophrenia is defined using the Kane criteria: failed 6-week trials of 2 separate agents and a third trial of a high-dose typical antipsychotic agent (e.g., haloperidol or fluphenazine 20 mg/day). In this patient population, response rates to typical antipsychotic agents, defined as 20% symptom reduction using standard rating scales (e.g., Positive and Negative Syndrome Scale [PANSS]), are 0%, and for any atypical antipsychotic except clozapine, are <10%. The therapeutic clozapine dose for a specific patient is not predictable, but various studies have found correlations between trough serum clozapine levels >327-504 ng/mL and likelihood of clinical response. When therapeutic serum concentrations are reached, response to clozapine occurs within 8 weeks.

Clozapine has numerous other adverse effects. These include agranulocytosis...
risk that mandates routine ongoing hematological monitoring, high metabolic risk, dose-dependent lowering of the seizure threshold, orthostasis, sedation, anticholinergic effects (especially constipation), and sialorrhea related to muscarinic agonism at M₄ receptors. As a result, clozapine use is limited to refractory schizophrenia patients. Electroconvulsive therapy is considered a treatment of last resort in refractory schizophrenia and is rarely employed.

PHARMACOLOGY OF ANTIPSYCHOTIC AGENTS

Tables 16–1 and 16–2 summarize the drug classes, dose ranges, severity metabolic side effects, and potencies at important CNS receptors for a variety of antipsychotic agents.

The introduction of clozapine stimulated research into agents with antipsychotic activity and low EPS risk. This search led to a series of atypical antipsychotic agents with certain pharmacological similarities to clozapine: namely lower affinity for D₂ receptors than typical antipsychotic drugs and high 5HT₂ antagonist effects. Currently available atypical antipsychotic medications include the structurally related olanzapine, quetiapine, and clozapine; risperidone, its active metabolite paliperidone, and iloperidone; ziprasidone; lurasidone; asenapine, and aripiprazole (see Table 16–1).

MECHANISM OF ACTION. All clinically available antipsychotics are antagonists at dopamine D₂ receptors. This reduction in dopaminergic neurotransmission is achieved through D₂ antagonism or partial D₂ agonism (e.g., aripiprazole).

Aripiprazole has an affinity for D₂ receptors only slightly less than DA itself, but its intrinsic activity is ~25% that of DA. That is, when DA is incubated with increasing concentrations of aripiprazole, maximal inhibition of D₂ activity do not exceed 25% of the DA response, the level of agonism provided by aripiprazole. Aripiprazole’s capacity to stimulate D₂ receptors in brain areas where synaptic DA levels are limited (e.g., PFC neurons) or decrease dopaminergic activity when DA concentrations are high (e.g., mesolimbic cortex) is thought to be the basis for its clinical effects in schizophrenia. Even with 100% receptor occupancy, aripiprazole’s intrinsic dopaminergic agonism
can generate a 25% postsynaptic signal, implying a maximal 75% reduction in DA neurotransmission, below the 78% threshold that triggers EPS in most individuals.

The pharmacological basis for the clinical efficacy atypical antipsychotics without EPS induction results from a significantly weaker D2 antagonism, combined with potent 5HT2 antagonism. Clozapine possesses activity at other receptors including antagonism and agonism at various muscarinic receptor subtypes and antagonism at dopamine D4 receptors. However D4 antagonists that do not have D2 antagonism lack antipsychotic activity. Clozapine’s active metabolite, N-desmethylclozapine, is a potent muscarinic M1 agonist.

The glutamate hypofunction hypothesis of schizophrenia has led to novel animal models that examine the influence of antipsychotic agents with agonist properties at metabotropic glutamate receptors mGlu2 and mGlu3 and other subtypes. Atypical antipsychotic drugs are better than typical antipsychotic medications at reversing the negative symptoms, cognitive deficits and social withdrawal induced by glutamate antagonists.

**DOPAMINE RECEPTOR OCCUPANCY AND BEHAVIORAL EFFECTS.** Excessive dopaminergic functions in the limbic system are central to the positive symptoms of psychosis. The behavioral effects and the time course of antipsychotic response parallel the rise in D2 occupancy and include calming of psychomotor agitation, decreased hostility, decreased social isolation, and less interference from disorganized or delusional thought processes and hallucinations. Occupation of ~78% of D2 receptors in the basal ganglia is associated with a risk of EPS across all DA antagonist antipsychotic agents, while occupancies in the range of 60-75% are associated with antipsychotic efficacy (see Figure 16–2). With the exception of aripiprazole, all atypical antipsychotic drugs at low doses have much greater occupancy of 5HT2A receptors (e.g., 75-99%) than typical agents (see Table 16–2).

*D3 and D4 Receptors in the Basal Ganglia and Limbic System.* D3 and D4
receptors are preferentially expressed in limbic areas. The D₄ receptors, which are preferentially localized in cortical and limbic brain regions in low abundance, are upregulated after repeated administration of most typical and atypical antipsychotic drugs. These receptors may contribute to clinical antipsychotic actions, but agents that are D₄ selective (e.g., sonepiprazole) or mixed D₄/5HT₂A antagonists (e.g., fananserin) lack antipsychotic efficacy in clinical studies.

D₃ receptors are unlikely to play a pivotal role in antipsychotic drug actions. The subtle and atypical functional activities of cerebral D₃ receptors suggest that D₃ agonists rather than antagonists may have useful psychotropic effects, particularly in antagonizing stimulant-reward and dependence behaviors.

The Role of Non-Dopamine Receptors for Atypical Antipsychotic Agents. The concept of atypicality was initially based on clozapine’s absence of EPS within the therapeutic range, combined with a prominent role of 5HT₂ receptor antagonism. As subsequent agents were synthesized using clozapine’s 5HT₂/D₂ ratio as a model, most of which possessed greater D₂ affinity and EPS risk than clozapine, there has been considerable debate on the definition of an atypical antipsychotic agent and its necessary properties. Nonetheless, the term “atypical” persists in common usage and designates lesser (but not absent) EPS risk and other decreased effects of excessive D₂ antagonism.

Antipsychotic agents with appreciable 5HT₂ affinity have significant effects at both 5HT₂A and 5HT₂C receptors with individual medications varying in their relative potencies at each subtype. As discussed previously, atypical antipsychotic agents exhibit potent functional antagonism at both subtypes of 5HT₂ receptors, but in vitro assays suggest that these effects result from inverse agonism at these G-coupled receptors.

TOLERANCE AND PHYSICAL DEPENDENCE. As defined in Chapter 24, antipsychotic drugs are not addicting; however, tolerance to the antihistaminic and anticholinergic effects of antipsychotic agents usually develops over days or weeks.

ABSORPTION, DISTRIBUTION, AND ELIMINATION. Most antipsychotic drugs are highly lipophilic, highly membrane- or protein-bound, and accumulate
in the brain, lung, and other tissues with a rich blood supply. They also enter the fetal circulation and breast milk. Despite half-lives that may be short, the biological effects of single doses of most antipsychotic medications usually persist for at least 24 h, permitting once-daily dosing for many agents once the patient has adjusted to initial side effects.

Absorption for most agents is quite high, and concurrent administration of anticholinergic anti-parkinsonian agents does not appreciably diminish intestinal absorption. Most ODTs and liquid preparations provide similar pharmacokinetics. Asenapine remains the only exception; it is available only as an ODT preparation administered sublingually, and all absorption occurs via oral mucosa, with bioavailability of 35% by this route. If asenapine is swallowed, the first pass effect is >98%, indicating that drug swallowed with oral secretions is not bioavailable. IM administration avoids much of the first-pass enteric metabolism and provides measurable concentrations in plasma within 15-30 min. Most agents are highly protein bound, but this protein binding may include glycoprotein sites. Antipsychotic medications are predominantly highly lipophilic with apparent volumes of distribution as high as 20 L/kg.

Elimination from the plasma may be more rapid than from sites of high lipid content and binding, notably the CNS. Slow removal of drug may contribute to the typical delay of exacerbation of psychosis after stopping drug treatment. Depot decanoate esters of fluphenazine and haloperidol, paliperidone palmitate, as well as risperidone-impregnated microspheres, are absorbed and eliminated much more slowly than are oral preparations. For example, the $t_{1/2}$ of oral fluphenazine is ~20 h, while the IM decanoate ester has a $t_{1/2}$ of 14.3 days; oral haloperidol has a $t_{1/2}$ of 24-48 h in CYP2D6-extensive metabolizers, while haloperidol decanoate has a $t_{1/2}$ of 21 days; paliperidone palmitate has a $t_{1/2}$ of 25-49 days compared to an oral paliperidone $t_{1/2}$ of 23 h. Clearance of fluphenazine and haloperidol decanoate following repeated dosing can require 6-8 months. Effects of LAI risperidone (RISPERDAL CONSTA) are delayed for 4 weeks because of slow biodegradation of the microspheres and persist for at least 4-6 weeks after the injections are discontinued. The dosing regimen recommended for starting patients on LAI paliperidone generates therapeutic levels in the first week, obviating the need for routine oral antipsychotic supplementation.
With the exception of asenapine, paliperidone, and ziprasidone, all antipsychotic drugs undergo extensive phase I metabolism by CYPs and subsequent phase II glucuronidation, sulfation, and other conjugations. Hydrophilic metabolites of these drugs are excreted in the urine and to some extent in the bile. Most oxidized metabolites of antipsychotic drugs are biologically inactive; a few (e.g., P88 metabolite of iloperidone, hydroxy metabolite of haloperidol, 9-OH risperidone, N-desmethylclozapine, and dehydroaripiprazole) are active. These active metabolites may contribute to biological activity of the parent compound and complicate correlating serum drug levels with clinical effects. Table 16–3 in the 12th edition of the parent text outlines the metabolic pathways of selected agents in common use.

Table 16–3

Neurological Side Effects of Antipsychotic Drugs
THERAPEUTIC USES

Antipsychotic agents are also used in several nonpsychotic neurological disorders and as antiemetics.

ANXIETY DISORDERS. Adjunctive treatments with antipsychotic drugs are beneficial in obsessive-compulsive disorder (OCD) and posttraumatic stress disorder (PTSD). Adjunctive low-dose quetiapine, olanzapine, and particularly risperidone significantly reduce the overall level of symptoms in SSRI-resistant PTSD, and OCD patients with limited response to the standard 12-week regimen of high-dose SSRI also benefit from adjunctive risperidone (mean dose 2.2 mg),
even in the presence of comorbid tic disorders. For generalized anxiety disorder, double-blind placebo-controlled clinical trials demonstrate efficacy for quetiapine as monotherapy, and for adjunctive low-dose risperidone.

TOURETTE DISORDER. The ability of antipsychotic drugs to suppress tics in patients with Tourette disorder relates to reduced D<sub>2</sub> neurotransmission in basal ganglia sites. While lacking FDA approval for tic disorders, risperidone and aripiprazole have indications for child and adolescent schizophrenia and bipolar disorder (acute mania) treatment, and these agents (as well as ziprasidone) have published data supporting their use for tic suppression.

HUNTINGTON DISEASE. Huntington disease is associated with basal ganglia pathology. DA blockade can suppress the severity of choreoathetotic movements, but is not strongly endorsed due to the risks associated of excessive DA antagonism that outweigh the marginal benefit. Inhibition of the vesicular monoamine transporter type 2 (VMAT2) with tetrabenazine has replaced DA receptor blockade in the management of chorea (see Chapter 22).

AUTISM. Risperidone has FDA approval for irritability associated with autism in child and adolescent patients ages 5-16, with common use for disruptive behavior problems in autism and other forms of mental retardation. Initial risperidone daily doses are 0.25 mg for patients weighing <20 kg, and 0.5 mg for others, with a target dose of 0.5 mg/day in those <20 kg weight, and 1.0 mg/day for other patients, with a range 0.5-3.0 mg/day.

ANTIEMETIC USE. Most antipsychotic drugs protect against the nausea- and emesis-inducing effects of DA agonists. Drugs or other stimuli that cause emesis by an action on the nodose ganglion, or locally on the GI tract, are not antagonized by antipsychotic drugs, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation. The commonly used antiemetic phenothiazines are weak DA antagonists (e.g., prochlorperazine) without antipsychotic activity, but can be associated with EPS or akathisia.

ADVERSE EFFECTS PREDICTED BY MONOAMINE RECEPTOR AFFINITIES (SEE TABLE 16–2)
Dopamine D₂ Receptor. With the exception of the D₂ partial agonist aripiprazole, all other antipsychotic agents possess D₂ antagonist properties, the strength of which determines the likelihood for EPS, akathisia, long-term tardive dyskinesia risk, and hyperprolactinemia. The manifestations of EPS are described in Table 16–3, along with the usual treatment approach. Acute dystonic reactions occur in the early hours and days of treatment with highest risk among younger patients (peak incidence ages 10-19), especially antipsychotic drug-naïve individuals, in response to abrupt decreases in nigrostriatal D₂ neurotransmission. The dystonia typically involves head and neck muscles, the tongue, and in its severest form, the oculogyric crisis, extraocular muscles, and is very frightening to the patient.

Parkinsonism resembling its idiopathic form occurs when striatal D₂ occupancy exceeds 78%. Clinically, there is a generalized slowing and impoverishment of volitional movement (bradykinesia) with masked facies and reduced arm movements during walking. The syndrome characteristically evolves gradually over days to weeks as the risk of acute dystonia diminishes. The treatment of acute dystonia and antipsychotic-induced parkinsonism involves the use of antiparkinsonian agents, although dose reduction should be considered as the initial strategy for parkinsonism. Muscarinic cholinergic receptors modulate nigrostriatal DA release, with blockade increasing synaptic DA availability. Important issues in the use of anticholinergics include the negative impact on cognition and memory, peripheral antimuscarinic adverse effects (e.g., urinary retention, dry mouth, cycloplegia, etc.), and the relative risk of exacerbating tardive dyskinesia.

Amantadine (SYMMETREL), originally marketed as an antiviral agent toward influenza A, represents the most commonly used nonanticholinergic medication for antipsychotic-induced parkinsonism. Its mechanism of action is unclear but appears to involve presynaptic DA reuptake blockade, facilitation of DA release, postsynaptic DA agonism, and receptor modulation.

Tardive dyskinesia is a situation of increased nigrostriatal dopaminergic activity as the result of postsynaptic receptor supersensitivity and upregulation from chronically high levels of postsynaptic D₂ blockade (and possible direct toxic effects of high-potency DA antagonists). Tardive dyskinesia is characterized by stereotyped, repetitive, painless, involuntary, quick choreiform (tic-like)
movements of the face, eyelids (blinks or spasm), mouth (grimaces), tongue, extremities, or trunk. The dyskinetic movements can be suppressed partially by use of a potent DA antagonist, but such interventions over time may worsen the severity. Switching patients from potent D₂ antagonists to weaker agents, especially clozapine has at times proven effective. When possible, drug discontinuation may be beneficial, but usually cannot be offered to schizophrenia patients.

Akathisia is seen quite commonly during treatment with high doses of high potency typical antipsychotic drugs, but also can be seen with atypical agents, including those with weak D₂ affinities (e.g., quetiapine), and aripiprazole. Despite the association with D₂ blockade, akathisia does not have a robust response to antiparkinsonian drugs, so other treatment strategies must be employed, including the use of high-potency benzodiazepines (e.g., clonazepam), nonselective β-blockers with good CNS penetration (e.g., propranolol), and also dose reduction, or switching to another antipsychotic agent. That clonazepam and propranolol have significant cortical activity and are ineffective for other forms of EPS, points to an extrastriatal origin for akathisia symptoms.

The rare neuroleptic malignant syndrome (NMS) resembles a very severe form of parkinsonism, with signs of autonomic instability (hyperthermia and labile pulse, blood pressure, and respiration rate), stupor, elevation of creatine kinase in serum, and sometimes myoglobinemia with potential nephrotoxicity. The prevalence of this reaction is greater when relatively high doses of potent agents are used, especially when they are administered parenterally.

Hyperprolactinemia results from blockade of the pituitary actions of the tuberoinfundibular dopaminergic neurons that deliver DA to the anterior pituitary. D₂ receptors on lactotropes in the anterior pituitary mediate the tonic prolactin-inhibiting action of DA. Correlations between the D₂ potency of antipsychotic drugs and prolactin elevations are excellent. With the exception of risperidone and paliperidone, atypical antipsychotic agents show limited (asenapine, iloperidone, olanzapine, quetiapine, ziprasidone) to almost no effects (clozapine, aripiprazole) on prolactin secretion.

H₁ Receptors. Central antagonism of H₁ receptors is associated with 2 major
adverse effects: sedation and weight gain via appetite stimulation. Examples of sedating antipsychotic drugs include low-potency typical agents such as chlorpromazine and thioridazine, and the atypical agents clozapine and quetiapine. The sedating effect is easily predicted by their high H$_1$ receptor affinities (see Table 16–2). Some tolerance to the sedative properties will develop.

**M$_1$ Receptors.** Muscarinic antagonism is responsible for the central and peripheral anticholinergic effects of medications. Most of the atypical antipsychotic drugs have no muscarinic affinity and no appreciable anticholinergic effects, while clozapine and low-potency phenothiazines have significant anticholinergic adverse effects (see Table 16–2). Quetiapine has modest muscarinic affinity, but its active metabolite norquetiapine is likely responsible for anticholinergic complaints. Clozapine is particularly associated with significant constipation. Routine use of stool softeners, and repeated inquiry into bowel habits are necessary to prevent serious intestinal obstruction from undetected constipation. Medications with significant anticholinergic properties should be particularly avoided in elderly patients, especially those with dementia or delirium.

**α$_1$ Receptors.** α$_1$ Adrenergic antagonism is associated with risk of orthostatic hypotension and can be particularly problematic for elderly patients who have poor vasomotor tone. Compared to high-potency typical agents, low-potency typical agents have significantly greater affinities for α$_1$ receptors and greater risk for orthostasis. While risperidone has a $K_i$ that indicates greater α$_1$ adrenergic affinity than chlorpromazine, thioridazine, clozapine, and quetiapine, in clinical practice risperidone is used at 0.01-0.005 times the dosages of these medications, and thus causes a relatively lower incidence of orthostasis in nonelderly patients. Since clozapine-treated patients have few other antipsychotic options, the potent mineralocorticoid fludrocortisone is sometimes tried at the dose of 0.1 mg/day as a volume expander.

**ADVERSE EFFECTS NOT PREDICTED BY MONOAMINE RECEPTOR**
AFFINITIES

ADVERSE METABOLIC EFFECTS. Such effects have become the area of greatest concern during long-term antipsychotic treatment, paralleling the overall concern for high prevalence of prediabetic conditions and type 2 DM, and 2-fold greater CV mortality among patients with schizophrenia. Aside from weight gain, the 2 predominant metabolic adverse effects seen with antipsychotic drugs are dyslipidemia, primarily elevated serum triglycerides, and impairments in glycemic control.

Low-potency phenothiazines were known to elevate serum triglyceride values, but this effect was not seen with high-potency agents. As atypical antipsychotic drugs became more widely used, significant increases in fasting triglyceride levels were noted during clozapine and olanzapine exposure, and to a lesser extent, with quetiapine. Mean increases during chronic treatment of 50-100 mg/dL are common, with serum triglyceride levels exceeding 7000 mg/dL in some patients. Effects on total cholesterol and cholesterol fractions are significantly less, but show expected associations related to agents of highest risk: clozapine, olanzapine, and quetiapine. Risperidone and paliperidone have fewer effects on serum lipids, while asenapine, iloperidone, aripiprazole, and ziprasidone appear to have none. Weight gain in general may induce deleterious lipid changes, but there is compelling evidence to indicate that antipsychotic-induced hypertriglyceridemia is a weight-independent adverse event that temporally occurs within weeks of starting an offending medication, and which similarly resolves within 6 weeks after medication discontinuation.

In individuals not exposed to antipsychotic drugs, elevated fasting triglycerides are a direct consequence of insulin resistance since insulin-dependent lipases in fat cells are normally inhibited by insulin. Elevated fasting triglyceride levels thus become a sensitive marker of insulin resistance, leading to the hypothesis that the triglyceride increases seen during antipsychotic treatment are the result of derangements in glucose-insulin homeostasis. Analysis of the FDA MedWatch database found that reversibility was high upon drug discontinuation (~78%) for olanzapine- and clozapine-associated diabetes and ketoacidosis, supporting the contention of a drug effect. Comparable rates for risperidone and quetiapine were significantly lower. The mechanism by which antipsychotic
drugs disrupt glucose-insulin homeostasis is not known.

Antipsychotics increase risk for metabolic disorders among patients with schizophrenia, and the medication itself seems to be the primary modifiable risk factor. As a result, all atypical antipsychotic drugs have a hyperglycemia warning in the drug label in the U.S., although there is essentially no evidence that asenapine, iloperidone, aripiprazole, and ziprasidone cause hyperglycemia. Clinicians should obtain baseline metabolic data, including fasting glucose, lipid panel, and also waist circumference, given the known association between central obesity and future type 2 diabetes risk. Ongoing follow-up of metabolic parameters is commonly built into psychiatric charts and community mental health clinic procedures to insure that all patients receive some level of metabolic monitoring.

**ADVERSE CARDIAC EFFECTS.** Ventricular arrhythmias and sudden cardiac death (SCD) are a concern with the use of antipsychotic agents.

Most of the older antipsychotic agents (e.g., thioridazine) inhibit cardiac K⁺ channels, and all antipsychotic medications marketed in the U.S. carry a class label warning regarding QTc prolongation. A black box warning exists for thioridazine, mesoridazine, pimozide, IM droperidol, and IV (but not oral or IM) haloperidol due to reported cases of torsade de pointes and subsequent fatal ventricular arrhythmias. Although the newer atypical agents are thought to have less effects on heart electrophysiology compared to the typical agents, a recent retrospective study found a dose-dependent increased risk for SCD among antipsychotic users of newer and older agents alike compared to antipsychotic nonusers, with a relative risk of 2.

**Other Adverse Effects.** Seizure risk is an unusual adverse effect of antipsychotic drugs. In the U.S., there is a class label warning for seizure risk on all antipsychotic agents, with reported incidences well below 1%. Among commonly used newer antipsychotic drugs, only clozapine has a dose-dependent seizure risk, with an incidence of 3-5% per year. Seizure disorder patients who commence antipsychotic treatment must receive adequate prophylaxis, with consideration given to avoiding carbamazepine and phenytoin due to their capacity to induce CYPs and P-glycoprotein. Carbamazepine is also
contraindicated during clozapine treatment due to its bone marrow effects, particularly leukopenia. Redistribution and increased spacing of doses to minimize high peak serum clozapine levels can help, but patients may eventually require antiseizure medication. Valproic acid derivatives (e.g., divalproex sodium) are often used, but will compound clozapine-associated weight gain.

Clozapine possesses a host of unusual adverse effects aside from seizure induction, the most concerning of which is agranulocytosis. Clozapine’s introduction in the U.S. was based on its efficacy in refractory schizophrenia, but came with FDA-mandated CBC monitoring that is overseen by industry-created registries. Now that several generic forms of clozapine are available in addition to proprietary CLOZARIL, clinicians must verify with each manufacturer the history of prior exposure. Increased risk is associated with certain HLA types and advanced age.

While rarely used due to its risk of QTc prolongation, thioridazine is also associated with pigmentary retinopathy at daily doses ≥800 mg/day. Low-potency phenothiazines are associated with the development of photosensitivity, which necessitated warnings regarding sun exposure. Phenothiazines are also associated with development of a cholestatic picture on laboratory assessments (e.g., elevated alkaline phosphatase), and rarely elevations in hepatic transaminases.

**Increased Mortality in Dementia Patients.** All antipsychotic agents carry a mortality warning in the drug label regarding their use in dementia patients. Mortality is due to heart failure, sudden death, or pneumonia. Overdose with typical antipsychotic agents is of particular concern with low-potency agents (e.g., chlorpromazine) due to the risk of torsade de pointes, sedation, anticholinergic effects, and orthostasis. Patients who overdose on high-potency typical antipsychotic drugs (e.g., haloperidol) and the substituted benzamides are at greater risk for EPS due to the high D₂ affinity, but also must be observed for ECG changes.

**DRUG-DRUG INTERACTIONS.** Antipsychotic agents are not significant inhibitors of CYP enzymes with a few notable exceptions (chlorpromazine, perphenazine, and thioridazine inhibit CYP 2D6). The plasma half-lives of a number of these agents are altered by
induction or inhibition of hepatic CYPs and by genetic polymorphisms that alter specific CYP activities (Table 7–3; see also Table 16–3 in the parent text, 12th edition). Smoking causes upregulation in CYP1A2 activity, and changes in smoking status can be especially problematic for clozapine-treated patients and will alter serum levels by 50% or more.

USE IN PEDIATRIC POPULATIONS. Both risperidone and aripiprazole have indications for child and adolescent bipolar disorder (acute mania) for ages 10-17, and for adolescent schizophrenia (ages 13-17). Risperidone and aripiprazole are FDA-approved for irritability associated with autism in child and adolescent patients ages 5-16. Antipsychotic drug-naïve patients and younger patients are more susceptible to EPS and to weight gain. Use of the minimum effective dose can minimize EPS risk.

USE IN GERIATRIC POPULATIONS. The increased sensitivity to EPS, orthostasis, sedation, and anticholinergic effects are important issues for the geriatric population, and often dictate the choice of antipsychotic medication. Avoidance of drug-drug interactions is also important, as older patients on numerous concomitant medications have multiple opportunities for interactions. Elderly patients have an increased risk for tardive dyskinesia and parkinsonism. Increased risk for cerebrovascular events and all-cause mortality is also seen in elderly patients with dementia. Compared to younger patients, antipsychotic-induced weight gain is lower in elderly patients.

USE DURING PREGNANCY AND LACTATION. Antipsychotic agents carry pregnancy class B or C warnings. Human data indicate no patterns of toxicity and no consistent increased rates of malformations. Haloperidol is often cited as the agent with the best safety record based on decades of accumulated human exposure reports. Antipsychotic drugs are designed to cross the blood-brain barrier, and all have high rates of placental passage. Use in lactation presents a separate set of concerns due to the low level of infant hepatic catabolic activity in the first 2 postpartum months. The inability of the newborn to adequately metabolize xenobiotics presents a significant risk for antipsychotic drug toxicity.

TREATMENT OF MANIA
Mania is a period of elevated, expansive, or irritable mood with coexisting symptoms of increased energy and goal-directed activity, and decreased need for sleep. Mania represents 1 pole of what had been termed manic-depressive illness, but is now referred to as bipolar disorder. Mania may be induced by medications (e.g., DA agonists, antidepressants, stimulants) or substances of abuse, primarily cocaine and amphetamines, although periods of substance-induced mania should not be relied on solely to make a diagnosis of bipolar disorder.

Mania is distinguished from its less severe form, hypomania, by the fact that hypomania, by definition, does not result in functional impairment or hospitalization, and is not associated with psychotic symptoms. Patients who experience periods of hypomania and major depression have bipolar II disorder, those with mania at any time, bipolar I, and those with hypomania, but less severe forms of depression, cyclothymia. The prevalence of bipolar I disorder is roughly 1% of the population, and the prevalence of all forms of bipolar disorder 3-5%. Genetics studies of bipolar disorder have yielded several loci of interest associated with disease risk and predictors of treatment response, but the data are not yet at the phase of clinical application.

There is no medication designed to treat the full spectrum of bipolar disorder. While many classes of agents demonstrate efficacy in acute mania, including lithium, antipsychotic drugs, and certain anticonvulsants, no medication has surpassed lithium’s efficacy for prophylaxis of future manic and depressive phases of bipolar disorder, and no other medication has demonstrated lithium’s reduction in suicidality among bipolar patients.

**PHARMACOLOGICAL PROPERTIES OF AGENTS FOR MANIA**

**ANTIPSYCHOTIC AGENTS.** The chemistry and pharmacology of antipsychotic medications are addressed earlier in this chapter.

**ANTICONVULSANTS.** The pharmacology and chemistry of the anticonvulsants with significant data for acute mania (valproic acid compounds, carbamazepine) and for bipolar maintenance
(lamotrigine) are covered in Chapter 21. These compounds are of
diverse chemical classes, but share the common property of functional
blockade of voltage-gated Na\(^+\) channels, albeit with differing binding
sites. These anticonvulsants have varying affinities for voltage-
dependent Ca\(^{2+}\) channels, and differ in their ability to facilitate
GABA-ergic (valproate) or inhibit glutamatergic neurotransmission
(lamotrigine).

**LITHIUM.** Salts of the monovalent cation lithium (Li\(^+\)) share some
characteristics with those of Na\(^+\) and K\(^+\). Traces of the ion occur normally in
animal tissues, but it has no known physiological role. Lithium carbonate and
lithium citrate are used therapeutically in the U.S.

*Hypotheses for the Mechanism of Action of Lithium, and Relationship to
Anticonvulsants.* In animal brain tissue, Li\(^+\) at concentrations of 1-10 mEq/L
inhibits the depolarization-provoked and Ca\(^{2+}\)-dependent release of NE and DA,
but not 5HT, from nerve terminals. Li\(^+\) may even transiently enhance release of
5HT. Li\(^+\) modifies some hormonal responses mediated by adenylly cyclase or
PLC in other tissues, including the actions of vasopressin and thyroid-
stimulating hormone on their peripheral target tissues. Li\(^+\) can inhibit the effects
of receptor-blocking agents that cause supersensitivity in such systems. In part,
the actions of Li\(^+\) may reflect its ability to interfere with the activity of both
stimulatory and inhibitory G proteins (G\(_s\) and G\(_i\)) by keeping them in their
inactive \(\alpha\beta\gamma\) trimeric states.

Lithium’s therapeutic efficacy may involve inhibition of inositol
monophosphatase of the phosphatidylinositol pathway (see Figure 16–1),
leading to decreased cerebral inositol concentrations (see Chapter 3). Further
support for the role of inositol signaling in mania rests on the finding that
valproate, and valproate derivatives, decrease intracellular inositol
concentrations. Li\(^+\) treatment also leads to consistent decreases in the
functioning of protein kinases in brain tissue, including PKC, particularly
isoforms \(\alpha\) and \(\beta\). This effect is also shared with valproic acid (particularly for
PKC) but not with carbamazepine. The impact of Li\(^+\) or valproate on PKC
activity may secondarily alter the release of amine neurotransmitters and
hormones as well as the activity of tyrosine hydroxylase. The proposed
mechanism of PKC inhibition has been the basis for therapeutic trials of
tamoxifen, a selective estrogen receptor modulator that is also a potent centrally active PKC inhibitor. In acutely manic bipolar I patients, tamoxifen has shown evidence of efficacy as adjunctive treatment.

Both Li+ and valproate treatment inhibit the activity of glycogen synthase kinase-3β (GSK-3β). GSK-3β inhibition increases hippocampal levels of β-catenin, a function implicated in mood stabilization. GSK-3β regulates mood stabilizer-induced axonal growth and synaptic remodeling and modulates brain-derived neurotrophic factor response. Li+ and valproate reduce arachidonic acid turnover in brain membrane phospholipids, and Li+ also decreases gene expression of PLA2 and decreases levels of COX-2.

**ABSORPTION, DISTRIBUTION, AND ELIMINATION.** Li+ is absorbed readily and almost completely from the GI tract. Peak plasma concentrations achieved 2-4 h after an oral dose. Slow-release preparations of lithium carbonate minimize early peaks in plasma concentrations, and may decrease local GI adverse effects, but the increased trough levels may increase the risk for nephrogenic diabetes insipidus. Li+ initially is distributed in the extracellular fluid, and gradually accumulates in various tissues. The concentration gradient across plasma membranes is much smaller than those for Na+ and K+. The final volume of distribution (0.7-0.9 L/kg) approaches that of total body water. Passage through the blood-brain barrier is slow, and at steady state, the concentration of Li+ in the cerebrospinal fluid and in brain tissue is ~40-50% of the concentration in plasma.

Approximately 95% of a single dose of Li+ is eliminated in the urine. From 33-66% of an acute dose is excreted during the first 6-12 h, followed by slow excretion over the next 10-14 days. The elimination $t_{1/2}$ averages 20-24 h. Steady state is achieved after ~5 half-lives. Loading with Na+ produces a small enhancement of Li+ excretion, but Na+ depletion promotes a clinically important degree of Li+ retention. Li+ is completely filtered, and 80% is reabsorbed in the proximal tubules. Heavy sweating leads to a preferential secretion of Li+ over Na+; however, the repletion of excessive sweating using free water without electrolytes can cause hyponatremia, and promote Li+ retention. Thiazide diuretics deplete Na+ and reduce Li+ clearance that may result in toxic levels.
The K⁺-sparing diuretics triamterene, spironolactone, and amiloride have modest effects on the excretion of Li⁺. Less than 1% of ingested Li⁺ leaves the human body in the feces; 4-5% is secreted in sweat. Li⁺ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. Li⁺ is secreted in human milk, but serum levels in breast-fed infants are ~20% that of maternal levels, and are not associated with notable behavioral effects.

**SERUM LEVEL MONITORING AND DOSE.** Because of the low therapeutic index for Li⁺, periodic determination of serum concentrations is crucial.

Concentrations considered to be effective and acceptably safe are between 0.6 and 1.5 mEq/L. The range of 1.0-1.5 mEq/L is favored for treatment of acutely manic or hypomanic patients. Somewhat lower values (0.6-1.0 mEq/L) are considered adequate and are safer for long-term prophylaxis. Serum concentrations of Li⁺ have been found to follow a clear dose-effect relationship between 0.4 and 1.0 mEq/L, but with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects. Nonetheless, patients who maintain trough levels of 0.8-1.0 mEq/L experience decreased relapse risk compared to those maintained at lower serum concentrations.

**THERAPEUTIC USES**

**DRUG TREATMENT OF BIPOLAR DISORDER.** Treatment with Li⁺ ideally is conducted in patients with normal cardiac and renal function. Li⁺ is the only mood stabilizer with data on suicide reduction in bipolar patients, and Li⁺ also has abundant efficacy data for augmentation in unipolar depressive patients who are inadequate responders to antidepressant therapy.

**DRUG TREATMENT OF MANIA.** While Li⁺, valproate, and carbamazepine have efficacy in acute mania, in clinical practice these are usually combined with atypical antipsychotic drugs, due to their delayed onset of action. Li⁺, carbamazepine, and valproic acid preparations are only effective with daily dosing that maintains
adequate serum levels, and require serum level monitoring. Acute IM forms of olanzapine, ziprasidone, and aripiprazole can be used to achieve rapid control of psychosis and agitation. Benzodiazepines are often used adjunctively for agitation and sleep induction.

A 600-mg loading dose of Li+ can be given to hasten the time to steady state. Acutely manic patients may require higher dosages to achieve therapeutic serum levels, and downward adjustment may be necessary once the patient is euthymic.

The anticonvulsant sodium valproate provides more rapid antimanic effects than Li+, with therapeutic benefit seen within 3-5 days. The most common form of valproate in use is divalproex sodium, preferred over valproic acid due to lower incidence of GI and other adverse effects. Divalproex is initiated at 25 mg/kg once daily and titrated to effect or the desired serum concentration. Serum concentrations of 90-120 μg/mL show the best response in clinical studies. With immediate release forms of valproic acid and divalproex sodium, 12-h troughs are used to guide treatment. With the extended-release divalproex preparation, patients respond best when the 24-h trough levels are in the high therapeutic range.

Carbamazepine is effective for acute mania. Immediate release forms of carbamazepine cannot be loaded or rapidly titrated over 24 h due to the development of neurological adverse effects such as dizziness or ataxia. The extended-release form is better tolerated and effective as monotherapy with once-daily dosing. Carbamazepine response rates are lower than those for valproate compounds or Li+; nevertheless, certain individuals respond to carbamazepine after failing Li+ and valproate. Initial doses are 400 mg/day, with the larger dose given at bedtime due to the sedating properties of carbamazepine. Titration proceeds by 200-mg increments every 24-48 h based on clinical response and serum trough levels. Due to increased risk of Stevens-Johnson syndrome in Asian individuals, HLA testing must be performed prior to treatment in populations at risk.

PROPHYLACTIC TREATMENT OF BIPOLAR DISORDER. Both aripiprazole and olanzapine are effective as monotherapy for mania
prophylaxis, but olanzapine use is eschewed out of concern for metabolic effects, and aripiprazole shows no benefit for prevention of depressive relapse. LAI risperidone is also approved for bipolar maintenance treatment to be used adjunctively with Li+ or valproate, or as monotherapy. Clozapine can be beneficial in refractory mania patients as adjunctive therapy and as monotherapy.

Bipolar disorder is a lifetime illness with high recurrence rates. Stopping mood stabilizer therapy can be considered in patients who have experienced only 1 lifetime manic episode, and who have been euthymic for extended periods. Discontinuation of maintenance Li+ treatment in bipolar I patients carries a high risk of early recurrence and of suicidal behavior over a period of several months. This risk may be moderated by slow, gradual removal of Li+, while rapid discontinuation should be avoided unless dictated by medical emergencies.

OTHER USES OF LITHIUM. Li+ has been shown to be effective as adjunct therapy in treatment-resistant major depression. Clinical data also support Li+ use as monotherapy for unipolar depression. Meta-analyses indicate that lithium’s benefit on suicide reduction extends to unipolar mood disorder patients. While maintenance Li+ levels of 0.6-1.0 mEq/L are used for bipolar prophylaxis, a lower range (0.4-0.8 mEq/L) is recommended for antidepressant augmentation.

INTERACTIONS WITH OTHER DRUGS. Interactions between Li+ and diuretics (especially thiazides spironolactone and amiloride), angiotensin-converting enzyme inhibitors, and nonsteroidal anti-inflammatory agents have been discussed earlier. Amiloride has been used safely to reverse the syndrome of nephrogenic diabetes insipidus associated with Li+ therapy, but requires careful monitoring and Li+ dosage reduction to prevent lithium toxicity.

ADVERSE EFFECTS

CNS Effects. The most common CNS effect of Li+ in the therapeutic dose range is fine postural hand tremor. Severity and risk for tremor are dose-dependent, with incidence ranging from 15-70%. In addition to the avoidance of caffeine and other agents that increase tremor amplitude, therapeutic options include dose reduction (bearing in
mind the increased relapse risk with lower serum Li+ levels), or β adrenergic blockade. Valproate treatment has a similar problem, and the approach to valproate-induced tremor is identical. At peak serum (and CNS) levels, some individuals may complain of incoordination, ataxia, or slurred speech, which can be avoided by dosing Li+ at bedtime. Li+ routinely causes EEG changes characterized by diffuse slowing, widened frequency spectrum, and potentiation with disorganization of background rhythm. Seizures have been reported in nonepileptic patients with therapeutic plasma concentrations of Li+. Li+ treatment has also been associated with increased risk of post-ECT confusion, and is generally tapered off prior to a course of ECT.

Li+ (and valproate) treatment results in significant weight gain, a problem that is magnified by concurrent use of antipsychotic drugs.

**Renal Effects.** The kidneys’ ability to concentrate urine decreases during Li+ therapy, and ~60% of individuals exposed to Li+ experience some form of polyuria and compensatory polydipsia. The mechanism of polyuria is unclear, but the result is decreased vasopressin stimulation of renal reabsorption of water, and the clinical picture of nephrogenic diabetes insipidus. Mean 24-h urinary volumes of 3 L/day are common among long-term Li+ users, but Li+ discontinuation or a switch to single daily dosing may reverse the effect on renal concentrating ability in patients with <5 years of Li+ exposure. Renal function should be monitored with biannual serum blood urea nitrogen and creatinine levels, calculation of estimated GFR using standard formulas, and annual measurement of 24-h urinary volume.

**Thyroid and Endocrine Effects.** A small number of patients on Li+ develop a benign, diffuse, nontender thyroid enlargement suggestive of compromised thyroid function, although many of these patients will have normal thyroid function. Measurable effects of Li+ on thyroid indices are seen in a fraction of patients: 7-10% develop overt hypothyroidism, and 23% have subclinical disease, with women at 3-9 times greater risk. Ongoing monitoring of TSH and free T4 is recommended throughout the course of Li+ treatment.

**ECG Effects.** The prolonged use of Li+ causes a benign and reversible T-wave
flattening in ~20% of patients and the appearance of U waves, effects unrelated to depletion of Na⁺ or K⁺. Li⁺-induced effects on cardiac conduction and pacemaker automaticity become pronounced during overdose and lead to sinus bradycardia, atrioventricular blocks, and possible CV compromise. Routine ECG monitoring may be considered in older patients, particularly those with a history of arrhythmia or coronary heart disease.

Skin Effects. Allergic reactions such as dermatitis, folliculitis, and vasculitis can occur with Li⁺ administration. Worsening of acne vulgaris, psoriasis, and other dermatological conditions are usually treatable by topical measures, but in some may improve only upon discontinuation of Li⁺. Some patients on Li⁺ (and valproate) may experience alopecia.

PREGNANCY AND LACTATION. Li⁺ is classified as risk category D. The use of Li⁺ in early pregnancy may be associated with an increase in the incidence of CV anomalies of the newborn, especially Ebstein malformation. Although the anticonvulsants valproic acid and carbamazepine are also pregnancy risk category D, these agents are associated with irreversible neural tube defects. Potentially safer treatments for acute mania include antipsychotic drugs or ECT.

In pregnancy, maternal polyuria may be exacerbated by Li⁺. Concomitant use of Li⁺ with medications that waste Na⁺ or a low-Na⁺ diet during pregnancy can contribute to maternal and neonatal Li⁺ intoxication. Li⁺ freely crosses the placenta, and fetal or neonatal Li⁺ toxicity may develop when maternal blood levels are within the therapeutic range. Fetal Li⁺ exposure is associated with neonatal goiter, CNS depression, hypotonia (“floppy baby” syndrome), and cardiac murmur. Most recommend withholding lithium therapy for 24-48 h before delivery.

Other Effects. A benign, sustained increase in circulating polymorphonuclear leukocytes (12,000-15,000 cells/mm³) occurs during the chronic use of Li⁺ and is reversed within a week after termination of treatment. Some patients complain of a metallic taste, making food less palatable. Myasthenia gravis may worsen during treatment with Li⁺.

ACUTE TOXICITY AND OVERDOSE. Acute intoxication is characterized by
vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the nervous system and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible, with persistent cerebellar tremor being the most common. Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria.

USE IN PEDIATRIC AND GERIATRIC POPULATIONS

Pediatric Use. Only Li+ has FDA approval for child/adolescent bipolar disorder for ages >12 years. Recently, aripiprazole and risperidone were FDA-approved for acute mania in children and adolescents ages 10-17. Children and adolescents have higher volumes of body water and higher GFR than adults. The resulting shorter $t_{1/2}$ of Li+ demands dosing increases on a mg/kg basis, and multiple daily dosing is often required. As with adults, ongoing monitoring of renal and thyroid function is important. A number of studies suggest that valproate has efficacy comparable to that of Li+ for mania in children or adolescents. As with Li+, weight gain and tremor can be problematic. Ongoing monitoring of platelets and liver function tests, in addition to serum drug levels, is recommended.

Geriatric Use. The majority of older patients on Li+ therapy are maintained for years on the medication. Age-related reductions in total body water and creatinine clearance reduce the safety margin for Li+ treatment in older patients. Li+ toxicity occurs more frequently in elderly patients, in part as the result of concurrent use of loop diuretics and angiotensin-converting enzyme inhibitors. Anticonvulsants, especially extended-release divalproex, are a reasonable alternative to Li+. Elderly patients who are drug-naïve may be more sensitive to CNS adverse effects.

MAJOR DRUGS AVAILABLE IN THE CLASS

FORMULATIONS. Most Li+ preparations currently used in the U.S.
are tablets or capsules of lithium carbonate in strengths of 150, 300, and 600 mg. Slow-release preparations of lithium carbonate also are available in strengths of 300 and 450 mg, as is lithium citrate syrup (with 8 mEq of Li+/5 mL citrate liquid, equivalent to 300 mg of lithium carbonate). Because slow-release forms carry an increased risk for polyuria, their use should be limited to patients who experience GI side effects related to rapid absorption.
The CNS depressants discussed in this chapter include benzodiazepines, other benzodiazepine receptor agonists (the “Z compounds”), barbiturates, and sedative-hypnotic agents of diverse chemical structure. Older sedative-hypnotic drugs depress the CNS in a dose-dependent fashion, progressively producing a spectrum of responses from mild sedation to coma and death. A sedative drug decreases activity, moderates excitement, and calms the recipient, whereas a hypnotic drug produces drowsiness and facilitates the onset and maintenance of a state of sleep that resembles natural sleep in its electroencephalographic characteristics and from which the recipient can be aroused easily.

Sedation is a side effect of many drugs that are not general CNS depressants (e.g., antihistamines and antipsychotic agents). Although such agents can intensify the effects of CNS depressants, they usually produce more specific therapeutic effects at concentrations far lower than those causing substantial CNS depression. The benzodiazepine sedative-hypnotics resemble such agents; although coma may occur at very high doses, neither surgical anesthesia nor fatal intoxication is produced by benzodiazepines in the absence of other drugs with CNS-depressant actions; an important exception is midazolam, which has been associated with decreased tidal volume and respiratory rate. Moreover, specific antagonists of benzodiazepines exist. This constellation of properties sets the benzodiazepine receptor agonists apart from other sedative-hypnotic drugs and imparts a measure of safety such that benzodiazepines and the newer Z compounds have largely displaced older agents for the treatment of insomnia and anxiety.

The sedative-hypnotic drugs that do not specifically target the benzodiazepine receptor belong to a group of agents that depress the CNS in a dose-dependent fashion, progressively producing calming or drowsiness (sedation), sleep (pharmacological hypnosis), unconsciousness, coma, surgical anesthesia, and
fatal depression of respiration and cardiovascular regulation. They share these properties with a large number of chemicals, including general anesthetics (see Chapter 19) and alcohols, most notably ethanol (see Chapter 23).

**BENZODIAZEPINES**

All benzodiazepines in clinical use promote the binding of the major inhibitory neurotransmitter γ-aminobutyric acid (GABA) to the GABA\(_A\) receptor, a multi-subunit, ligand-gated chloride channel. GABA binding induces the Cl\(^–\) current through these channels (see Figure 14–6).

Pharmacological data suggest heterogeneity among sites of binding and action of benzodiazepines; different subunit combinations comprise the GABA-gated chloride channels expressed in different neurons. Receptor subunit composition appears to govern the interaction of various allosteric modulators with these channels, giving hope to efforts to find agents displaying different combinations of benzodiazepine-like properties that reflect selective actions on 1 or more subtypes of GABA\(_A\) receptors. A number of distinct mechanisms of action are thought to contribute to the sedative-hypnotic, muscle-relaxant, anxiolytic, and anticonvulsant effects of the benzodiazepines, and specific subunits of the GABA\(_A\) receptor are responsible for specific pharmacological properties of benzodiazepines. While only the benzodiazepines used primarily for hypnosis are discussed in detail, this chapter describes the general properties of the group and important differences among individual agents (see also Chapters 15 and 21).

![Benzodiazepine structure](image)

*Benzodiazepine* refers to the portion of the this structure composed of a benzene ring (A) fused to a 7-membered diazepine ring (B). Because all the important
benzodiazepines contain a 5-aryl substituent (ring C) and a 1,4-diazepine ring, the term has come to mean the 5-aryl-1,4-benzodiazepines. Numerous modifications in the structure of the ring systems and substituents have yielded compounds with similar activities, including flumazenil (ROMAZICON, in which ring C is replaced with a keto function at position 5 and a methyl substituent is added at position 4), a benzodiazepine receptor antagonist. A large number of nonbenzodiazepine compounds compete with classic benzodiazepines and flumazenil for binding at specific sites in the CNS (e.g., β-carbolines, zolpidem, eszopiclone).

PHARMACOLOGICAL PROPERTIES

Virtually all effects of the benzodiazepines result from their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only 2 effects of these drugs result from peripheral actions: coronary vasodilation, seen after intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

CNS. While benzodiazepines depress activity at all levels of the neuraxis, some structures are affected preferentially. The benzodiazepines do not produce the same degrees of neuronal depression produced by barbiturates and volatile anesthetics. All the benzodiazepines have similar pharmacological profiles. Nevertheless, the drugs differ in selectivity, and the clinical usefulness of individual benzodiazepines thus varies considerably.

As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. The clinical literature often refers to the “anesthetic” effects and uses of certain benzodiazepines, but the drugs do not cause a true general anesthesia because awareness usually persists, and immobility sufficient to allow surgery cannot be achieved. Nonetheless, at “preanesthetic” doses, there is amnesia for events subsequent to administration of the drug. Despite to separate the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects, distinguishing between these behaviors is problematic. Measurements of anxiety and sedation are difficult in humans, and the validity of animal models for anxiety and sedation is uncertain. The existence of multiple benzodiazepine
receptors may explain in part the diversity of pharmacological responses in different species.

**Tolerance to Benzodiazepines.** Studies on tolerance in laboratory animals often are cited to support the belief that disinhibitory effects of benzodiazepines are distinct from their sedative-ataxic effects. Although most patients who ingest benzodiazepines chronically report that drowsiness wanes over a few days, tolerance to the impairment of some measures of psychomotor performance (e.g., visual tracking) usually is not observed. Whether tolerance develops to the anxiolytic effects of benzodiazepines remains a subject of debate. Many patients can maintain themselves on a fairly constant dose; increases or decreases in dosage appear to correspond with changes in problems or stresses. Conversely, some patients either do not reduce their dosage when stress is relieved or steadily escalate dosage. Such behavior may be associated with the development of drug dependence (see Chapter 24).

Some benzodiazepines induce muscle hypotonia without interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. Clonazepam in nonsedative doses does cause muscle relaxation, but diazepam and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Clonazepam, nitrazepam, and nordazepam have more selective anticonvulsant activity than most other benzodiazepines. Benzodiazepines also suppress photic seizures in baboons and ethanol-withdrawal seizures in humans. However, the development of tolerance to the anticonvulsant effects has limited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders in humans (see Chapter 21).

Although analgesic effects of benzodiazepines have been observed in experimental animals, only transient analgesia is apparent in humans after intravenous administration. Such effects actually may involve the production of amnesia. Unlike barbiturates, benzodiazepines do not cause hyperalgesia.

**Effects on the Electroencephalogram (EEG) and Sleep Stages.** The effects of benzodiazepines on the waking EEG resemble those of other sedative-hypnotic drugs. Alpha activity is decreased, but there is an increase in low-voltage fast activity. Tolerance occurs to these effects. With respect to sleep, some
differences in the patterns of effects exerted by the various benzodiazepines have been noted, but benzodiazepine use usually imparts a sense of deep or refreshing sleep. Benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the time from onset of spindle sleep to the first burst of rapid-eye-movement (REM) sleep; the time spent in REM sleep usually is shortened, however, the number of cycles of REM sleep usually is increased, mostly late in the sleep time. Zolpidem and zaleplon suppress REM sleep to a lesser extent than do benzodiazepines and thus may be superior to benzodiazepines for use as hypnotics.

Despite the shortening of stage 4 and REM sleep, benzodiazepine administration typically increases total sleep time, largely by increasing the time spent in stage 2 (which is the major fraction of non-REM sleep). The effect is greatest in subjects with the shortest baseline total sleep time. In addition, despite the increased number of REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. When such use is discontinued, the pattern of drug-induced changes in sleep parameters may “rebound,” and an increase in the amount and density of REM sleep may be especially prominent. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

**MOLECULAR TARGETS FOR BENZODIAZEPINE ACTIONS IN THE CNS.** Benzodiazepines act at GABA$_A$ receptors by binding directly to a specific site that is distinct from that of GABA binding (see Figure 14–6). Unlike barbiturates, benzodiazepines do not activate GABA$_A$ receptors directly; rather, benzodiazepines act allosterically by modulating the effects of GABA. Benzodiazepines and GABA analogs bind to their respective sites on brain membranes with nanomolar affinity. Benzodiazepines modulate GABA binding, and GABA alters benzodiazepine binding in an allosteric fashion.
Benzodiazepines and related compounds can act as agonists, antagonists, or inverse agonists at the benzodiazepine-binding site on GABA\(_A\) receptors. Agonists at the binding site increase, and inverse agonists decrease, the amount of chloride current generated by GABA\(_A\)-receptor activation. Agonists at the benzodiazepine binding site shift the GABA concentration-response curve to the left, whereas inverse agonists shift the curve to the right. Both these effects are blocked by antagonists at the benzodiazepine binding site. In the absence of an agonist or inverse agonist for the benzodiazepine binding site, an antagonist for this binding site does not affect GABA\(_A\) receptor function. One such antagonist, flumazenil, is used clinically to reverse the effects of high doses of benzodiazepines. The behavioral and electrophysiological effects of benzodiazepines also can be reduced or prevented by prior treatment with antagonists at the GABA binding site (e.g., bicuculline).

Each GABA\(_A\) receptor is believed to consist of a pentamer of homologous subunits. Thus far 16 different subunits have been identified and classified into 7 subunit families. The exact subunit structures of native GABA receptors still are unknown; most GABA receptors are likely of α, β, and γ subunits that co-assemble with some uncertain stoichiometry. The multiplicity of subunits generates heterogeneity in GABA\(_A\) receptors and is responsible, at least in part, for the pharmacological diversity in benzodiazepine effects in behavioral, biochemical, and functional studies. An understanding of which GABA\(_A\) receptor subunits are responsible for particular effects of benzodiazepines in vivo is emerging from KO animal studies. The attribution of specific behavioral effects of benzodiazepines to individual receptor subunits will, hopefully, aid in the development of new compounds exhibiting fewer undesired side effects.

**GABA\(_A\) Receptor-Mediated Electrical Events.** Benzodiazepines exert their major actions by increasing the gain of inhibitory neurotransmission mediated by GABA\(_A\) receptors. Enhancement of GABA-induced chloride currents by benzodiazepines results primarily from an increase in the frequency of bursts of Cl– channel opening produced by submaximal amounts of GABA. At therapeutically relevant concentrations, benzodiazepines potentiate inhibitory synaptic transmission measured after stimulation of afferent fibers.

The remarkable safety of the benzodiazepines likely relates to the fact that their effects in vivo depend on the presynaptic release of GABA; in the absence of
GABA, benzodiazepines have no effects on GABA<sub>A</sub> receptor function. This is in distinction to barbiturates, which also enhance the effects of GABA at low concentrations, but, in addition, directly activate GABA receptors at higher concentrations, which can lead to profound CNS depression.

The behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABA-ergic pathways that serve to regulate the firing of monoamine-containing neurons known to promote behavioral arousal and to be important mediators of the inhibitory effects of fear and punishment on behavior. Finally, inhibitory effects on muscular hypertonia or the spread of seizure activity can be rationalized by potentiation of inhibitory GABA-ergic circuits at various levels of the neuraxis. The magnitude of the effects produced by benzodiazepines varies widely depending on such factors as the types of inhibitory circuits that are operating, the sources and intensity of excitatory input, and the manner in which experimental manipulations are performed and assessed. Accordingly, benzodiazepines markedly prolong the period after brief activation of recurrent GABA-ergic pathways during which neither spontaneous nor applied excitatory stimuli can evoke neuronal discharge; this effect is reversed by the GABA<sub>A</sub> receptor antagonist bicuculline (see Figure 14–5).

**Respiration.** Hypnotic doses of benzodiazepines are without effect on respiration in normal subjects, but special care must be taken in the treatment of children and individuals with impaired hepatic function. At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with chronic obstructive pulmonary disease (COPD), and alveolar hypoxia and CO<sub>2</sub> narcosis may result. These drugs can cause apnea during anesthesia or when given with opioids. Patients severely intoxicated with benzodiazepines only require respiratory assistance when they also have ingested another CNS-depressant drug, most commonly ethanol.

In contrast, hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO<sub>2</sub>. The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD. In patients with obstructive sleep apnea (OSA), hypnotic doses of benzodiazepines may
decrease muscle tone in the upper airway and exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Benzodiazepines may promote the appearance of episodes of apnea during REM sleep (associated with decreases in oxygen saturation) in patients recovering from a myocardial infarction; however, no impact of these drugs on survival of patients with cardiac disease has been reported.

Cardiovascular System. The cardiovascular effects of benzodiazepines are minor in normal subjects except in severe intoxication. In preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate. With midazolam, effects appear to be secondary to a decrease in peripheral resistance; with diazepam, effects are secondary to a decrease in left ventricular work and cardiac output. Diazepam increases coronary flow, possibly by an action to increase interstitial concentrations of adenosine, and the accumulation of this cardiodepressant metabolite also may explain the negative inotropic effects of the drug. In large doses, midazolam decreases cerebral blood flow and oxygen assimilation considerably.

GI Tract. Benzodiazepines are thought by some gastroenterologists to improve a variety of “anxiety-related” GI disorders. Diazepam markedly decreases nocturnal gastric secretion in humans. Other drug classes are considerably more effective in acid-peptic disorders (see Chapter 45).

ABSORPTION, FATE, AND EXCRETION. All the benzodiazepines are absorbed completely (clorazepate is decarboxylated rapidly in gastric juice to N-desmethyldiazepam [nordazepam], which subsequently is absorbed completely). Drugs active at the benzodiazepine receptor may be divided into 4 categories based on their elimination $t_{1/2}$:

- Ultra-short-acting benzodiazepines
- Short-acting agents ($t_{1/2}$ 6 h), including triazolam, the non-benzodiazepine zolpidem ($t_{1/2}$ 2 h), and eszopiclone ($t_{1/2}$ 5-6 h)
- Intermediate-acting agents ($t_{1/2}$ 6-24 h), including estazolam and temazepam
- Long-acting agents ($t_{1/2}$ > 24 h), including flurazepam, diazepam, and quazepam

Flurazepam itself has a short $t_{1/2}$ (~2.3 h), but a major active metabolite, N-des-
alkyl-flurazepam, is long-lived ($t_{1/2}$ 47-100 h); such features complicate the classification of individual benzodiazepines.

The benzodiazepines and their active metabolites bind to plasma proteins. The extent of binding correlates strongly with lipid solubility and ranges from ~70% for alprazolam to nearly 99% for diazepam. The concentration in the cerebrospinal fluid is approximately equal to the concentration of free drug in plasma. The plasma concentrations of most benzodiazepines exhibit patterns that are consistent with 2-compartment models, but 3-compartment models appear to be more appropriate for the compounds with the highest lipid solubility. Accordingly, there is rapid uptake of benzodiazepines into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound); rapid uptake is followed by a phase of redistribution into tissues that are less well perfused, especially muscle and fat. Redistribution is most rapid for drugs with the highest lipid solubility. The kinetics of redistribution of diazepam and other lipophilic benzodiazepines are complicated by enterohepatic circulation. The volumes of distribution of the benzodiazepines are large and in many cases are increased in elderly patients. These drugs cross the placental barrier and are secreted into breast milk.

Benzodiazepines are metabolized extensively by hepatic CYPs, particularly CYPs 3A4 and 2C19. Some benzodiazepines, such as oxazepam, are conjugated directly and are not metabolized by these enzymes. Erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice are inhibitors of CYP3A4 (see Chapter 6) and can affect the metabolism of benzodiazepines. Because active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds, the duration of action of many benzodiazepines bears little relationship to the $t_{1/2}$ of elimination of the parent drug that was administered, as noted above for flurazepam. Conversely, the rate of biotransformation of agents that are inactivated by the initial reaction is an important determinant of their duration of action; these agents include oxazepam, lorazepam, temazepam, triazolam, and midazolam.

Because the benzodiazepines apparently do not significantly induce the synthesis of hepatic CYPs, their chronic administration usually does not result in the accelerated metabolism of other substances or of the benzodiazepines. Cimetidine and oral contraceptives inhibit $N$-dealkylation and 3-hydroxylation of
benzodiazepines. Ethanol, isoniazid, and phenytoin are less effective in this regard. These reactions usually are reduced to a greater extent in elderly patients and in patients with chronic liver disease than are those involving conjugation.

PHARMACOKINETICS AND THE IDEAL HYPNOTIC. An ideal hypnotic agent would have a rapid onset of action when taken at bedtime, a sufficiently sustained action to facilitate sleep throughout the night, and no residual action by the following morning. Among the benzodiazepines that are used commonly as hypnotic agents, triazolam theoretically fits this description most closely. Because of the slow rate of elimination of desalkylflurazepam, flurazepam (or quazepam) might seem to be unsuitable for this purpose. In practice, there appear to be some disadvantages to the use of agents that have a relatively rapid rate of disappearance, including the early-morning insomnia that is experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation. With careful selection of dosage, flurazepam and other benzodiazepines with slower rates of elimination than triazolam can be used effectively.

THERAPEUTIC USES

The therapeutic uses and routes of administration of individual benzodiazepines that are marketed in the U.S. are summarized in Table 17–1. Most benzodiazepines can be used interchangeably. For example, diazepam can be used for alcohol withdrawal, and most benzodiazepines work as hypnotics. Benzodiazepines that are useful as anticonvulsants have a long $t_{1/2}$, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. A short elimination $t_{1/2}$ is desirable for hypnotics. Antianxiety agents, in contrast, should have a long $t_{1/2}$ despite the drawback of the risk of neuropsychological deficits caused by drug accumulation.

Table 17–1

Therapeutic Uses of Benzodiazepines
UNTOWARD EFFECTS. At peak concentration in plasma, hypnotic doses of benzodiazepines cause varying degrees of light-headedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. All of these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol. When the drug is given at the intended time of sleep, the persistence of these effects during the waking hours is adverse. The intensity and incidence of CNS toxicity generally increase with age. Other common side effects of benzodiazepines are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much rarer. Anticonvulsant benzodiazepines sometimes increase the frequency of seizures in patients with epilepsy.

ADVERSE PSYCHOLOGICAL EFFECTS. Benzodiazepines may cause paradoxical effects. Flurazepam occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, sleep-walking, sleep-talking, other complex behaviors, and hypomanic behavior have been reported to occur during use of various benzodiazepines. Bizarre uninhibited behavior has been noted in some users, whereas hostility and rage may occur in others; collectively, these are sometimes referred to as disinhibition or dyscontrol reactions. Paranoia,
depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and appear to be dose related. Because of reports of an increased incidence of confusion and abnormal behaviors, triazolam has been banned in the U.K., although the FDA declared triazolam to be safe and effective in low doses of 0.125-0.25 mg.

Chronic benzodiazepine use poses a risk for development of dependence and abuse. Abuse of benzodiazepines includes the use of flunitrazepam (Rohypnod; not licensed for use in the U.S.) as a “date-rape drug.” Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (e.g., insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly. Despite their adverse effects, benzodiazepines are relatively safe drugs. Ethanol is a common contributor to deaths involving benzodiazepines, and true coma is uncommon in the absence of another CNS depressant. Benzodiazepines can further compromise respiration in patients with COPD or obstructive sleep apnea (OSA).

A wide variety of serious allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is quite low; these reactions have been associated with the use of flurazepam, triazolam, and temazepam. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. Ethanol increases both the rate of absorption of benzodiazepines and the associated CNS depression. Valproate and benzodiazepines in combination may cause psychotic episodes. Pharmacokinetic interactions were discussed earlier.

**NOVEL BENZODIAZEPINE RECEPTOR AGONISTS**

Hypnotics in this class are commonly referred to as “Z compounds.” They include zolpidem (AMBIEN), zaleplon (SONATA), zopiclone (not
marketed in the U.S.), and eszopiclone (LUNESTA), which is the S(+) enantiomer of zopiclone. Although the Z compounds are structurally unrelated to each other and to benzodiazepines, their therapeutic efficacy as hypnotics is due to agonist effects on the benzodiazepine site of the GABA_A receptor. Compared to benzodiazepines, Z compounds are less effective as anticonvulsants or muscle relaxants, which may be related to their relative selectivity for GABA_A receptors containing the α1 subunit. Over the last decade, Z compounds have largely replaced benzodiazepines in the treatment of insomnia. Z compounds were initially promoted as having less potential for dependence and abuse than traditional benzodiazepines. However, based on postmarketing clinical experience with zopiclone and zolpidem, tolerance and physical dependence can be expected during long-term use of Z compounds, especially with higher doses. Zopiclone and its isomers are classified as schedule IV drugs in the U.S. The clinical presentation of overdose with Z compounds is similar to that of benzodiazepine overdose and can be treated with the benzodiazepine antagonist flumazenil.

Zaleplon and zolpidem are effective in relieving sleep-onset insomnia. Both drugs are FDA-approved for use as long as to 7-10 days at a time. Zaleplon and zolpidem have sustained hypnotic efficacy without occurrence of rebound insomnia on abrupt discontinuation. Zaleplon and zolpidem have similar degrees of efficacy. Zolpidem has a \( t_{1/2} \) of ~2 h, which is sufficient to cover most of a typical 8-h sleep period, and is presently approved for bedtime use only. Zaleplon has a shorter \( t_{1/2} \) ~1 h, which offers the possibility for safe dosing later in the night, within 4 h of the anticipated rising time. Zaleplon and zolpidem differ in residual side effects; late-night administration of zolpidem has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas zaleplon does not differ from placebo.

**ZALEPLON.** Zaleplon (SONATA, generic) is a nonbenzodiazepine and is a member of the pyrazolopyrimidine class. Zaleplon preferentially binds to the benzodiazepine-binding site on GABA_A receptors containing the α1 receptor subunit. Zaleplon is absorbed rapidly and reaches peak plasma concentrations in
~1 h. Its bioavailability is ~30% because of presystemic metabolism. Zaleplon is metabolized largely by aldehyde oxidase and to a lesser extent by CYP3A4. Its oxidative metabolites are converted to glucuronides and eliminated in urine. Less than 1% of zaleplon is excreted unchanged in urine. None of zaleplon’s metabolites are pharmacologically active. Zaleplon is usually administered in 5-, 10-, or 20-mg doses.

**ZOLPIDEM.** Zolpidem (AMBIEN, others) is a non-benzodiazepine sedative-hypnotic drug. The actions of zolpidem are due to agonist effects on GABA_A receptors and generally resemble those of benzodiazepines. Zolpidem has little effect on the stages of sleep in normal human subjects. The drug is effective in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of zolpidem, the beneficial effects on sleep reportedly persist for up to 1 week, but mild rebound insomnia on the first night also has occurred. Tolerance and physical dependence are rare. Nevertheless, zolpidem is approved only for the short-term treatment of insomnia. At therapeutic doses (5-10 mg), zolpidem infrequently produces residual daytime sedation or amnesia, and the incidence of other adverse effects also is low. As with the benzodiazepines, large overdoses of zolpidem do not produce severe respiratory depression unless other agents (e.g., ethanol) also are ingested. Hypnotic doses increase the hypoxia and hypercarbia of patients with OSA.

Zolpidem is absorbed readily from the GI tract; first-pass hepatic metabolism results in an oral bioavailability of ~70%, but this value is lower when the drug is ingested with food. Zolpidem is eliminated almost entirely by conversion to inactive products in the liver, largely through oxidation of the methyl groups on the phenyl and imidazopyridine rings to the corresponding carboxylic acids. Its plasma t1/2 is ~2 h in individuals with normal hepatic blood flow or function. This value may be increased 2-fold or more in those with cirrhosis and also tends to be greater in older patients; adjustment of dosage often is necessary in both categories of patients. Although little or no unchanged zolpidem is found in the urine, elimination of the drug is slower in patients with chronic renal insufficiency largely owing to an increase in its apparent volume of distribution.

**ESZOPICLONE.** Eszopiclone (LUNESTA) is the active S(+) enantiomer of zopiclone. Eszopiclone has no structural similarity to benzodiazepines, zolpidem, or zaleplon. Eszopiclone is believed to exert its sleep-promoting
effects through its enhancement of GABA$_A$ receptor function at the benzodiazepine binding site. Eszopiclone is used for the long-term treatment of insomnia and for sleep maintenance. It is available in 1-, 2-, or 3-mg tablets. Eszopiclone decreases the latency to onset of sleep. In clinical studies, no tolerance was observed; no signs of serious withdrawal, such as seizures or rebound insomnia, were seen on discontinuation of the drug (however, there are such reports for zopiclone, the racemate used outside the U.S.). Mild withdrawal consisting of abnormal dreams, anxiety, nausea, and upset stomach can occur (rate <2%). A minor reported adverse effect of eszopiclone was a bitter taste. Eszopiclone is a schedule IV controlled substance in the U.S.

Eszopiclone is absorbed rapidly after oral administration, with a bioavailability of ~80%; it is metabolized by CYPs 3A4 and 2E1 and has a $t_{1/2}$ of 6 h.

**FLUMAZENIL: A BENZODIAZEPINE RECEPTOR ANTAGONIST**

Flumazenil (ROMAZICON, generic), the only member of this class, is an imidazobenzodiazepine that binds with high affinity to specific sites on the GABA$_A$ receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands. Flumazenil antagonizes both the electrophysiological and behavioral effects of agonist and inverse-agonist benzodiazepines and β-carbolines.

Flumazenil is available only for intravenous administration. Flumazenil is eliminated almost entirely by hepatic metabolism to inactive products with a $t_{1/2}$ of ~1 h; the duration of clinical effects usually is only 30-60 min. Although absorbed rapidly after oral administration, <25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism; effective oral doses are apt to cause headache and dizziness. The administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg flumazenil given over 1-3 min usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines. Additional courses of treatment with flumazenil may be needed within 20-30 min should sedation reappear.

The primary indications for the use of flumazenil are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced
by benzodiazepines administered during either general anesthesia or diagnostic and/or therapeutic procedures. Flumazenil is not effective in single-drug overdoses with either barbiturates or tricyclic antidepressants or in patients who had been taking benzodiazepines for protracted periods and in whom tolerance and/or dependence may have developed. The administration of flumazenil in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants.

MELATONIN CONGENERS

RAMELTEON. Ramelteon (ROZEREM) is a synthetic tricyclic analog of melatonin, approved in the U.S. for the treatment of insomnia, specifically difficulties of sleep onset.

Mechanism of Action. Melatonin levels in the suprachiasmatic nucleus rise and fall in a circadian fashion, with concentrations increasing in the evening as an individual prepares for sleep, and then reaching a plateau and ultimately decreasing as the night progresses. Two GPCRs for melatonin, MT₁ and MT₂, occur in the suprachiasmatic nucleus, each playing a different role in sleep. Binding of agonists such as melatonin to MT₁ receptors promotes the onset of sleep; melatonin binding to MT₂ receptors shifts the timing of the circadian system. Ramelteon binds to both MT₁ and MT₂ receptors with high affinity but, unlike melatonin, it does not bind appreciably to quinone reductase 2, the structurally unrelated MT₃ receptor. Ramelteon is not known to bind to any other classes of receptors.

CLINICAL PHARMACOLOGY. Prescribing guidelines suggest that an 8-mg tablet be taken ~30 min before bedtime. Ramelteon is rapidly absorbed from the GI tract. Because of the significant first-pass metabolism that occurs after oral administration, ramelteon bioavailability is <2%. The drug is largely metabolized by hepatic CYPs 1A2, 2C, and 3A4, with t₁/₂ of ~2 h in humans. Of the 4 metabolites, one, M-II, acts as an agonist at MT₁ and MT₂ receptors and may contribute to the sleep-promoting effects of ramelteon. Ramelteon is efficacious in combating both transient and chronic insomnia. Studies indicate that the drug is generally well tolerated by patients and does not impair next-day cognitive function. Sleep latency was consistently found to be shorter in patients given ramelteon compared to placebo controls. No evidence of rebound
insomnia or withdrawal effects were noted upon ramelteon withdrawal. Unlike most agents mentioned in this chapter, ramelteon is not a controlled substance.

**BARBITURATES**

The barbiturates were once used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been largely replaced by the much safer benzodiazepines. Table 17–2 lists the common barbiturates and their pharmacological properties.

**Table 17–2**

<sup>a</sup>Terminal $t_{1/2}$ due to hepatic metabolism; redistribution following parenteral administration produces effects lasting only a few minutes.

Barbiturates are derivatives of this parent structure:
The presence of alkyl or aryl groups at position 5 confers sedative-hypnotic and sometimes other activities. Barbiturates in which the oxygen at C2 is replaced by sulfur sometimes are called *thiobarbiturates*. These compounds are more lipid-soluble than the corresponding *oxybarbiturates*. In general, structural changes that increase lipid solubility decrease duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and increase hypnotic potency.

**PHARMACOLOGICAL PROPERTIES**

The barbiturates reversibly depress the activity of all excitable tissues. The CNS is exquisitely sensitive, and even when barbiturates are given in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication.

**ABSORPTION, FATE, AND EXCRETION.** For sedative-hypnotic use, the barbiturates usually are administered orally (see Table 17–2). Na⁺ salts are absorbed more rapidly than the corresponding free acids, especially from liquid formulations. The onset of action varies from 10-60 min, and is delayed by the presence of food. Intramuscular injections of solutions of the Na⁺ salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. The intravenous route usually is reserved for the management of status epilepticus (phenobarbital sodium) or for the induction and/or maintenance of general anesthesia (e.g., thiopental or methohexital). Barbiturates are distributed widely and readily cross the placenta. Uptake into less vascular tissues, especially muscle and fat, leads to a decline in the concentration of barbiturate in the plasma and brain. With thiopental and methohexital, this results in the awakening of patients within 5-15 min of the injection of the usual anesthetic doses (see Chapter 19).
Except for the less lipid-soluble aprobarbital and phenobarbital, nearly complete metabolism and/or conjugation of barbiturates in the liver precedes their renal excretion. The oxidation of radicals at C5 is the most important biotransformation that terminates biological activity. In some instances (e.g., phenobarbital), N-glycosylation is an important metabolic pathway. Other biotransformations include N-hydroxylation, desulfuration of thiobarbiturates to oxybarbiturates, opening of the barbituric acid ring, and N-dealkylation of N-alkyl barbiturates to active metabolites (e.g., mephobarbital to phenobarbital). About 25% of phenobarbital and nearly all of aprobarbital are excreted unchanged in the urine.

The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and t1/2 are increased during pregnancy partly because of the expanded volume of distribution. Chronic liver disease often increases the t1/2 of the biotransformable barbiturates. Repeated administration, especially of phenobarbital, shortens the t1/2 of barbiturates that are metabolized as a result of the induction of microsomal enzymes.

The barbiturates commonly used as hypnotics in the U.S. have t1/2 values such that the drugs are not fully eliminated in 24 h (see Table 17–2). Thus, these barbiturates will accumulate during repetitive administration unless appropriate adjustments in dosage are made. Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.

Central Nervous System

Sites and Mechanisms of Action on the CNS. Barbiturates act throughout the CNS; nonanesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamic relay neurons, or presynaptic, as in the spinal cord. Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at GABA_A receptors. Mechanisms underlying the actions of barbiturates on GABA_A receptors appear to be distinct from those of either GABA or the benzodiazepines. Barbiturates activate inhibitory GABA_A receptors and inhibit excitatory AMPA/kainate receptors. These actions can explain their CNS-depressant effects. For details, see the 12th edition of the parent text.
Barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia (see Chapter 19). Certain barbiturates, particularly those containing a 5-phenyl substituent (e.g., phenobarbital and meprobamate), have selective anticonvulsant activity (see Chapter 21). The anti-anxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of phenobarbital and its congeners, the barbiturates possess a low degree of selectivity and a narrow therapeutic index. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, barbiturates increase reactions to painful stimuli. Hence, they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

Effects on Stages of Sleep. Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, these drugs decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the parameters reported to be decreased by barbiturates.

Tolerance. With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its peak in a few days to a week. Tolerance to the effects on mood, sedation, and hypnosis occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers cross-tolerance to all general CNS-depressant drugs, including ethanol.

Abuse and Dependence. Like other CNS depressant drugs, barbiturates are abused, and some individuals develop a dependence on them (see Chapter 24). Moreover, the barbiturates may have euphoriant effects.

Peripheral Nervous Structures. Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters. This effect
may account, at least in part, for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both tubocurarine and decamethonium are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit the passage of current through nicotinic cholinergic receptors. Several distinct mechanisms appear to be involved, and little stereoselectivity is evident.

**RESPIRATION.** Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is essentially eliminated by a dose 3 times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultra-short-acting barbiturates to be used, with suitable precautions, as anesthetic agents. The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Coughing, sneezing, hiccoughing, and laryngospasm may occur when barbiturates are employed as intravenous anesthetic agents.

**CARDIOVASCULAR SYSTEM.** When given orally in sedative or hypnotic doses, barbiturates do not produce significant overt cardiovascular effects. In general, the effects of thiopental anesthesia on the cardiovascular system are benign in comparison with those of the volatile anesthetic agents; there usually is either no change or a fall in mean arterial pressure (see Chapter 19).

Other cardiovascular changes often noted when thiopental and other intravenous thiobarbiturates are administered after conventional preanesthetic medication include decreased renal and cerebral blood flow with a marked fall in CSF pressure. Although cardiac arrhythmias are observed only infrequently, intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when epinephrine and halothane also are present. Anesthetic concentrations of barbiturates have direct electrophysiological effects on the heart; in addition to depressing Na\(^+\) channels, they reduce the function of at least 2 types of K\(^+\) channels. However, direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered.
GI TRACT. The oxybarbiturates tend to decrease the tone of the GI musculature and the amplitude of rhythmic contractions. A hypnotic dose does not significantly delay gastric emptying in humans. The relief of various GI symptoms by sedative doses is probably largely due to the central-depressant action.

LIVER. The effects vary with the duration of exposure to the barbiturate. Acutely, the barbiturates combine with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations.

Chronic administration of barbiturates markedly increases the protein and lipid content of the hepatic smooth endoplasmic reticulum, as well as the activities of glucuronyl transferase and CYPs 1A2, 2C9, 2C19, and 3A4. The induction of these enzymes increases the metabolism of a number of drugs and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D. This also results in an increased rate of barbiturate metabolism, which partly accounts for tolerance to barbiturates. The inducing effect is not limited to the microsomal enzymes; e.g., there are increases in δ-aminolevulinic acid (ALA) synthetase, a mitochondrial enzyme, and aldehyde dehydrogenase, a cytosolic enzyme. The effect of barbiturates on ALA synthetase can cause dangerous disease exacerbations in persons with intermittent porphyria.

KIDNEY. Severe oliguria or anuria may occur in acute barbiturate poisoning largely as a result of the marked hypotension.

THERAPEUTIC USES

The major uses of individual barbiturates are listed in Table 17–2. As with the benzodiazepines, the selection of a particular barbiturate for a given therapeutic indication is based primarily on pharmacokinetic considerations. Benzodiazepines and other compounds for sedation have largely replaced barbiturates.

Untoward Effects

After-Effects. Drowsiness may last for only a few hours after a hypnotic dose of
barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea, or sometimes may be manifested as overt excitement.

Paradoxical Excitement. In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This type of idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with phenobarbital and N-methylbarbiturates. Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain and may worsen a patient’s perception of pain.

Hypersensitivity. Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by phenobarbital and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

DRUG INTERACTIONS. Barbiturates combine with other CNS depressants to cause severe depression; ethanol is the most frequent offender, and interactions with first-generation antihistamines also are common. Isoniazid, methylphenidate, and monoamine oxidase inhibitors also increase the CNS-depressant effects.

Barbiturates competitively inhibit the metabolism of certain other drugs; however, the greatest number of drug interactions results from induction of hepatic CYPs (as described above) and the accelerated disappearance of many drugs and endogenous substances. Hepatic enzyme induction enhances metabolism of endogenous steroid hormones, which may cause endocrine disturbances, as well as of oral contraceptives, which may result in unwanted pregnancy. Barbiturates also induce the hepatic generation of toxic metabolites of chlorocarbons (chloroform, trichloroethylene, carbon tetrachloride) and consequently promote lipid peroxidation, which facilitates periportal necrosis of the liver caused by these agents.

Other Untoward Effects. Because barbiturates enhance porphyrin synthesis, they
are absolutely contraindicated in patients with acute intermittent porphyria or porphyria variegata. Hypnotic doses, in the presence of pulmonary insufficiency are contraindicated. Rapid intravenous injection of a barbiturate may cause cardiovascular collapse before anesthesia ensues. Blood pressure can fall to shock levels; even slow intravenous injection of barbiturates often produces apnea and occasionally laryngospasm, coughing, and other respiratory difficulties.

Barbiturate Poisoning. Most of the cases are the result of attempts at suicide, but some are from accidental poisonings in children or in drug abusers. The lethal dose of barbiturate varies, but severe poisoning is likely to occur when b10 times the full hypnotic dose has been ingested at once. The lethal dose becomes lower if alcohol or other depressant drugs also are present. The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. If renal and cardiac functions are satisfactory, and the patient is hydrated, forced diuresis and alkalization of the urine will hasten the excretion of phenobarbital. See Chapter 4, Drug Toxicity and Poisoning.

MISCELLANEOUS SEDATIVE-HYPNOTIC DRUGS

Many drugs with diverse structures have been used for their sedative-hypnotic properties, including ramelteon, chloral hydrate, meprobamate, and paraldehyde. With the exception of ramelteon and meprobamate, the pharmacological actions of these drugs generally resemble those of the barbiturates: they all are general CNS depressants that can produce profound hypnosis with little or no analgesia; their effects on the stages of sleep are similar to those of the barbiturates; their therapeutic index is limited, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning; their chronic use can result in tolerance and physical dependence; and the syndrome after chronic use can be severe and life-threatening.

CHLORAL HYDRATE. Chloral hydrate may be used to treat patients with paradoxical reactions to benzodiazepines. Chloral hydrate is reduced rapidly to
the active compound, trichloroethanol ($\text{CCl}_3\text{CH}_2\text{OH}$), largely by hepatic alcohol dehydrogenase. Its pharmacological effects probably are caused by trichloroethanol, which can exert barbiturate-like effects on $\text{GABA}_A$ receptor channels in vitro.

Chloral hydrate is best known in the U.S. as a literary poison, the “knock-out drops” added to a strong alcoholic beverage to produce a “Mickey Finn” or “Mickey,” a cocktail given to an unwitting imbibers to render him malleable or unconscious, most famously Sam Spade in Dashiell Hammett’s 1930 novel, The Maltese Falcon. Now that detectives drink white wine rather than whiskey, this off-label use of chloral hydrate has waned.

MEPROBAMATE. Meprobamate a bis-carbamate ester, was introduced as an antianxiety agent and this remains its only approved use in the U.S. However, it also became popular as a sedative-hypnotic agent. The pharmacological properties of meprobamate resemble those of the benzodiazepines in a number of ways. Meprobamate can release suppressed behaviors in experimental animals at doses that cause little impairment of locomotor activity, and although it can cause depression of the CNS, it cannot produce anesthesia. Large doses of meprobamate cause severe respiratory depression, hypotension, shock, and heart failure. Meprobamate appears to have a mild analgesic effect in patients with musculoskeletal pain, and it enhances the analgesic effects of other drugs.

Meprobamate is well absorbed when administered orally. Nevertheless, an important aspect of intoxication with meprobamate is the formation of gastric bezoars consisting of undissolved meprobamate tablets; hence treatment may require endoscopy, with mechanical removal of the bezoar. Most of the drug is metabolized in the liver, mainly to a side-chain hydroxy derivative and a glucuronide; the kinetics of elimination may depend on the dose. The $t_{1/2}$ of meprobamate may be prolonged during its chronic administration, even though the drug can induce some hepatic CYPs.

The major unwanted effects of the usual sedative doses of meprobamate are drowsiness and ataxia; larger doses impair learning and motor coordination and prolongation of reaction time. Meprobamate enhances the CNS depression produced by other drugs. The abuse of meprobamate has continued despite a substantial decrease in the clinical use of the drug. Carisoprodol (SOMA), a
skeletal muscle relaxant whose active metabolite is meprobamate, also has abuse potential and has become a popular “street drug.”

**PARALDEHYDE.** Paraldehyde is a polymer of acetaldehyde, basically a cyclic polyether. It has a strong odor and a disagreeable taste. Orally, it is irritating to the throat and stomach, and it is not administered parenterally because of its injurious effects on tissues. Use of paraldehyde has been discontinued in the U.S.

**OTHER AGENTS.** *Etomidate (Amidate, generic)* is used in the U.S. and other countries as an intravenous anesthetic, often in combination with fentanyl. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the heart. Its pharmacology and anesthetic uses are described in Chapter 19. *Clomethiazole* has sedative, muscle relaxant, and anticonvulsant properties. Given alone, its effects on respiration are slight, and the therapeutic index is high. However, deaths from adverse interactions with ethanol are relatively frequent. *Propofol (Diprivan)* is a rapidly acting and highly lipophilic diisopropylphenol used in the induction and maintenance of general anesthesia (see Chapter 19), as well as in the maintenance of long-term sedation.

**NONPRESCRIPTION HYPNOTIC DRUGS.** The antihistamines diphenhydramine and doxylamine are FDA-approved as ingredients in over-the-counter (OTC) nonprescription sleep aids. With elimination $t_{1/2}$ of ~9-10 h, these antihistamines can be associated with prominent residual daytime sleepiness when taken the prior evening as a sleep aid.

**MANAGEMENT OF INSOMNIA**
The “perfect” hypnotic would allow sleep to occur with normal sleep architecture rather than produce a pharmacologically altered sleep pattern. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without causing dependence or rebound insomnia on discontinuation. Controversy in the management of insomnia revolves around 2 issues:

- Pharmacological versus nonpharmacological treatment
- Use of short-acting versus long-acting hypnotics
CATEGORIES OF INSOMNIA

- **Transient insomnia** lasts 3 days and usually is caused by a brief environmental or situational stressor.
- **Short-term insomnia** lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Hypnotics are best used intermittently during this time, with the patient skipping a dose after 1-2 nights of good sleep.
- **Long-term insomnia** is insomnia that has lasted for >3 weeks; no specific stressor may be identifiable.

**Insomnia Accompanying Major Psychiatric Illnesses.** The insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment for that illness. In major depressive episodes with insomnia, e.g., the selective serotonin reuptake inhibitors, which may cause insomnia as a side effect, usually will result in improved sleep because they treat the depressive syndrome. In patients whose depression is responding to the serotonin reuptake inhibitor but who have persistent insomnia as a side effect of the medication, judicious use of evening trazodone may improve sleep, as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety in patients with anxiety disorders often produces adequate resolution of the accompanying insomnia. The profound insomnia of patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine-receptor antagonists (see Chapters 13 and 16). Benzodiazepines often are used adjunctively in this situation to reduce agitation and improved sleep.

**Insomnia Accompanying Other Medical Illnesses.** For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia. Adequate pain management in conditions of chronic pain will treat both the pain and the insomnia and may make hypnotics unnecessary. Adequate attention to sleep hygiene, including reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.

**Long-Term Insomnia.** Nonpharmacological treatments are important for all
patients with long-term insomnia. These include education about sleep hygiene, relaxation training, and behavioral-modification approaches, such as sleep-restriction and stimulus-control therapies.

Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture. The barbiturates reduce REM sleep; the benzodiazepines reduce slow-wave non-REM sleep and, to a lesser extent, REM sleep. While the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may aid in the consolidation of learning. The blockade of slow-wave sleep by benzodiazepines may partly account for their diminishing effectiveness over the long term, and it also may explain their effectiveness in blocking sleep terrors, a disorder of arousal from slow-wave sleep.

Long-acting benzodiazepines can cause next-day confusion, whereas shorter-acting agents can produce rebound next-day anxiety. Paradoxically, the acute amnestic effects of benzodiazepines may be responsible for the patient’s subsequent report of restful sleep. Anterograde amnesia may be more common with triazolam. Hypnotics should not be given to patients with sleep apnea, especially of the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia.

**Insomnia in Older Patients.** The elderly, like the very young, tend to sleep in a polyphasic (multiple sleep episodes per day) pattern rather than the monophasic pattern characteristic of younger adults. This pattern makes assessment of adequate sleep time difficult. Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer \( t_{\frac{1}{2}} \) for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 may produce daytime confusion and amnesia by week 3 as the level continues to rise, particularly with long-acting hypnotics.

**MANAGEMENT OF PATIENTS AFTER LONG-TERM TREATMENT WITH HYPNOTIC AGENTS.** If a benzodiazepine has been used regularly for a2 weeks, it should be tapered rather than discontinued abruptly. In some patients on hypnotics with a short \( t_{\frac{1}{2}} \), it is easier to switch first to a hypnotic with a long
$t_{1/2}$ and then to taper.

**PRESCRIBING GUIDELINES FOR THE MANAGEMENT OF INSOMNIA.**
Hypnotics that act at GABA\textsubscript{A} receptors, including the benzodiazepine hypnotics and the newer agents zolpidem, zopiclone, and zaleplon, are preferred to barbiturates because they have a greater therapeutic index, have smaller effects on sleep architecture, and have less abuse potential. Compounds with a shorter $t_{1/2}$ are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness during the day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. Benzodiazepines with longer $t_{1/2}$ are favored for patients who have significant daytime anxiety. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2-4 weeks of treatment) as a result of drug accumulation with repeated administration.

*Older agents such as barbiturates, chloral hydrate, and meprobamate should be avoided for the management of insomnia. They have high abuse potential and are dangerous in overdose.*
Pain is a component of virtually all clinical pathologies, and management of pain is a primary clinical imperative. Opioids are a mainstay of pain treatment, but depending upon the pain state, therapy may involve NSAIDs, anticonvulsants, or antidepressants.

The term *opiate* refers to compounds structurally related to products found in opium derived from the resin of the opium poppy, *Papaver somniferum*. Opiates include the natural plant alkaloids, such as morphine, codeine, thebaine, and many semisynthetic derivatives. An *opioid* is any agent that has the functional and pharmacological properties of an opiate. Endogenous opioids are naturally occurring ligands for opioid receptors found in animals. The term *endorphin* is used synonymously with *endogenous opioid peptides* but also refers to a specific endogenous opioid, β-endorphin. Although the term *narcotic* originally referred to any drug that induced narcosis or sleep, the word has become associated with opioids and is often used in a legal context to refer to substances with abuse or addictive potential.

**ENDOGENOUS OPIOID PEPTIDES**

Several distinct families of endogenous opioids peptides have been identified: principally the *enkephalins, endorphins*, and *dynorphins* (*Table 18–1*). These families have several common properties:

*Table 18–2*

| Endogenous Opioid Peptides |
• Each derives from a distinct precursor protein, pre-pro-opiomelanocortin (pre-POMC), preproenkephalin, and preprodynorphin, respectively, encoded by a corresponding gene.

• Each precursor is subject to complex cleavages by distinct trypsin-like enzymes, and to a variety of posttranslational modifications resulting in the synthesis of multiple peptides, some of which are active.

• Most opioid peptides with activity at a receptor share the common amino-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu) followed by various C-terminal extensions yielding peptides of 5-31 residues; the endomorphins, with different terminal sequences, are exceptions.

The opioid peptide precursors are a protean family (Figure 18–1). The major opioid peptide derived from POMC is the potent opioid agonist, β-endorphin. The POMC sequence also is processed into a variety of nonopioid peptides including adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (α-MSH), and β-lipotropin (β-LPH). Although β-endorphin contains the sequence for met-enkephalin at its
amino terminus, it is not converted to this peptide. *Proenkephalin* contains multiple copies of *met-enkephalin*, as well as a single copy of *leu-enkephalin*. *Prodynorphin* contains 3 peptides of differing lengths that all begin with the leu-enkephalin sequence: *dynorphin A*, *dynorphin B*, and *neoendorphin*. *Nociceptin peptide* or *orphanin FQ* (now termed N/OFQ) shares structural similarity with dynorphin A.

**Figure 18–1 Peptide precursors.** (Reproduced with permission from Akil H, Owens C, Gustein H, et al. Endogenous opioids: Overview and current issues. *Drug Alcohol Depend*, 1998;51:127-140. Copyright © Elsevier.)

*Endomorphins* belong to a novel family of peptides that include: *endomorphin-1* (Tyr-Pro-Trp-Phe-NH$_2$) and *endomorphin-2* (Tyr-Pro-Phe-Phe-NH$_2$). Endomorphins have an atypical structure and display selectivity towards the μ opioid receptor. **Several points should be stressed:**

- Not all cells that make a given opioid prohormone precursor store and release the same mixture of opioid peptides; this results from differential
processing secondary to variations in the cellular complement of peptidases that produce and degrade the active opioid fragments.

- Processing of these peptides is altered by physiological demands, leading to the release of a different mix of posttranslationally derived peptides by a given cell under different conditions.
- Opioid peptides are found in plasma and reflect release from secretory systems such as the pituitary and the adrenals that do not reflect neuraxial release. Conversely, levels of these peptides in brain/spinal cord and in cerebrospinal fluid (CSF) arise from neuraxial systems and not from peripheral systems.

**OPIOID RECEPTORS**

The 3 opioid receptors—μ, δ, and κ (MOR, DOR, and KOR)—belong to the rhodopsin family of GPCRs (see Chapter 3) and share extensive sequence homologies (55-58%). Highly selective agonists have been developed that show specific affinity for the respective binding site (e.g., DAMGO for μ, DPDPE for δ, and U-50,488, and U-69,593 for κ) (Table 18–2). Commonly used antagonists (Table 18–3) include cyclic analogs of somatostatin such as CTOP as a μ receptor antagonist, a derivative of naloxone called naltrindole as a δ receptor antagonist, and a bivalent derivative of naltrexone called norbinaltorphimine (nor-BNI) as a κ-receptor antagonist.

#### Opioid Antagonists
In the membrane, opiate receptors can form both homo- and heterodimers. Dimerization can alter the pharmacological properties of the respective receptors. Splice variants exist within each of the 3 opioid receptor families, and this alternative splicing of receptor transcripts may be crucial for the diversity of opioid receptors. Given the functional importance of the intracellular components of the GPCRs, it is not surprising that significant differences exist for the receptor isoforms in terms of agonist-induced G protein activation and receptor internalization.

An opiate receptor-like protein (ORL1 or NOP) was cloned based on its structural homology (48-49% identity) to other members of the opioid receptor family; it is G-protein coupled, has an endogenous ligand (nociception/orphanin, FQ: N/OFQ), but does not display an opioid pharmacology.

**OPIATE RECEPTOR SIGNALING**

The μ, δ, and κ receptors couple through pertussis toxin-sensitive, Gᵢ/Gₒ proteins (but occasionally to Gₛ or Gₓ). Upon receptor
activation, the $G_i/G_o$ coupling results in a large number of intracellular events, including:

- Inhibition of adenylyl cyclase activity
- Reduced opening of voltage-gated $\text{Ca}^{2+}$ channels (reduces neurotransmitter release from presynaptic terminals)
- Stimulation of $K^+$ current through several channels including $G$ protein-activated inwardly rectifying $K^+$ channels (GIRKs) (hyperpolarizes and inhibits postsynaptic neurons)
- Activation of PKC and PLC$_\beta$

**FUNCTIONAL CONSEQUENCES OF ACUTE AND CHRONIC OPIATE RECEPTOR ACTIVATION**

The loss of effect with exposure to opiates occurs over short- and long-term intervals.

**INTERNALIZATION.** $\mu$ and $\delta$ receptors can undergo rapid agonist-mediated internalization via a classic endocytic, $\beta$-arrestin-mediated pathway, whereas $\kappa$ receptors do not internalize after prolonged agonist exposure. Internalization of the $\mu$ and $\delta$ receptors may be induced differentially as a function of the structure of the ligand.

**DESENSITIZATION.** In the face of a transient activation (minutes to hours), acute tolerance or desensitization occurs that is specific for that receptor and disappears with a time course parallel to the clearance of the agonist. Short-term desensitization probably involves phosphorylation of the receptors resulting in an uncoupling of the receptor from its $G$-protein and/or internalization of the receptor.

**TOLERANCE.** Here tolerance refers to a decrease in the apparent effectiveness of a drug with continuous or repeated agonist administration (days to weeks), that, following removal of the agonist, disappears over several weeks. This tolerance is reflected by a
reduction in the maximum achievable effect or a right shift in the dose-effect curve. This loss of effect with persistent exposure to an opiate agonist has several key properties:

- Different physiological responses develop tolerance at different rates. Thus, at the organ system level, some end points show little or no tolerance development (pupillary miosis), some show moderate tolerance (constipation, emesis, analgesia, sedation), and some show rapid tolerance (euphorogenic).
- In general, opiate agonists of a given class will typically show a reduced response in a system rendered tolerant to another agent of that class (e.g., cross-tolerance between the μ agonists, such as morphine and fentanyl). This cross-tolerance is not consistent or complete, thereby forming the basis for the switching between opioid drugs in clinical therapy.

**DEPENDENCE.** Dependence represents a state of adaptation manifested by receptor/drug class-specific withdrawal syndrome produced by cessation of drug exposure (e.g., by drug abstinence) or administration of an antagonist (e.g., naloxone). At the organ system level, withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hyperthermia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression).

**ADDITION.** Addiction is a behavioral pattern characterized by compulsive use of a drug. The positive, rewarding effects of opiates are considered to be the driving component for initiating the recreational use of opiates. This positive reward property is subject to the development of tolerance. Given the aversive nature of withdrawal symptoms, avoidance and alleviation of withdrawal symptoms may become a primary motivation for compulsive drug taking. Drug dependence is not synonymous with drug addiction. Tolerance and dependence are physiological responses seen in all patients but are not
predictors of addiction (see Chapter 24). For example, cancer pain often requires prolonged treatment with high doses of opioids, leading to tolerance and dependence. Yet abuse in this setting is considered to be unusual.

MECHANISMS OF TOLERANCE/DEPENDENCE-WITHDRAWAL. The mechanisms underlying chronic tolerance and dependence/withdrawal are controversial. Several types of events may to contribute.

Receptor Disposition. Acute desensitization or receptor internalization may play a role in the initiation of chronic tolerance but is not sufficient to explain persistent changes observed with chronic exposure. Thus, morphine, unlike other μ agonists, does not promote μ receptor internalization or receptor phosphorylation and desensitization. Receptor desensitization and downregulation are agonist specific. Endocytosis and sequestration of receptors do not invariably lead to receptor degradation but can also result in receptor dephosphorylation and recycling to the surface of the cell. Accordingly, opioid tolerance may not be related to receptor desensitization but rather to a lack of desensitization. Agonists that rapidly internalize opioid receptors also would rapidly desensitize signaling, but this desensitization would be at least partially reset by recycling of “reactivated” opioid receptors.

Adaptation of Intracellular Signaling Mechanisms in the Opioid Receptor-Bearing Neurons. Coupling of MOR to cellular effectors, such as inhibition of adenyl cyclase, activation of inwardly rectifying $K^+$ channels, inhibition of $Ca^{2+}$ currents, and inhibition of terminal release of transmitters demonstrates functional uncoupling of receptor occupancy from effector function. Importantly, the chronic opioid effect initiates adaptive counter-regulatory change. The best example of such cellular counter-regulatory processes is the rebound increase in cellular cyclic AMP levels produced by “superactivation” of adenyl cyclase and upregulation of the amount of enzyme.

System Level Counter-Adaptation. With chronic opiate exposure, there is a loss of drug effect; this may reflect an enhanced excitability of the regulated link. Thus, tolerance to the analgesic action of chronically administered μ opiates may result in an activation of bulbospinal pathways that increases the excitability of spinal dorsal horn pain transmission linkages. With chronic opiate exposure,
opiate receptor occupancy will lead to the activation of PKC, which can phosphorylate and, accordingly, enhance the activation of local NMDA glutamate receptors (see Chapter 14). These receptors mediate a facilitated state leading to enhanced spinal pain processing. Blocking of these receptors can at least partially attenuate the loss of analgesic efficacy with continued opiate exposure. These system level counter-adaptation hypotheses represent mechanisms that may apply to specific systems (e.g., pain modulation) but not necessarily to others (e.g., sedation or miosis).

**EFFECTS OF CLINICALLY USED OPIOIDS**

Opiates, depending on their receptor specificities, produce a variety of effects consistent with the role played by the organ systems with which the receptors are associated. Although the primary clinical use of opioids is for their pain-relieving properties, opioids produce a host of other effects. This is not surprising in view of the wide distribution of opioid receptors in the brain and the periphery.

**ANALGESIA.** Morphine-like drugs produce *analgesia, drowsiness, and euphoria* (changes in mood, and mental clouding). When therapeutic doses of morphine are given to patients with pain, they report the pain to be less intense or entirely gone. In addition to relief of distress, some patients may experience euphoria. Analgesia often occurs without loss of consciousness, though drowsiness commonly occurs. Morphine at these doses does not have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant motor uncoordination. When morphine in an analgesic dose is given to normal, pain-free individuals, the patients may report the drug experience to be frankly unpleasant. There may be drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced. The relief of pain by morphine-like opioids is selective in that other sensory modalities, such as light touch, proprioception, and the sense of moderate temperatures, are unaffected. Low doses of morphine produce reductions in the affective but not the perceived intensity of pain. Continuous dull pain (as generated by tissue injury and inflammation) is relieved more effectively than sharp intermittent (incident) pain, such as that associated with the movement of an inflamed joint, but with sufficient amounts of opioid it is
possible to relieve even the severe piercing pain associated with acute renal or biliary colic.

PAIN STATES AND MECHANISMS UNDERLYING DIFFERENT PAIN STATES

Acute Nociception. Acute activation of small high-threshold sensory afferents (Aδ and C fibers) generates transient input into the spinal cord, which in turn leads to activation of neurons that project contralaterally to the thalamus and thence to the somatosensory cortex. A parallel spinofugal projection is to the medial thalamus and from there to the anterior cingulate cortex, part of the limbic system. The output produced by acutely activating this ascending system is sufficient to evoke pain reports. Examples of such stimuli include a hot coffee cup, a needle stick, or an incision.

Tissue Injury. Following tissue injury or local inflammation (e.g., local skin burn, toothache, rheumatoid joint), an ongoing pain state arises that is characterized by burning, throbbing, or aching and an abnormal pain response (hyperalgesia) and can be evoked by otherwise innocuous or mildly aversive stimuli (tepid bathwater on a sunburn; moderate extension of an injured joint). This pain typically reflects the effects of active factors (such as prostaglandins, bradykinin, cytokines, and H+ ions, among many mediators) released into the injury site, which have the ability to activate the terminal of small high-threshold afferents (Aδ and C fibers) and to reduce the stimulus intensity required to activate these sensory afferents (peripheral sensitization). In addition, the ongoing afferent traffic initiated by the injury leads to the activation of spinal facilitatory cascades, yielding a greater output to the brain for any given input. This facilitation is thought to underlie the hyperalgesic states. Such tissue injury-evoked pain is often referred to as “nociceptive” pain (Figure 18–2). Examples of such states would be burn, post-incision, abrasion of the skin, inflammation of the joint, and musculoskeletal injury.
Nerve Injury. Injury to the peripheral nerve yields complex anatomical and biochemical changes in the nerve and spinal cord that induce spontaneous dysesthesias (shooting, burning pain) and allodynia (light touch hurts). This nerve injury pain state may not depend on the activation of small afferents, but may be initiated by low-threshold sensory afferents (e.g., Aβ fibers). Such nerve injuries result in the development of ectopic activity arising from neuromas formed by nerve injury and the dorsal root ganglia of the injured axons as well as a dorsal horn reorganization, such that low-threshold afferent input carried by Aβ fibers evokes a pain state. Examples of such nerve injury-inducing events include nerve trauma or compression (carpal tunnel syndrome), chemotherapy (as for cancer), diabetes, and in the post-herpetic state (shingles). These pain states are said to be neuropathic (Figure 18–3). Many clinical pain syndromes, such as found in cancer, typically represent a combination of these inflammatory
and neuropathic mechanisms. Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain is typically considered to respond less well to opioid analgesics.

Figure 18–3 Mechanisms of nerve injury-evoked nociception.

**Sensory Versus Affective Dimensions.** When pain does not evoke its usual responses (anxiety, fear, panic, and suffering), a patient’s ability to tolerate the pain may be markedly increased, even when the capacity to perceive the sensation is relatively unaltered. It is clear, however, that alteration of the emotional reaction to painful stimuli is not the sole mechanism of analgesia. Thus, intrathecal administration of opioids can produce profound segmental analgesia without causing significant alteration of motor or sensory function or subjective effects.

**MECHANISMS OF OPIOID-INDUCED ANALGESIA.** The analgesic actions of opiates after systemic delivery represent actions in the brain, spinal cord, and in some instances in the periphery.

**Supraspinal Actions.** Microinjections of morphine into the mesencephalic periaqueductal gray (PAG) matter region will block nociceptive responses; naloxone will reverse these effects. Several mechanisms exist whereby opiates
with an action limited to the PAG may act to alter nociceptive transmission. These are summarized in Figure 18–4. MOR agonists block release of the inhibitory transmitter GABA from tonically active PAG systems that regulate activity in projections to the medulla. PAG projections to the medulla activate medullospinal release of NE and 5HT at the level of the spinal dorsal horn. This release can attenuate dorsal horn excitability. Interestingly, this PAG organization can also serve to increase excitability of dorsal raphe and locus coeruleus from which ascending serotonergic and noradrenergic projections to the limbic forebrain originate.

Figure 18–4 Mechanisms of opiate action in producing analgesia. Top left: Schematic of organization of opiate action in the periaqueductal gray. Top right: Opiate-sensitive pathways in PAG μ-opiate actions block the release of GABA from tonically active systems that other-wise regulate the projections to the medulla (1) leading to an activation of PAG outflow resulting in activation of forebrain (2) and spinal (3) monoamine receptors that regulate spinal cord
projections (4), which provide sensory input to higher centers and mood. Bottom left: Schematic of primary afferent synapse with second-order dorsal horn spinal neuron, showing pre- and postsynaptic opiate receptors coupled to Ca\(^{2+}\) and K\(^{+}\) channels, respectively. Opiate-receptor binding is highly expressed in the superficial spinal dorsal horn (substantia gelatinosa). These receptors are located pre-synaptically on the terminals of small primary afferents (C fibers) and postsynaptically on second-order neurons. Presynaptically, activation of MOR blocks the opening of the voltage-sensitive Ca\(^{2+}\) channel, which otherwise initiates transmitter release. Postsynaptically, MOR activation enhances opening of K\(^{+}\) channels, leading to hyperpolarization. Thus, an opiate agonist acting at these sites jointly serves to attenuate the afferent-evoked excitation of the second-order neuron.

**Spinal Opiate Action.** A local action of opiates in the spinal cord will selectively depress the discharge of spinal dorsal horn neurons evoked by small (high-threshold) but not large (low-threshold) afferent nerve fibers. Intrathecal administration of opioids in animals ranging from mouse to human will reliably attenuate the response of the organism to a variety of somatic and visceral stimuli that otherwise evoke pain states. Specific opiate binding and receptor protein are limited for the most part to the substantia gelatinosa of the superficial dorsal horn, the region in which small, high-threshold sensory afferents show their principal termination. A significant proportion of these opiate receptors are associated with small peptidergic primary afferent C fibers; the remainder are on local dorsal horn neurons.

Spinal opiates reduce the release of primary afferent peptide transmitters such as substance P contained in small afferents. The presynaptic action corresponds to the ability of opiates to prevent the opening of voltage-sensitive Ca\(^{2+}\) channels, thereby preventing transmitter release. A postsynaptic action is demonstrated by the ability of opiates to block excitation of dorsal horn neurons directly evoked by glutamate, reflecting a direct activation of dorsal horn projection neurons. The activation of K\(^{+}\) channels in these postsynaptic neurons, leading to hyperpolarization, is consistent with a direct postsynaptic inhibition. The joint capacity of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers and to decrease the excitability of dorsal horn neurons is believed to account for the powerful and selective effect of opiates on spinal nociceptive processing. A variety of opiates delivered spinally (intrathecally or epidurally)
can induce a powerful analgesia that is reversed by low doses of systemic naloxone.

Peripheral Action. Direct application of opiates to a peripheral nerve can, in fact, produce a local anesthetic-like action at high concentrations, but this is not naloxone reversible and is believed to reflect a “nonspecific” action. Conversely, direct injection of these agents into peripheral sites have demonstrated that under conditions of inflammation, where there is an increased terminal sensitivity leading to an exaggerated pain response (e.g., hyperalgesia), the local action of opiates can exert a normalizing effect on the exaggerated thresholds. Whether the effects are uniquely on the afferent terminal, whether the opiate acts on inflammatory cells that release products that sensitize the nerve terminal, or both, is not known.

MOOD ALTERATIONS AND REWARDING PROPERTIES. The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are complex and not entirely clear. Neural systems that mediate opioid reinforcement overlap with, but are distinct from, those involved in physical dependence and analgesia. Behavioral and pharmacological data point to a pivotal role of the mesocorticolimbic dopamine system that projects to the nucleus accumbens (NAc) in drug-induced reward and motivation (Figure 18–5).
Figure 18–5 Schematic pathways underlying rewarding properties of opiates.

Upper panel: This sagittal section of rat brain shows DA and GABA inputs from the ventral tegmental area (VTA) and prefrontal cortex (PFC), respectively, into the nucleus accumbens (NAc). Lower panel: Neurons are labeled with their primary neurotransmitters. At a cellular level, MOR agonists reduce excitability and transmitter release at the sites indicated by inhibiting Ca\(^{2+}\) influx and enhancing K\(^{+}\) current (see Figure 18–4). Thus, opiate-induced inhibition in the VTA on GABA-ergic interneurons or in the NAc reduce GABA-mediated inhibition and increase outflow from the ventral pallidum (VP), which appears to correlate with a positive reinforcing state (enhanced reward).
RESPIRATION. Although effects on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard analgesic doses in the absence of other contributing variables (discussed in the next sections). It should be stressed, however, that respiratory depression represents the primary cause of morbidity secondary to opiate therapy. In humans, death from opiate poisoning is nearly always due to respiratory arrest or obstruction. Opiates depress all phases of respiratory activity (rate, minute volume, and tidal exchange) and produce irregular and aperiodic breathing. The diminished respiratory volume is due primarily to a slower rate of breathing; with toxic amounts of opioids, the rate may fall to 3-4 breaths/min. Thus, opioids must be used with caution in patients with asthma, chronic obstructive pulmonary disease (COPD), cor pulmonale, decreased respiratory reserve, preexisting respiratory depression, hypoxia, or hypercapnia to avoid apnea due to a decrease in respiratory drive coinciding with an increased airway resistance. Although respiratory depression is not considered to be a favorable therapeutic effect of opiates, their ability to suppress respiratory drive is used to therapeutic advantage to treat dyspnea resulting, e.g., in patients with COPD, where air hunger leads to extreme agitation, discomfort, and gasping; similarly, opiates find use in patients who require artificial ventilation.

Morphine-like opioids depress respiration through \( \mu \) receptors and \( \delta \) receptors in part by a direct depressant effect on rhythm generation. A key property of opiate effects on respiration is the depression of the ventilatory response to increased \( \text{CO}_2 \). Opiates also will depress ventilation otherwise driven by hypoxia through an effect on carotid and aortic body chemosensors. Importantly, with opiates, hypoxic stimulation of chemoreceptors still may be effective when opioids have decreased the responsiveness to \( \text{CO}_2 \), and inhalation of \( \text{O}_2 \) may remove the residual drive resulting from the elevated \( \text{PO}_2 \) and produce apnea. In addition to the effect upon respiratory rhythm and chemosensitivity, opiates can have mechanical effects on airway function by increasing chest wall rigidity and diminishing upper airway patency.

FACTORS EXACERBATING OPIATE-INDUCED RESPIRATORY DEPRESSION. A number of factors are recognized as increasing the risk of opiate-related respiratory depression even at therapeutic doses:

- **Other medications.** The combination of opiates with other depressant
medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics, produces additive depression of respiratory activity.

- **Sleep.** Natural sleep decreases the sensitivity of the medullary center to CO₂, and the depressant effects of morphine and sleep are at least additive. Obstructive sleep apnea is considered to be an important risk factor for increasing the likelihood of fatal respiratory depression.

- **Age.** Newborns can show significant respiratory depression and desaturation; and this may be evident in lower Apgar scores if opioids are administered parenterally to women within 2-4 h of delivery because of transplacental passage of opioids. Elderly patients are at greater risk of depression because of reduced lung elasticity, chest wall stiffening, and decreased vital capacity.

- **Disease.** Opiates may cause a greater depressant action in patients with chronic cardiopulmonary or renal diseases because they can manifest a desensitization of the response to increased CO₂.

- **COPD.** Enhanced depression can also be noted in patients with COPD and sleep apnea secondary to diminished hypoxic drive (although morphine can relieve gasping in late-stage COPD by this mechanism).

- **Relief of Pain.** Pain stimulates respiration; removal of the painful condition (as with the analgesia resulting from the therapeutic use of the opiate) will reduce the ventilatory drive and lead to apparent respiratory depression.

Respiratory depression produced by any opiate agonist can be readily reversed by delivery of an opiate antagonist. Opiate antagonist reversal in the somnolent patient is considered to be indicative of an opiate-mediated somnolence. It is important to remember that most opiate antagonists have a relatively short duration of action as compared to an agonist such as morphine or methadone and fatal “re-narcotization” can occur if vigilance is not exercised.

**NEUROENDOCRINE EFFECTS.** The regulation of the release of hormones and factors from the pituitary is under complex regulation by opiate receptors in the hypothalamic-pituitary-adrenal (HPA) axis. Broadly considered, morphine-like opioids block the release of a large number of HPA hormones.

**Sex Hormones.** In males, acute opiate therapy reduces plasma cortisol, testosterone, and gonadotrophins. Inhibition of adrenal function is reflected by reduced cortisol production and reduced adrenal androgens.
(dehydroepiandrosterone, DHEA). In females, morphine will additionally result in lower LH and FSH release. In both males and females, chronic therapy can result in endocrinopathies, including hypogonadotrophic hypogonadism. In men, this may result in decreased libido and, with extended exposure, reduced secondary sex characteristics. In women these exposures are associated with menstrual cycle irregularities. These changes are reversible with removal of the opiate.

**Prolactin.** Prolactin release from the anterior pituitary is under inhibitory control by DA released from neurons of the arcuate nucleus. MOR agonists act presynaptically on these DA-releasing terminals to inhibit DA release and thereby increase plasma prolactin.

**Antidiuretic Hormone and Oxytocin.** KOR agonists inhibit the release of oxytocin and antidiuretic hormone (and cause prominent diuresis). It should be noted that agents such as morphine may yield a hypotension secondary to histamine release and this would, by itself, promote ADH release.

**MIOSIS.** MOR agonists induce pupillary constriction (miosis) in the awake state and block pupillary reflex dilation during anesthesia. The parasympathetic outflow is locally regulated by GABA-ergic interneurons. Opiates are believed to block the GABA-ergic interneuron-mediated inhibition.

**OTHER EFFECTS**

**SEIZURES AND CONVULSIONS.** In older children and adults, moderately higher doses of opiates produce EEG slowing. In the newborn, morphine has been shown to produce epileptiform activity and occasionally seizure activity. Several mechanisms are most certainly involved in these excitatory actions:

- *Inhibition of inhibitory interneurons.* Morphine-like drugs excite certain groups of neurons, especially hippocampal pyramidal cells, probably from inhibition of the release of GABA by interneurons.
- *Direct stimulatory effects.*
- *Actions mediated by non-opioid receptors.* The metabolites of several opiates (morphine-3-glucuronide, normeperidine) have been implicated in
seizure activity.

**COUGH.** Morphine and related opioids depress the cough reflex at least in part by a direct effect on a cough center in the medulla and this can be achieved without altering the protective glottal function. Cough is a protective reflex evoked by airway stimulation. It involves rapid expression of air against a transiently closed glottis.

**NAUSEANT AND EMETIC EFFECTS.** Nausea and vomiting produced by morphine-like drugs are side effects caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla.

**CARDIOVASCULAR SYSTEM.** In the supine patient, therapeutic doses of morphine-like opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses can, however, produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Thus, when supine patients assume the head-up position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by morphine involves several mechanisms:

- Morphine induces release of histamine from mast cells, leading to vasodilation; this effect is reversed by naloxone but only partially blocked by H₁ antagonists
- Morphine blunts reflex vasoconstriction caused by increased P<sub>CO₂</sub>

Morphine may exert its therapeutic effect in the treatment of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial O₂ consumption. Morphine has been shown to produce cardioprotective effects. Morphine can mimic the phenomenon of ischemic preconditioning, where a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated through receptors signaling through a mitochondrial ATP-sensitive K⁺ channel in cardiac myocytes; the effect also is produced by other GPCRs signaling through G<sub>i</sub>. Morphine-like opioids should be used with caution in patients who have decreased blood volume because these agents can aggravate hypovolemic shock. Morphine should be used with great care in patients with cor pulmonale; deaths after ordinary therapeutic doses have been reported.
Concurrent use of certain phenothiazines may increase the risk of morphine-induced hypotension.

**MOTOR TONE.** High doses of opioids, as used for anesthetic induction, produce muscular rigidity. Myoclonus, ranging from mild twitching to generalized spasm, is an occasional side effect, which has been reported with all clinical opiate agonists; it is particularly prevalent in patients receiving high doses. Increase motor tone and rigidity are reversed by opiate antagonists.

**GI TRACT.** Between 40% and 95% of patients treated with opioids develop constipation and changes in bowel function. Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexi and on a variety of secretory cells.

**Esophagus.** Morphine inhibits lower esophageal sphincter relaxation induced by swallowing and by esophageal distension; the effect is believed to be centrally mediated.

**Stomach.** Morphine increases in tonic contracture of the antral musculature and upper duodenum and reduces resting tone in the musculature of the gastric reservoir, thereby prolonging gastric emptying time and increasing the likelihood of esophageal reflux. Passage of the gastric contents through the duodenum may be delayed by as much as 12 h, and the absorption of orally administered drugs is retarded. Morphine and other agonists usually decrease secretion of hydrochloric acid.

**Intestine.** Morphine reduces propulsatile activity in the small and large intestine and diminishes intestinal secretions. Opiate agonists suppress rhythmic inhibition of muscle tone leading to concurrent increases in basal tone in the circular muscle of the small and large intestine. This results in enhanced high-amplitude phasic contractions, which are nonpropulsive. The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the hypertonicity. The reduced rate of passage of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing viscosity of the bowel contents, and constipation. The tone of the anal sphincter is augmented greatly, and reflex relaxation in response to rectal distension is reduced. Patients who take opioids chronically remain constipated. Intestinal secretion arises from activation of
enterocytes by local cholinergic submucosal plexus secretomotor neurons. Opioids act though μ/δ receptors on these secretomotor neurons to inhibit their excitatory output to the enterocytes and thereby reduce intestinal secretion.

**Biliary Tract.** Morphine constricts the sphincter of Oddi, and the pressure in the common bile duct may rise >10-fold within 15 min. Fluid pressure also may increase in the gallbladder and produce symptoms that may vary from epigastric distress to typical biliary colic. All opioids can cause biliary spasm. Some patients with biliary colic experience exacerbation rather than relief of pain when given opioids. Spasm of the sphincter of Oddi probably is responsible for elevations of plasma amylase and lipase that occur sometimes after morphine administration.

**OTHER SMOOTH MUSCLE**

**Ureter and Urinary Bladder.** Morphine inhibits the urinary voiding reflex and increases the tone of the external sphincter with a resultant increase in the volume of the bladder. Tolerance develops to these effects of opioids on the bladder. Clinically, opiate-mediated inhibition of micturition can be of such clinical severity that catheterization sometimes is required after therapeutic doses of morphine, particularly with spinal drug administration. Importantly, the inhibition of systemic opiate effects on micturition is reversed by peripherally restricted antagonists.

**Uterus.** Morphine may prolong labor. If the uterus has been made hyperactive by oxytocics, morphine tends to restore the contractions to normal.

**SKIN.** Therapeutic doses of morphine cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. These changes may be due in part to the release of histamine and may be responsible for the sweating and some of the pruritus that commonly follow the systemic administration of morphine (described later). Histamine release probably accounts for the urticaria commonly seen at the site of injection. Itching is readily seen with morphine and meperidine but to a much lesser extent with oxymorphine, methadone, fentanyl, or sufentanil. This pruritus can be caused by systemic as well as intraspinal injections of opioids, but it is more intense after epidural or intrathecal administration.
IMMUNE SYSTEM. Opioids modulate immune function by direct effects on cells of the immune system and indirectly through centrally mediated neuronal mechanisms. The acute central immunomodulatory effects of opioids may be mediated by activation of the sympathetic nervous system; the chronic effects of opioids may involve modulation of the HPA axis. Direct effects on immune cells may involve unique variants of the classical neuronal opioid receptors, with μ receptor variants being most prominent. A proposed mechanism for the immune suppressive effects of morphine on neutrophils is through NO–dependent inhibition of NF-kB activation. Activation of MAP kinase also may play a role.

TEMPERATURE REGULATION. Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. Agonists at the μ receptor (e.g., alfentanil and meperidine), acting in the CNS, result in slightly increased thresholds for sweating and significantly lower the threshold temperatures for evoking vasoconstriction and shivering.

FUNCTIONAL OPIOID DRUG TYPES

Most of the clinically used opioid agonists presented in Table 18–4 are relatively selective for MOR. They produce analgesia, affect mood and rewarding behavior, and alter respiratory, cardiovascular, GI, and neuroendocrine function. KOR agonists, with few exceptions (e.g., butorphanol), are not typically employed for long-term therapy as they may produce dysphoric and psychotomimetic effects. DOR agonists have not found clinical utility, and NOP agonists lack analgesic effects. Opiates that are relatively receptor selective at lower doses will interact with additional receptor types when given at high doses, especially as doses are escalated to overcome tolerance.

These data are merely guidelines. Clinical response must be the guide for each patient, with consideration to hepatic and renal function, disease, age, concurrent medications (their effects and dose limitations [acetaminophen, 3 g/day for adults]), and other factors that could modify pharmacokinetics and drug response. Recommended start doses are approximately but not precisely equianalgesic and are driven by doses available from manufacturers. Transdermal fentanyl is contraindicated for acute pain and in patients receiving <60 mg oral morphine equivalent per day. Use Table 18–8 for converting morphine to methadone dosing.

For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences.
The mixed agonist–antagonist agents frequently interact with more than 1 receptor class at usual clinical doses. A “ceiling effect” limiting the amount of analgesia attainable often is seen with these drugs, such as buprenorphine, which is approved for the treatment of opioid dependence. Some mixed agonist–antagonist drugs, such as pentazocine and nalorphine (not available in the U.S.), can precipitate withdrawal in opioid-tolerant patients. For these reasons, except for the sanctioned use of buprenorphine to manage opioid addiction, the clinical use of mixed agonist–antagonist drugs is generally limited.

The dosing guidelines and duration of action for the numerous drugs that are part of opioid therapy are summarized in Table 18–4.
MORPHINE AND STRUCTURALLY RELATED AGONISTS

**MORPHINE.** Morphine remains the standard against which new analgesics are measured.

Morphine is obtained from opium or extracted from poppy straw. Powdered opium contains a number of alkaloids; only a few—morphine, codeine, and papaverine—have clinical utility. These alkaloids are divided into 2 distinct chemical classes, phenanthrenes and benzylisoquinolines. The principal phenanthrenes are morphine (10% of opium), codeine (0.5%), and thebaine (0.2%). The principal benzylisoquinolines are papaverine (1%) (a smooth muscle relaxant) and noscapine (6%). Many semisynthetic derivatives are made by relatively simple modifications of morphine or thebaine.

**Absorption.** Opioids are absorbed from the GI tract; absorption through the rectal mucosa is adequate and a few agents (e.g., morphine, hydromorphone) are available in suppositories. The more lipophilic opioids are absorbed readily through the nasal or buccal mucosa. Those with the greatest lipid solubility also can be absorbed transdermally. Opioids, particularly morphine, have been widely used for spinal delivery to produce analgesia through a spinal action. These agents display useful transdural movement adequate to permit their use epidurally.

With most opioids, including morphine, the effect of a given dose is less after oral than after parenteral administration because of variable but significant first-pass metabolism in the liver. For example, the bioavailability of oral preparations of morphine is only ~25%. The shape of the time-effect curve also varies with the route of administration, so the duration of action often is
somewhat longer with the oral route. If adjustment is made for variability of first-pass metabolism and clearance, adequate relief of pain can be achieved with oral administration of morphine. Satisfactory analgesia in cancer patients is associated with a very broad range of steady-state concentrations of morphine in plasma (16-364 ng/mL). When morphine and most opioids are given intravenously, they act promptly. Compared with more lipid-soluble opioids such as codeine, heroin, and methadone, morphine crosses the blood-brain barrier at a considerably lower rate.

**Distribution and Metabolism.** About one-third of morphine in the plasma is protein-bound after a therapeutic dose. Morphine itself does not persist in tissues, and 24 h after the last dose, tissue concentrations are low. The major pathway for the metabolism of morphine is conjugation with glucuronic acid. The 2 major metabolites formed are morphine-6-glucuronide and morphine-3-glucuronide. Morphine-6-glucuronide has pharmacological actions indistinguishable from those of morphine. With chronic administration, the 6-glucuronide accounts for a significant portion of morphine’s analgesic actions. Morphine-6-glucuronide is excreted by the kidney. In renal failure, the levels of morphine-6-glucuronide can accumulate, perhaps explaining morphine’s potency and long duration in patients with compromised renal function. In adults, the $t_{1/2}$ of morphine is ~2 h; the $t_{1/2}$ of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of morphine are recommended based on a smaller volume of distribution and the general decline in renal function. Morphine-3-glucuronide has little affinity for opioid receptors but may contribute to excitatory effects of morphine. N-Dealkylation also is important in the metabolism of some congeners of morphine.

**Excretion.** *Morphine* is eliminated by glomerular filtration, primarily as morphine-3-glucuronide; 90% of the total excretion takes place during the first day. Very little morphine is excreted unchanged.

**CODEINE.** In contrast to morphine, codeine is ~60% as effective orally as parenterally as an analgesic and as a respiratory depressant. Codeine analogs such as levorphanol, oxycodone, and methadone have a high ratio of oral-to-parenteral potency. The greater oral efficacy of these drugs reflects lower first-pass metabolism in the liver. Once absorbed, codeine is metabolized by the liver,
and its metabolites are excreted chiefly as inactive forms in the urine. A small fraction (~10%) of administered codeine is O-demethylated to morphine, and free and conjugated morphine can be found in the urine after therapeutic doses of codeine. Codeine has an exceptionally low affinity for opioid receptors, and the analgesic effect of codeine is due to its conversion to morphine. However, codeine’s antitussive actions may involve distinct receptors that bind codeine itself, and codeine is commonly employed for the management of cough. The $t_{1/2}$ of codeine in plasma is 2-4 h.

CYP2D6 catalyzes the conversion of codeine to morphine. Genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for ~10% of the Caucasian population. Other polymorphisms (e.g., the CYP2D6*2×2 genotype) can lead to ultrarapid metabolism and thus increased sensitivity to codeine’s effects due to higher than expected serum morphine levels. Thus, it is important to consider the possibility of metabolic enzyme polymorphism in any patient who experiences toxicity or does not receive adequate analgesia from codeine or other opioid prodrugs (e.g., hydrocodone and oxycodone).

**HEROIN.** Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-monoacetylmorphine (6-MAM), which in turn is hydrolyzed to morphine. Heroin and 6-MAM are more lipid soluble than morphine and enter the brain more readily. Evidence suggests that morphine and 6-MAM are responsible for the pharmacological actions of heroin. Heroin is excreted mainly in the urine largely as free and conjugated morphine.

**UNTOWARD EFFECTS AND PRECAUTIONS**

Morphine and related opioids produce a wide spectrum of unwanted effects, including respiratory depression, nausea, vomiting, dizziness, mental clouding, dysphoria, pruritus, constipation, increased pressure in the biliary tract, urinary retention, and hypotension. Rarely, a patient may develop delirium. Increased sensitivity to pain after analgesia has worn off and between-dose withdrawal also may occur.

A number of factors may alter a patient’s sensitivity to opioid analgesics, including the integrity of the blood-brain barrier. Morphine is hydrophilic, so
proportionately less morphine normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than morphine. In adults, the duration of the analgesia produced by morphine increases progressively with age; however, the degree of analgesia that is obtained with a given dose changes little. The patient with severe pain may tolerate larger doses of morphine. However, as the pain subsides, the patient may exhibit sedation and even respiratory depression as the stimulatory effects of pain are diminished.

All opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease. Renal disease also significantly alters the pharmacokinetics of morphine, codeine, dihydrocodeine, meperidine, and propoxyphene. Although single doses of morphine are well tolerated, the active metabolite, morphine-6-glucuronide, may accumulate with continued dosing, and symptoms of opioid overdose may result. This metabolite also may accumulate during repeated administration of codeine to patients with impaired renal function.

Morphine and related opioids must be used cautiously in patients with compromised respiratory function (e.g., emphysema, kyphoscoliosis, severe obesity). The respiratory-depressant effects of opioids and the related capacity to elevate intracranial pressure must be considered in the presence of head injury or an already elevated intracranial pressure. Patients with reduced blood volume are more susceptible to the vasodilating effects of morphine and related drugs, and these agents must be used cautiously in patients with hypotension from any cause.

Morphine causes histamine release, which can cause bronchoconstriction and vasodilation. Morphine has the potential to precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. Other receptor agonists associated with a lower incidence of histamine release, such as the fentanyl derivatives, may be better choices for such patients. Opioid analgesics may evoke allergic phenomena, the effects usually are manifested as urticaria and other types of skin rashes.

**LEVORPHANOL**

Levorphanol (LEVO-DROMORAN) is the principal available opioid
agonist of the morphinan series.

The D-isomer (dextrorphan) is devoid of analgesic action but has inhibitory effects at NMDA receptors. It has affinity at the MOR, KOR, and DORs and is available for intravenous (IV), intramuscular (IM), and oral administration. The pharmacological effects of levorphanol closely parallel those of morphine. However, clinical reports suggest that it may produce less nausea and vomiting. Levorphanol is metabolized less rapidly than morphine and has a $t_{1/2}$ of 12-16 h; repeated administration at short intervals may thus lead to accumulation of the drug in plasma.

**MEPERIDINE, DIPHENOXYLATE, LOPERAMIDE**

These agents are MOR agonists with principal pharmacological effects on the CNS and neural elements in the bowel.

**MEPERIDINE**

Meperidine is predominantly an MOR agonist that produces a pattern of effects similar but not identical to those already described for morphine.

*CNS Actions.* Meperidine is a potent MOR agonist yielding strong analgesic actions. Meperidine causes pupillary constriction, increases the sensitivity of the labyrinthine apparatus, and has effects on the secretion of pituitary hormones similar to those of morphine. Meperidine sometimes causes CNS excitation, characterized by tremors, muscle twitches, and seizures; these effects are due largely to accumulation of a metabolite, normeperidine. Meperidine has well-known local anesthetic properties, particularly noted after epidural administration. As with morphine, respiratory depression is responsible for an accumulation of CO$_2$, which in turn leads to cerebrovascular dilation, increased cerebral blood flow, and elevation of cerebrospinal fluid pressure.

*Cardiovascular System.* The effects of meperidine on the cardiovascular system generally resemble those of morphine, including the ability to release histamine following parenteral administration. Intramuscular administration of meperidine does not affect heart rate significantly, but IV administration frequently produces
a marked increase in heart rate.

**Smooth Muscle, GI Tract.** Meperidine does not cause as much constipation as does morphine, even when given over prolonged periods of time; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. As with other opioids, clinical doses of meperidine slow gastric emptying sufficiently to delay absorption of other drugs significantly. The uterus of a nonpregnant woman usually is mildly stimulated by meperidine. Administered before an oxytocic, meperidine does not exert any antagonistic effect.

**ADME.** Meperidine is absorbed by all routes of administration. The peak plasma concentration usually occurs at ~45 min, but the range is wide. After oral administration, only ~50% of the drug escapes first-pass metabolism to enter the circulation, and peak concentrations in plasma usually are observed in 1-2 h. Meperidine is metabolized chiefly in the liver, with a $t_{1/2} \sim 3$ h. In patients with cirrhosis, the bioavailability of meperidine (the N-demethyl metabolite) is increased to as much as 80%, and the $t_{1/2}$ of both meperidine and normeperidine are prolonged. Only a small amount of meperidine is excreted unchanged.

**UNTOWARD EFFECTS, PRECAUTIONS, AND CONTRAINDICATIONS.** The overall incidence of untoward effects are similar to those observed after equianalgesic doses of morphine, except that constipation and urinary retention may be less common. Patients who experience nausea and vomiting with morphine may not do so with meperidine; the converse also may be true. In patients or addicts who are tolerant to the depressant effects of meperidine, large doses repeated at short intervals may produce an excitatory syndrome including hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of normeperidine, which has a $t_{1/2}$ of 15-20 h, compared to 3 h for meperidine. Decreased renal or hepatic function increases the likelihood of toxicity. As a result of these properties, meperidine is not recommended for the treatment of chronic pain because of concerns over metabolite toxicity. It should not be used for longer than 48 h or in doses >600 mg/day.
INTERACTIONS WITH OTHER DRUGS. Severe reactions may follow the administration of meperidine to patients being treated with MAO inhibitors. Two basic types of interactions can be observed. The more prominent is an excitatory reaction (“serotonin syndrome”) with delirium, hyperthermia, headache, hyper- or hypotension, rigidity, convulsions, coma, and death. This reaction may be due to the ability of meperidine to block neuronal reuptake of 5HT, resulting in serotonergic overactivity. Conversely, the MAO inhibitor interaction with meperidine may resemble acute narcotic overdose owing to the inhibition of hepatic CYPs. Therefore, meperidine and its congeners are contraindicated in patients taking MAO inhibitors or within 14 days after discontinuation of an MAO inhibitor. Dextromethorphan (an analog of levorphanol used as a nonnarcotic cough suppressant) also inhibits neuronal 5HT uptake and must be avoided in these patients.

Chlorpromazine increases the respiratory-depressant effects of meperidine, as do tricyclic antidepressants (but not diazepam). Concurrent administration of drugs such as promethazine or chlorpromazine also may greatly enhance meperidine-induced sedation without slowing clearance of the drug. Treatment with phenobarbital or phenytoin increases systemic clearance and decreases oral bioavailability of meperidine. As with morphine, concomitant administration of amphetamine has been reported to enhance the analgesic effects of meperidine and its congeners while counteracting sedation.

THERAPEUTIC USES. The major use of meperidine is for analgesia. The analgesic effects of meperidine are detectable ~15 min after oral administration, peak in 1-2 h, and subside gradually. The onset of analgesic effect is faster (within 10 min) after subcutaneous or IM administration, and the effect reaches a peak in ~1 h, corresponding closely to peak concentrations in plasma. In clinical use, the duration of effective analgesia is ~1.5-3 h. In general, 75-100 mg meperidine hydrochloride (pethidine, DEMEROL, others) given parenterally is approximately equivalent to 10 mg morphine. In terms of total analgesic effect, meperidine is about one-third as effective when given orally as when administered parenterally.

Single doses of meperidine can be effective in the treatment of postanesthetic shivering. Meperidine, 25-50 mg, is used frequently with antihistamines, corticosteroids, acetaminophen, or NSAIDs to prevent or ameliorate infusion-related rigors and shaking chills that accompany the IV administration of agents
such as amphotericin B, aldesleukin (interleukin-2), trastuzumab, and alemtuzumab. Meperidine crosses the placental barrier and even in reasonable analgesic doses causes a significant increase in the percentage of babies who show delayed respiration, decreased respiratory minute volume, or decreased $O_2$ saturation or who require resuscitation. Fetal and maternal respiratory depression induced by meperidine can be treated with naloxone.

**DIPHENOXYLATE**

Diphenoxylate is a meperidine congener that has a definite constipating effect in humans. Its only approved use is in the treatment of diarrhea (see Chapter 46). Diphenoxylate is unusual in that even its salts are virtually insoluble in aqueous solution, thus reducing the probability of abuse by the parenteral route. Diphenoxylate hydrochloride is available only in combination with atropine sulfate (LOMOTIL, others). The recommended daily dosage of diphenoxylate for the treatment of diarrhea in adults is 20 mg in divided doses. Difenoxin a metabolite of diphenoxylate, is marketed in a fixed dose with atropine (MOTOFEN) for the management of diarrhea.

**LOPERAMIDE**

Loperamide (IMODIUM, others), like diphenoxylate, is a piperidine derivative. It slows GI motility by effects on the circular and longitudinal muscles of the intestine. Part of its antidiarrheal effect may be due to a reduction of GI secretion. In controlling chronic diarrhea, loperamide is as effective as diphenoxylate and little tolerance develops to its constipating effect. Concentrations of drug in plasma peak $\sim 4$ h after ingestion. The apparent elimination $t_{1/2}$ is 7-14 h. Loperamide is poorly absorbed after oral administration and, in addition, apparently does not penetrate well into the brain due to the exporting activity of P-glycoprotein, which is widely expressed in the brain endothelium. The usual dosage is 4-8 mg/day; the daily dose should not exceed 16 mg.
FENTANYL AND CONGENERS

FENTANYL

Fentanyl is a synthetic opioid related to the phenylpiperidines. The actions of fentanyl and its congeners, sufentanil, remifentanil, and alfentanil, are similar to those of other MOR agonists. Fentanyl and sufentanil are very important drugs in anesthetic practice because of their relatively short time to peak analgesic effect, rapid termination of effect after small bolus doses, and cardiovascular safety and their capacity to significantly reduce the dosing requirement for the volatile agents (see Chapter 19). In addition to a role in anesthesia, fentanyl also is used in the management of severe pain states.

PHARMACOLOGICAL PROPERTIES

CNS. Fentanyl and its congeners are all extremely potent analgesics and typically exhibit a very short duration of action when given parenterally. As with other opioids, nausea, vomiting, and itching can be observed. Muscle rigidity, while possible after all narcotics, appears to be more common after the high doses used in anesthetic induction. Rigidity can be treated with depolarizing or nondepolarizing neuromuscular blocking agents while controlling the patient’s ventilation. Care must be taken to make sure that the patient is not simply immobilized but aware. Respiratory depression is similar to that observed with other MOR agonists, but onset is more rapid. As with analgesia, respiratory depression after small doses is of shorter duration than with morphine but of similar duration after large doses or long infusions. Delayed respiratory depression also can be seen after the use of fentanyl or sufentanil, possibly owing to enterohepatic circulation.

Cardiovascular System. Fentanyl and its derivatives decrease heart rate and mildly decrease blood pressure. However, these drugs do not release histamine and direct depressant effects on the myocardium are minimal.

ADME. These agents are highly lipid soluble and rapidly cross the blood-brain barrier. This is reflected in the $t_{1/2}$ for equilibration between the plasma and CSF of ~5 min for fentanyl and sufentanil. The levels in plasma and CSF decline
rapidly owing to redistribution of fentanyl from highly perfused tissue groups to other tissues, such as muscle and fat. As saturation of less well-perfused tissue occurs, the duration of effect of fentanyl and sufentanil approaches the length of their elimination $t_{1/2}$, 3-4 h. Fentanyl and sufentanil undergo hepatic metabolism and renal excretion. With the use of higher doses or prolonged infusions, the drugs accumulate, these clearance mechanisms become progressively saturated, and fentanyl and sufentanil become longer acting.

**THERAPEUTIC USES.** Fentanyl citrate (SUBLIMAZE, others) and sufentanil citrate (SUFINTE, others) have widespread popularity as anesthetic adjuvants (see Chapter 19), administered intravenously, epidurally, or intrathecally. Fentanyl is ~100 times more potent than morphine; sufentanil is ~1000 times more potent than morphine. The time to peak analgesic effect after IV administration of fentanyl and sufentanil (~5 min) is notably less than that for morphine and meperidine (~15 min). Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the effects of these drugs become more lasting, with durations of action becoming similar to those of longer-acting opioids.

The use of fentanyl and sufentanil in chronic pain treatment has become more widespread. Transdermal patches (DURAGESIC, others) that provide sustained release of fentanyl for 48-72 h are available. However, factors promoting increased absorption (e.g., fever) can lead to relative overdosage and increased side effects. Transbuccal absorption by the use of buccal tablets, and lollipop-like lozenges permits rapid absorption and has found use in the management of acute incident pain (FENTORA, ACTIQ, ONSOLIS, others) and for the relief of breakthrough cancer pain. As fentanyl is poorly absorbed in the GI tract, the optimal absorption is through buccal absorption. Epidural use of fentanyl and sufentanil for postoperative or labor analgesia is popular. A combination of epidural opioids with local anesthetics permits reduction in the dosage of both components.

**REMIFENTANIL**

The pharmacological properties of remifentanil are similar to those of fentanyl and sufentanil. Remifentanil produces similar incidences of nausea, vomiting, and dose-dependent muscle rigidity.
ADME. Remifentanil has a more rapid onset of analgesic action than fentanyl or sufentanil. Analgesic effects occur within 1-1.5 min following IV administration. Peak respiratory depression after bolus doses of remifentanil occurs after 5 min. Remifentanil is metabolized by plasma esterases, with a $t_{1/2}$ of 8-20 min; thus, elimination is independent of hepatic metabolism or renal excretion. Age and weight can affect clearance of remifentanil. After 3- to 5-h infusions of remifentanil, recovery of respiratory function can be seen within 3-5 min; full recovery from all effects of remifentanil is observed within 15 min. The primary metabolite, remifentanil acid, has 0.05-0.025% of the potency of the parent compound, and is excreted renally.

THERAPEUTIC USES. Remifentanil hydrochloride (ULTIVA) is useful for short, painful procedures that require intense analgesia and blunting of stress responses; the drug is routinely given by continuous IV infusion because its short duration of action. When postprocedural analgesia is required, remifentanil alone is a poor choice. In this situation, either a longer-acting opioid or another analgesic modality should be combined with remifentanil for prolonged analgesia, or another opioid should be used. Remifentanil is not used intraspinally because of its formulation with glycine, an inhibitory transmitter in the spinal dorsal horn.

METHADONE AND PROPOXYPHENE

METHADONE

Methadone is a long-acting MOR agonist with pharmacological properties qualitatively similar to those of morphine. The analgesic activity of methadone, a racemate, is almost entirely the result of its content of L-methadone, which is 8-50 times more potent than the D-isomer. D-methadone also lacks significant respiratory depressant action and addiction liability but possesses antitussive activity.

MAJOR EFFECTS; SIDE EFFECTS. The outstanding properties of methadone are its analgesic activity, its efficacy by the oral route, its extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and its tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for >24 h after a single dose;
on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of morphine. Side effects are similar to those described for morphine. Rifampin and phenytoin accelerate the metabolism of methadone and can precipitate withdrawal symptoms. Unlike other opioids, methadone is associated with the prolonged QT syndrome and is additive with agents known to prolong the QT interval.

ADME. Methadone is absorbed well from the GI tract and can be detected in plasma within 30 min of oral ingestion; it reaches peak concentrations at ~4 h. Peak concentrations occur in brain within 1-2 h of subcutaneous or IM administration, and this correlates well with the intensity and duration of analgesia. Methadone also can be absorbed from the buccal mucosa. Methadone undergoes extensive biotransformation in the liver. The major metabolites, pyrrolidine and pyrroline, are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of methadone excreted in the urine is increased when the urine is acidified. The $t_{1/2}$ of methadone is long, 15-40 h. Methadone appears to be firmly bound to protein in various tissues, including brain. After repeated administration, there is gradual accumulation in tissues. When administration is discontinued, low concentrations are maintained in plasma by slow release from extravascular binding sites; this process probably accounts for the relatively mild but protracted withdrawal syndrome.

THERAPEUTIC USES. The primary uses of methadone hydrochloride (DOLOPHINE, others) are relief of chronic pain, treatment of opioid abstinence syndromes, and treatment of heroin users. The onset of analgesia occurs 10-20 min after parenteral administration and 30-60 min after oral medication. The typical oral dose is 2.5-10 mg repeated every 8-12 h as needed depending on the severity of the pain and the response of the patient. Care must be taken when increasing the dosage because of the prolonged $t_{1/2}$ of the drug and its tendency to accumulate over a period of several days with repeated dosing. The peak respiratory depressant effects of methadone typically occur later and persist longer than peak analgesia, so it is necessary to exercise vigilance and strongly caution patients against self-medicating with CNS depressants, particularly during treatment initiation and dose titration. Methadone should not be used in labor. Despite its longer plasma $t_{1/2}$, the duration of the analgesic action of single doses is essentially the same as that of morphine. With repeated use, cumulative
effects are seen, so either lower dosages or longer intervals between doses become possible.

Because of its oral bioavailability and long $t_{1/2}$, methadone has been widely implemented as a replacement modality to treat heroin dependence. Methadone, like other opiates, will produce tolerance and dependence. Thus, addicts who receive daily subcutaneous or oral therapy develop partial tolerance to the nauseant, anorectic, miotic, sedative, respiratory-depressant, and cardiovascular effects of methadone. Many former heroin users treated with oral methadone show virtually no overt behavioral effects. Development of physical dependence during the long-term administration of methadone can be demonstrated following abrupt drug withdrawal or by administration of an opioid antagonist. Likewise, subcutaneous administration of methadone to former opioid addicts produces euphoria equal in duration to that caused by morphine, and its overall abuse potential is comparable with that of morphine.

**PROPOXYPHENE**

Propoxyphene is structurally related to methadone. Its analgesic effect resides in the D-isomer. However, L-propoxyphene seems to have some antitussive activity.

**PHARMACOLOGICAL ACTIONS.** Although slightly less selective than morphine, propoxyphene binds primarily to MOR and produces analgesia and other CNS effects that are similar to those seen with morphine-like opioids. At equianalgesic doses, the incidence of side effects such as nausea, anorexia, constipation, abdominal pain, and drowsiness are similar to those of codeine. As an analgesic, propoxyphene is about one-half to two-thirds as potent as codeine given orally. A dose of 90-120 mg of propoxyphene hydrochloride administered orally provides the analgesic effects of 60 mg of codeine, a dose that usually produces about as much analgesia as 600 mg aspirin. Combinations of propoxyphene and aspirin, like combinations of codeine and aspirin, afford a higher level of analgesia than does either agent given alone. Given orally, propoxyphene is approximately one-third as potent as orally administered codeine in depressing respiration. Large toxic doses may produce convulsions in addition to respiratory depression. Naloxone antagonizes the respiratory-depressant, convulsant, and some of the cardiotoxic effects of propoxyphene.
ADME. After oral administration, peak plasma concentrations occur at 1-2 h. There is great variability between subjects in the rate of clearance. The average \( t_{1/2} \) of propoxyphene in plasma after a single dose is 6-12 h, which is longer than that of codeine. In humans, the major route of metabolism is N-demethylation to yield norpropoxyphene. The \( t_{1/2} \) of norpropoxyphene is \(~30 \) h; it may accumulate with repeated doses and cause some toxicity.

Higher than expected serum levels of propoxyphene will occur from the concomitant administration of strong CYP3A4 inhibitors (e.g., ritonavir, ketoconazole, itraconazole, clarithromycin, nefazodone, amiodarone, amprenavir, aprepitant, diltiazem, erythromycin, fluconazole, fosamprenavir, grapefruit juice, and verapamil). Propoxyphene alternatives should be considered for patients receiving a strong CYP3A4 inhibitor and others at risk for overdose, particularly those with preexisting heart disease.

TOLERANCE AND DEPENDENCE. Very large doses (800 mg propoxyphene hydrochloride [Darvon, others] or 1200 mg of the napsylate [Darvon-N] per day) reduce the intensity of the morphine withdrawal syndrome somewhat less effectively than do 1500 mg doses of codeine. Maximal tolerated doses are equivalent to daily doses of 20-25 mg morphine given subcutaneously. The use of higher doses of propoxyphene is accompanied by untoward effects including toxic psychoses. Very large doses produce some respiratory depression in morphine-tolerant addicts, suggesting that cross-tolerance between propoxyphene and morphine is incomplete. Abrupt discontinuation of chronically administered propoxyphene hydrochloride (up to 800 mg/day given for almost 2 months) results in mild abstinence phenomena, and large oral doses (300-600 mg) produce subjective effects that are considered pleasurable by post-addicts. The drug is quite irritating when administered either intravenously or subcutaneously, so abuse by these routes results in severe damage to veins and soft tissues.

THERAPEUTIC USES. The European Medicines Agency has concluded that the benefits of dextropropoxyphene do not outweigh the risks, that dextropropoxyphene-containing medicines are weak painkillers with a narrow therapeutic index and limited effectiveness in the treatment of pain, and that acetaminophen-containing combinations with dextropropoxyphene are no more effective than acetaminophen alone. Consequently, the Agency has
recommended a gradual withdrawal of marketing authorization throughout the E.U. In the U.S., the FDA has asked companies to voluntarily remove propoxyphene-containing products from the market due to concerns related to cardiotoxic effects of the drug at therapeutic doses.

**OTHER OPIOID AGONISTS**

**TRAMADOL.** Tramadol (ULTRAM) is a synthetic codeine analog that is a weak MOR agonist. Part of its analgesic effect is produced by inhibition of uptake of NE and 5HT. In the treatment of mild to moderate pain, tramadol is as effective as morphine or meperidine. However, for the treatment of severe or chronic pain, tramadol is less effective. Tramadol is as effective as meperidine in the treatment of labor pain and may cause less neonatal respiratory depression.

**ADME.** Tramadol is 68% bioavailable after a single oral dose and 100% available when administered intramuscularly. Its affinity for the μ-opioid receptor is only 1/6000 that of morphine. The primary O-demethylated metabolite of tramadol is 2-4 times more potent than the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemate that is more effective than either enantiomer alone. The (+)-enantiomer binds to the receptor and inhibits 5HT uptake. The (–)-enantiomer inhibits NE uptake and stimulates α₂ adrenergic receptors. Tramadol undergoes extensive hepatic metabolism by a number of pathways, including CYP2D6 and CYP3A4, as well as by conjugation with subsequent renal excretion. The elimination $t_{1/2}$ is 6 h for tramadol and 7.5 h for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2-3 h. The duration of analgesia is ~6 h. The maximum recommended daily dose is 400 mg.

**Side Effects; Adverse Effects.** Side effects of tramadol include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression appears to be less than with equianalgesic doses of morphine, and the degree of constipation is less than that seen after equivalent doses of codeine. Tramadol can cause seizures and possibly exacerbate seizures in patients with predisposing factors. Tramadol-induced respiratory depression is reversed by naloxone. Precipitation of withdrawal necessitates that tramadol be tapered prior to discontinuation. Tramadol should not be used in patients taking MAO inhibitors,
SSRIs, or other drugs that lower the seizure threshold.

**TAPENTADOL.** Tapentadol (Nucynta) is structurally and mechanistically similar to tramadol. It displays a mild opioid activity and possesses monoamine reuptake inhibitor activity. It is considered similar to tramadol in activity, efficacy, and side-effect profile.

**OPIOID AGONISTS/ANTAGONISTS AND PARTIAL AGONISTS**

Drugs such as *nalbuphine* and *butorphanol* are competitive MOR antagonists but exert their analgesic actions by acting as agonists at KOR receptors. *Pentazocine* qualitatively resembles these drugs, but it may be a weaker MOR receptor antagonist or partial agonist while retaining its KOR agonist activity. *Buprenorphine*, however, is a partial agonist at MOR. The stimulus for the development of mixed agonist–antagonist drugs was a desire for analgesics with less respiratory depression and addictive potential. However, the clinical use of these compounds is limited by undesirable side effects and limited analgesic effects.

**PENTAZOCINE**

Pentazocine was synthesized as part of a deliberate effort to develop an effective analgesic with little or no abuse potential. It has agonistic actions and weak opioid antagonistic activity.

**PHARMACOLOGICAL ACTIONS AND SIDE EFFECTS.** The pattern of CNS effects produced by pentazocine generally is similar to that of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at KOR. Higher doses of pentazocine (60-90 mg) elicit dysphoric and psychotomimetic effects; these effects may be reversible by naloxone. The cardiovascular responses to pentazocine differ from those seen with typical receptor agonists, in that high doses cause an increase in blood pressure and heart rate. Pentazocine acts as a weak antagonist or partial agonist at MOR. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients
dependent on morphine or other MOR agonists, pentazocine may precipitate withdrawal. Ceiling effects for analgesia and respiratory depression are observed at doses above 50-100 mg of pentazocine.

**THERAPEUTIC USES.** Pentazocine lactate (TALWIN) injection is indicated for the relief of moderate to severe pain and is also used as a preoperative medication and as a supplement to anesthesia. Pentazocine tablets for oral use are only available in fixed-dose combinations with acetaminophen (TALACEN, others) or naloxone (TALWIN NX). Combination of pentazocine with naloxone reduces the potential misuse of tablets as a source of injectable pentazocine by producing undesirable effects in subjects dependent on opioids. An oral dose of ~50 mg pentazocine results in analgesia equivalent to that produced by 60 mg of codeine orally.

**NALBUPHINE**

Nalbuphine is a KOR agonist-MOR antagonist opioid with effects that qualitatively resemble those of pentazocine; however, nalbuphine produces fewer dysphoric side effects than pentazocine.

**PHARMACOLOGICAL ACTIONS AND SIDE EFFECTS.** An IM dose of 10 mg nalbuphine is equianalgesic to 10 mg morphine, with similar onset and duration of analgesic and subjective effects. Nalbuphine depresses respiration as much as do equianalgesic doses of morphine; however, nalbuphine exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression or analgesia. In contrast to pentazocine and butorphanol, 10 mg nalbuphine given to patients with stable coronary artery disease does not produce an increase in cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are relatively stable when nalbuphine is given to patients with acute myocardial infarction. Nalbuphine produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are the most common. At much higher doses (70 mg), psychotomimetic side effects (e.g., dysphoria, racing thoughts, and distortions of body image) can occur. Nalbuphine is metabolized in the liver and has a plasma $t_{1/2}$ of 2-3 h. Nalbuphine is 20-25% as potent when administered orally as when given intramuscularly. Prolonged administration of nalbuphine can produce physical dependence. The withdrawal syndrome is similar in
intensity to that seen with pentazocine.

**THERAPEUTIC USE.** Nalbuphine hydrochloride (NUBAIN, others) is used to produce analgesia. Because it is an agonist–antagonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed. The usual adult dose is 10 mg parenterally every 3-6 h; this may be increased to 20 mg in nontolerant individuals. A caveat: Agents that act through the KOR have been reported to be relatively more effective in women than in men.

**BUTORPHANOL**

Butorphanol is a morphinan congener with a profile of actions similar to those of pentazocine and nalbuphine: KOR agonist and MOR antagonist.

**PHARMACOLOGICAL ACTIONS AND SIDE EFFECTS.** In postoperative patients, a parenteral dose of 2-3 mg butorphanol produces analgesia and respiratory depression approximately equal to that produced by 10 mg morphine or 80-100 mg meperidine. The plasma $t_{1/2}$ of butorphanol is ~3 h. Like pentazocine, analgesic doses of butorphanol produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased. The major side effects of butorphanol are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence of psychotomimetic side effects is lower than that with equianalgesic doses of pentazocine, they are qualitatively similar. Nasal administration is associated with drowsiness and dizziness. Physical dependence can occur.

**THERAPEUTIC USE.** Butorphanol tartrate (STADOL, others) is used for the relief of acute pain (e.g., postoperative), and because of its potential for antagonizing MOR agonists should not be used in combination. Because of its side effects on the heart, it is less useful than morphine or meperidine in patients with congestive heart failure or myocardial infarction. The usual dose is 1-4 mg of the tartrate given intramuscularly, or 0.5-2 mg given intravenously, every 3-4 h. A nasal formulation is available and has proven to be effective in pain relief,
including migraine pain.

**BUPRENORPHINE**

Buprenorphine is a highly lipophilic MOR agonist, 25-50 times more potent than morphine. It is a partial MOR agonist (e.g., has limited intrinsic activity) and accordingly can display antagonism when used in conjunction with a full agonist.

**PHARMACOLOGICAL ACTIONS.** Buprenorphine produces analgesia and other CNS effects that are qualitatively similar to those of morphine. About 0.4 mg buprenorphine is equianalgesic with 10 mg morphine given intramuscularly. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of morphine. Buprenorphine is a partial MOR agonist; thus, it may cause symptoms of abstinence in patients who have been receiving μ receptor agonists for several weeks. It antagonizes the respiratory depression produced by anesthetic doses of fentanyl about as well as naloxone without completely reversing opioid pain relief. The respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by high doses of naloxone once the effects have been produced, probably due to slow dissociation of buprenorphine from opioid receptors. The \( t_{1/2} \) for dissociation from the receptor is 166 min for buprenorphine, as opposed to 7 min for fentanyl. Therefore, plasma levels of buprenorphine may not parallel clinical effects. Cardiovascular and other side effects (e.g., sedation, nausea, vomiting, dizziness, sweating, and headache) appear to be similar to those of morphine-like opioids.

Administered sublingually, buprenorphine (0.4-0.8 mg) produces satisfactory analgesia in postoperative patients. Concentrations in blood peak within 5 min of IM injection and within 1-2 h of oral or sublingual administration. While the plasma \( t_{1/2} \) in plasma is ~3 h, this value bears little relationship to the rate of disappearance of effects. Both N-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces. When buprenorphine is discontinued, a withdrawal syndrome develops that is delayed in onset for 2-14 days and persists for 1-2 weeks.

**THERAPEUTIC USES.** Buprenorphine (BUPRENEX) injection is indicated for
use as an analgesic. Oral formulations of buprenorphine (SUBUTEX) and buprenorphine in fixed-dose combination with naloxone (SUBOXONE) are used for treatment of opioid dependence. The usual IM or IV dose for analgesia is 0.3 mg given every 6 h. Buprenorphine is metabolized to norbuprenorphine by CYP3A4 and should not be taken with known inhibitors of CYP3A4 (e.g., azole antifungals, macrolide antibiotics, and HIV protease inhibitors), or drugs that induce CYP3A4 activity (e.g., certain anticonvulsants and rifampin).

**OPIOID ANTAGONISTS**

A variety of agents bind competitively to 1 or more of the opioid receptors, display little or no intrinsic activity, and robustly antagonize the effects of receptor agonists.

Relatively minor changes in the structure of an opioid can convert a drug that is primarily an agonist into 1 with antagonistic actions at 1 or more types of opioid receptors. Simple substitutions transform morphine to nalorphine, levorphanol to levallorphan, and oxymorphone to naloxone (NARCAN, others) or naltrexone (REVIA, VIVITROL, others). In some cases, congeners are produced that are competitive antagonists at MOR but that also have agonistic actions at KORs; nalorphine and levallorphan have such properties. Other congeners, especially naloxone and naltrexone, appear to be devoid of agonistic actions and interact with all types of opioid receptors, albeit with somewhat different affinities. Nalmefene (not marketed in the U.S.) is a relatively pure MOR antagonist that is more potent than naloxone. The majority of these agents are relatively lipid soluble and have excellent CNS bioavailability after systemic delivery. A recognition that there was a need for antagonism limited to peripheral sites led to the development of agents that have poor CNS bioavailability such as methylnaltrexone (RELISTOR).

**PHARMACOLOGICAL PROPERTIES**

Opioid antagonists have obvious therapeutic utility in the treatment of opioid overdose. Under ordinary circumstances, these opioid antagonists produce few effects in the absence of an exogenous agonist. However, under certain conditions (e.g., shock), when the endogenous opioid systems are activated, the administration of an
opioid antagonist alone may have visible consequences.

EFFECTS IN THE ABSENCE OF OPIOID AGONISTS. Subcutaneous doses of naloxone up to 12 mg produce no discernible effects in humans, and 24 mg causes only slight drowsiness. Naltrexone also is a relatively pure antagonist but with higher oral efficacy and a longer duration of action. The effects of opiate receptor antagonists are usually both subtle and limited. Most likely this reflects the low levels of tonic activity and organizational complexity of the opioid systems in various physiologic systems. Opiate antagonism in humans is associated with variable effects ranging from no effect to a mild hyperalgesia. A number of studies have, however, suggested that agents such as naloxone appear to attenuate the analgesic effects of placebo medications and acupuncture.

Endogenous opioid peptides participate in the regulation of pituitary secretion apparently by exerting tonic inhibitory effects on the release of certain hypothalamic hormones (see Chapter 38). Thus, the administration of naloxone or naltrexone increases the secretion of gonadotropin-releasing hormone and corticotropin-releasing hormone and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. Naloxone stimulates the release of prolactin in women. Endogenous opioid peptides probably have some role in the regulation of feeding or energy metabolism; however, naltrexone does not accelerate weight loss in very obese subjects, even though short-term administration of opioid antagonists reduces food intake in lean and obese individuals. Long-term administration of antagonists increases the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists.

EFFECTS IN THE PRESENCE OF OPIOID AGONISTS

Antagonistic Effects. Small doses (0.4-0.8 mg) of naloxone given intramuscularly or intravenously prevent or promptly reverse the effects of receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1-2 min. Sedative effects are reversed, and blood pressure, if depressed, returns to normal. Higher doses of naloxone are required to antagonize the respiratory-depressant effects of buprenorphine; 1 mg naloxone intravenously completely blocks the effects of 25 mg heroin. Naloxone reverses
the psychotomimetic and dysphoric effects of agonist–antagonist agents such as pentazocine, but much higher doses (10-15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1-4 h. Antagonism of opioid effects by naloxone often is accompanied by an “overshoot” phenomenon. For example, respiratory rate depressed by opioids transiently becomes higher than that before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported.

**Effects in Opioid-Dependent Patients.** In subjects who are dependent on morphine-like opioids, small subcutaneous doses of naloxone (0.5 mg) precipitate a moderate to severe withdrawal syndrome that is very similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in ~2 h. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Naloxone produces overshoot phenomena suggestive of early acute physical dependence 6-24 h after a single dose of a μ agonist.

**ADME**

Although absorbed readily from the GI tract, naloxone is almost completely metabolized by the liver before reaching the systemic circulation and thus must be administered parenterally. The $t_{1/2}$ of naloxone is ~1 h, but its clinically effective duration of action can be even less. Compared with naloxone, naltrexone has more efficacy by the oral route, and its duration of action approaches 24 h after moderate oral doses. Peak concentrations in plasma are reached within 1-2 h and then decline with an apparent $t_{1/2}$ of ~3 h. Naltrexone is metabolized to 6-naltrexol, which is a weaker antagonist with longer $t_{1/2}$, ~13 h. Naltrexone is much more potent than naloxone, and 100-mg oral doses given to patients addicted to opioids produce concentrations in tissues sufficient to block the euphorogenic effects of 25-mg IV doses of heroin for 48 h. Methylnaltrexone is similar to naltrexone; it is converted to methyl-6-naltrexol isomers and eliminated primarily as the unchanged drug with active renal
secretion. The $t_{1/2}$ of methylnaltrexone is $\sim 8$ h.

**THERAPEUTIC USES**

**TREATMENT OF OPIOID OVERDOSAGE.** Opioid antagonists, particularly naloxone, have an established use in the treatment of opioid-induced toxicity, especially respiratory depression. Its specificity is such that reversal by naloxone is virtually diagnostic for the contribution of an opiate to the depression. Naloxone acts rapidly to reverse the respiratory depression associated with high doses of opioids. It should be titrated cautiously because it also can precipitate withdrawal in dependent subjects and cause undesirable cardiovascular side effects. The duration of action of naloxone is relatively short, and it often must be given repeatedly or by continuous infusion. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression secondary to the IV or IM administration of opioids to the mother. In the neonate, the initial dose is 10 μg/kg given intravenously, intramuscularly, or subcutaneously.

**MANAGEMENT OF CONSTIPATION.** The peripherally limited antagonists such as methylnaltrexone have a very important role in the management of the constipation and the reduced GI motility present in the patient undergoing chronic opioid therapy (as for chronic pain or methadone maintenance). Other strategies for the management of opioid-induced constipation are described in Chapter 46.

**MANAGEMENT OF ABUSE SYNDROMES.** There is interest in the use of opiate antagonists such as naltrexone as an adjuvant in treating a variety of nonopioid dependency syndromes such as alcoholism (see Chapters 23 and 24), where an opiate antagonist decreases the chance of relapse. Interestingly, patients with a single nucleotide polymorphism (SNP) in the MOR gene have significantly lower relapse rates to alcoholism when treated with naltrexone. Naltrexone is FDA-approved for treatment of alcoholism.

**CENTRALLY ACTIVE ANTITUSSIVES**

Cough is a useful physiological mechanism that serves to clear the respiratory passages of foreign material and excess secretions. It should not be suppressed indiscriminately. There are, however,
situations in which cough does not serve any useful purpose but may, instead, annoy the patient, prevent rest and sleep, or hinder adherence to otherwise beneficial medication regimens (e.g., angiotensin-converting enzyme [ACE] inhibitor-induced cough). In such situations, the physician should try to substitute a drug with a different side-effect profile (e.g., an AT1 antagonist in place of an ACE inhibitor) or add an antitussive agent that will reduce the frequency or intensity of the coughing. A number of drugs reduce cough as a result of their central actions, including opioid analgesics (codeine, hydrocodone, and dihydrocodeine are most commonly used). Cough suppression often occurs with lower doses of opioids than those needed for analgesia. A 10- or 20-mg oral dose of codeine, although ineffective for analgesia, produces a demonstrable antitussive effect, and higher doses produce even more suppression of chronic cough. A few other antitussive agents are noted below.

**DEXTROMETHORPHAN**

Dextromethorphan (D-3-methoxy-N-methylmorphinan) is the D-isomer of the codeine analog methorphan; however, unlike the L-isomer, it has no analgesic or addictive properties and does not act through opioid receptors. The drug acts centrally to elevate the threshold for coughing. Its effectiveness in patients with pathological cough has been demonstrated in controlled studies; its potency is nearly equal to that of codeine, but dextromethorphan produces fewer subjective and GI side effects. In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5-6 h. Its toxicity is low, but extremely high doses may produce CNS depression. The average adult dosage of dextromethorphan hydrobromide is 10-30 mg 3-6 times daily, not to exceed 120 mg daily. The drug is marketed for over-the-counter sale in liquids, syrups, capsules, soluble strips, lozenges, and freezer pops or in combinations with antihistamines, bronchodilators, expectorants, and decongestants. An extended-release dextromethorphan suspension (**Delsym**) is approved for twice-daily administration.

Although dextromethorphan is known to function as an NMDA receptor
antagonist, the dextromethorphan binding sites are not limited to the known distribution of NMDA receptors. Thus, the mechanism by which dextromethorphan exerts its antitussive effect still is not clear.

**OTHER ANTITUSSIVES.** Pholcodine [3-O-(2-morpholinoethyl) morphine] is used clinically in many countries outside the U.S. Although structurally related to the opioids, pholcodine has no opioid-like actions. Pholcodine is at least as effective as codeine as an antitussive; it has a long $t_{1/2}$ and can be given once or twice daily.

Benzonatate (TESSALON, others) is a long-chain polyglycol derivative chemically related to procaine and believed to exert its antitussive action on stretch or cough receptors in the lung, as well as by a central mechanism. It is available in oral capsules and the dosage is 100 mg 3 times daily; doses as high as 600 mg daily have been used safely.

**ROUTES OF ANALGESIC DRUG ADMINISTRATION**

In addition to the traditional oral and parenteral formulations for opioids, many other methods of administration have been developed in an effort to improve therapeutic efficacy while minimizing side effects.

**PATIENT-CONTROLLED ANALGESIA (PCA).** With this modality, the patient has limited control of the dosing of opioid from an infusion pump programmed within tightly mandated parameters. PCA can be used for IV, epidural, or intrathecal administration of opioids. This technique avoids delays inherent in administration by a caregiver and generally permits better alignment between pain control and individual differences in pain perception and responsiveness to opioids.

**SPINAL DELIVERY.** Administration of opioids into the epidural or intrathecal space provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. This permits the use of doses substantially lower than those required for oral or parenteral administration (Table 18–5).
Epidural and intrathecal opioids have their own dose-dependent side effects, such as pruritus, nausea, vomiting, respiratory depression, and urinary retention. Hydrophilic opioids such as morphine (DURAMORPH, others) have a longer residence times in the cerebrospinal fluid; as a consequence, after intrathecal or epidural morphine, delayed respiratory depression can be observed for as long as 24 h after a bolus dose. The risk of delayed respiratory depression is reduced with more lipophilic opioids. Use of intraspinal opioids in the opioid-naïve patient is reserved for postoperative pain control in an inpatient monitored setting. Epidural administration of opioids has become popular in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic opioid levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn. Agents approved for spinal delivery are certain preservative-free formulations of morphine sulfate (DURAMORPH, DEPODUR, others).

*Low doses may be effective when administered to the elderly or when injected in the thoracic region.
*I If combining with a local anesthetic, consider using 0.0625% bupivacaine.
*Duration of analgesia varies widely; higher doses produce longer duration. With the exception of epidural/intrathecal morphine or epidural sufentanil, all other spinal opioid use is considered to be off label.
Source: Adapted from International Association for the Study of Pain, 1992.
and sufentanil (SUFENTA). The spinal route of delivery represents a novel environment wherein the neuraxis may be exposed to exceedingly high concentrations of an agent for an extended period of time; safety by another route (e.g., PO, IV) may not translate to safety after spinal delivery.

Intraspinal narcotics often are combined with other agents that include local anesthetics, N-type Ca\(^+\) channel blockers (e.g., ziconotide), \(\alpha_2\) adrenergic agonists, and GABA\(_B\) agonists. The synergy between drugs with different mechanisms allows the use of lower concentrations of both agents, minimizing side effects and opioid-induced complications.

**RECTAL ADMINISTRATION.** This route is an alternative for patients with difficulty swallowing or other oral pathology and who prefer a less invasive route than parenteral administration. This route is not well tolerated by most children. Onset of action is within 10 min. In the U.S., only morphine and hydromorphone are available in rectal suppository formulations.

**ORAL TRANSMUCOSAL ADMINISTRATION.** Opioids can be absorbed through the oral mucosa more rapidly than through the stomach. Bioavailability is greater owing to avoidance of first-pass metabolism, and lipophilic opioids are absorbed better by this route than are hydrophilic compounds such as morphine. A transmucosal delivery system that suspends fentanyl in a dissolvable sugar-based lollipop (ACTIQ, others) or rapidly dissolving buccal tablet (FENTORA) and a buccal fentanyl “film” are FDA-approved for the treatment of cancer pain (ONSOLIS).

**TRANSNASAL ADMINISTRATION.** Butorphanol, a KOR agonist/MOR antagonist, has been employed intranasally. A transnasal pectin-based fentanyl spray is currently in clinical trials for the treatment of cancer-related pain. Administration is well tolerated and pain relief occurs within 10 min of delivery.

**TRANSDERMAL ADMINISTRATION.** Transdermal fentanyl patches are approved for use in sustained pain. The opioid permeates the skin, and a “depot” is established in the stratum corneum layer. However, fever and external heat sources (heating pads, hot baths) can increase absorption of fentanyl and potentially lead to an overdose. This modality is well suited for cancer pain
treatment because of its ease of use, prolonged duration of action, and stable blood levels. There may be great variability in plasma levels after a given dose. The plasma $t_{1/2}$ after patch removal is $\sim 17$ h. Thus, if excessive sedation or respiratory depression is experienced, antagonist infusions may need to be maintained for an extended period. Dermatological side effects from the patches, such as rash and itching, usually are mild. Opiate-addicted patients have been known to chew the patches and receive an overdose.

**THERAPEUTIC CONSIDERATIONS**

Management of pain is an important element in any therapeutic intervention. Failure to adequately manage pain can have important negative consequences on physiological function such as autonomic hyperreactivity (increased blood pressure, heart rate, suppression of gastrointestinal motility, reduced secretions), reduced mobility leading to deconditioning, muscle wasting, joint stiffening, and decalcification, and can contribute to deleterious changes in the psychological state (depression, helplessness syndromes, anxiety). By many hospital accrediting organizations, and by law in many states, appropriate pain assessment and adequate pain management are considered to be standard of care, with pain being considered the “fifth vital sign.”

**GUIDELINES FOR OPIATE DOSING**

The World Health Organization provides a 3-step ladder as a guide to treat both cancer pain and chronic noncancer pain (Table 18–6). The 3-step ladder encourages the use of more conservative therapies before initiating opioid therapy. Weaker opioids can be supplanted by stronger opioids in cases of moderate and severe pain. Antidepressants such as duloxetine and amitriptyline that are used in the treatment of chronic neuropathic pain have limited intrinsic analgesic actions in acute pain; however, antidepressants may enhance morphine-induced analgesia. In the presence of severe pain, the opioids should be considered sooner rather than later.
Numerous societies and agencies have published guidelines for the use of strong opioids in treating pain. While slightly different in particulars, all guidelines to date share the criteria of Table 18–7. Methadone dosing is considered separately in Table 18–8.

Guidelines for the Use of Opioids to Treat Chronic Pain
Suggestions for the oral and parenteral dosing of commonly used opioids (see Table 18–2) are only guidelines. They are typically constructed with the use of these agents in the management of acute (e.g., postoperative) pain in opioid-naïve patients. A number of factors will contribute to the dosing requirement (described in subsequent sections).
VARIABLES MODIFYING THE THERAPEUTIC RESPONSE TO OPIATES

There is substantial individual variability in responses to opioids. A standard IM dose of 10 mg morphine sulfate will relieve severe pain adequately in only 2 of 3 patients. The minimal effective analgesic concentration for opioids, such as morphine, meperidine (pethidine), alfentanil, and sufentanil, varies among patients by factors of 5-10.

The 12th edition of the parent text covers a variety of issues that can affect patient response to opiates, including physical condition of the patient, disease, intensity of pain, type of pain, acuity and chronicity of pain, opioid tolerance, pharmacokinetic variables, and genetic factors. These factors will affect the choice of agent and mode of delivery. Other considerations include opioid rotation (changing to a different opioid when the patient fails to achieve benefit or side effects become limiting before analgesia is sufficient), and combination therapy.

Certain opiate combinations are useful. For example, in a chronic pain state with periodic incident or breakthrough pain, the patient might receive a slow-release formulation of morphine for baseline pain relief and the acute incident pain may be managed with a rapid-onset/short-lasting formulation such as buccal fentanyl. For inflammatory or nociceptive pain, opioids may be usefully combined with other analgesic agents, such as NSAIDs or acetaminophen. In some situations, NSAIDs can provide analgesia equal to that produced by 60 mg codeine. In the case of neuropathic pain, other drug classes may be useful in combination with the opiate. For example, antidepressants that block amine reuptake, such as amitriptyline or duloxetine, and anticonvulsants such as gabapentin, may enhance the analgesic effect and may be synergistic in some pain states.

Table 18–9
Summary of Drug Target and Site of Action of Common Drug Classes and Relative Efficacy by Pain State
NONANALGESIC THERAPEUTIC USES OF OPIOIDS

DYSPNEA. Morphine is used to alleviate the dyspnea of acute left ventricular failure and pulmonary edema, and the response to IV morphine may be dramatic. The mechanism underlying this relief is not clear. It may involve an alteration of the patient’s reaction to impaired respiratory function and an indirect reduction of the work of the heart owing to reduced fear and apprehension. However, it is more probable that the major benefit is due to cardiovascular effects, such as decreased peripheral resistance and an increased capacity of the peripheral and splanchnic vascular compartments. Nitroglycerin, which also causes vasodilation, may be superior to morphine in this condition. In patients with normal blood gases but severe breathlessness owing to chronic obstruction of airflow (“pink puffers”), dihydrocodeine, 15 mg orally before exercise, reduces the feeling of breathlessness and increases exercise tolerance. Nonetheless, opioids generally are contraindicated in pulmonary edema unless severe pain also is present.

ANESTHETIC ADJUVANTS. High doses of opioids, notably fentanyl and sufentanil, are widely used as the primary anesthetic agents in many surgical procedures. They have powerful “MAC-sparing” effects, e.g., they reduce the concentrations of volatile anesthetic otherwise required to produce an adequate anesthetic depth. Although respiration is so depressed that physical assistance is
required, patients can retain consciousness. Therefore, when using an opioid as the primary anesthetic agent, use it in conjunction with an agent that results in unconsciousness and produces amnesia such as the benzodiazepines or low concentrations of volatile anesthetics. High doses of opiate also result in prominent rigidity of the chest wall and masseters requiring concurrent treatment with muscle relaxants to permit intubations and ventilation.

TREATMENT OF ACUTE OPIOID TOXICITY

Acute opioid toxicity may result from clinical overdosage, accidental overdosage, or attempts at suicide. Occasionally, a delayed type of toxicity may occur from the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed, and therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly. In nontolerant individuals, serious toxicity with methadone may follow the oral ingestion of 40-60 mg. In the case of morphine, a normal, pain-free adult is not likely to die after oral doses <120 mg or to have serious toxicity with <30 mg parenterally.

SYMPTOMS AND DIAGNOSIS. The patient who has taken an overdose of an opioid usually is stuporous or, if a large overdose has been taken, may be in a profound coma. The respiratory rate will be very low, or the patient may be apneic, and cyanosis may be present. If adequate oxygenation is restored early, the blood pressure will improve; if hypoxia persists untreated, there may be capillary damage, and measures to combat shock may be required. The pupils will be symmetrical and pinpoint in size; however, if hypoxia is severe, they may be dilated. Urine formation is depressed. Body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may fall back and block the airway. Frank convulsions occasionally may be noted in infants and children. When death occurs, it is nearly always from respiratory failure. Even if respiration is restored, death still may occur as a result of complications that develop during the period of coma, such as pneumonia or shock.

TREATMENT. The first step is to establish a patent airway and ventilate the
patient. Opioid antagonists can produce dramatic reversal of the severe respiratory depression, and the antagonist naloxone is the treatment of choice. However, care should be taken to avoid precipitating withdrawal in dependent patients, who may be extremely sensitive to antagonists. The safest approach is to dilute the standard naloxone dose (0.4 mg) and slowly administer it intravenously, monitoring arousal and respiratory function. With care, it usually is possible to reverse the respiratory depression without precipitating a major withdrawal syndrome. If no response is seen with the first dose, additional doses can be given. Patients should be observed for rebound increases in sympathetic nervous system activity, which may result in cardiac arrhythmias and pulmonary edema. For reversing opioid poisoning in children, the initial dose of naloxone is 0.01 mg/kg. If no effect is seen after a total dose of 10 mg, one can reasonably question the accuracy of the diagnosis. Pulmonary edema sometimes associated with opioid overdosage may be countered by positive-pressure respiration. Tonic-clonic seizures, occasionally seen as part of the toxic syndrome with meperidine, propoxyphene, and tramadol, are ameliorated by treatment with naloxone.

The presence of general CNS depressants does not prevent the salutary effect of naloxone, and in cases of mixed intoxications, the situation will be improved largely owing to antagonism of the respiratory-depressant effects of the opioid (however, some evidence indicates that naloxone and naltrexone also may antagonize some of the depressant actions of sedative-hypnotics). One need not attempt to restore the patient to full consciousness. The duration of action of the available antagonists is shorter than that of many opioids; hence patients can slip back into coma. This is particularly important when the overdosage is due to methadone. The depressant effects of these drugs may persist for 24-72 h, and fatalities have occurred as a result of premature discontinuation of naloxone. In cases of overdoses of these drugs, a continuous infusion of naloxone should be considered. Toxicity owing to overdose of pentazocine and other opioids with mixed actions may require higher doses of naloxone.
General Anesthetics

General anesthetics depress the central nervous system to a sufficient degree to permit the performance of surgery and unpleasant procedures. General anesthetics have low therapeutic indices and thus require great care in administration. The selection of specific drugs and routes of administration to produce general anesthesia is based on their pharmacokinetic properties and on the secondary effects of the various drugs, in the context of the proposed diagnostic or surgical procedure and with the consideration of the individual patient’s age, and associated medical condition.

GENERAL PRINCIPLES OF SURGICAL ANESTHESIA

The administration of general anesthesia is driven by 3 general objectives:

1. Minimizing the potentially deleterious direct and indirect effects of anesthetic agents and techniques
2. Sustaining physiologic homeostasis during surgical procedures that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation
3. Improving postoperative outcomes by choosing techniques that block or treat components of the surgical stress response, which may lead to short- or long-term sequelae

HEMODYNAMIC EFFECTS OF GENERAL ANESTHESIA. The most prominent physiological effect of anesthesia induction is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, or both; a blunting of baroreceptor control; and a generalized decrease in central sympathetic tone. Agents vary in the magnitude of their specific effects, but in all cases the hypotensive response is enhanced by
underlying volume depletion or preexisting myocardial dysfunction.

**RESPIRATORY EFFECTS OF GENERAL ANESTHESIA.** Nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation has been a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (see Chapter 11). Alternatives to an endotracheal tube include a face mask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis.

**HYPOTHERMIA.** Patients commonly develop hypothermia (body temperature <36°C) during surgery. The reasons include low ambient temperature, exposed body cavities, cold intravenous (IV) fluids, altered thermoregulatory control, and reduced metabolic rate. Metabolic rate and total body oxygen consumption decrease with general anesthesia by ~30%, reducing heat generation. Hypothermia may lead to an increase in perioperative morbidity. Prevention of hypothermia is a major goal of anesthetic care.

**NAUSEA AND VOMITING.** Nausea and vomiting continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by serotonin (5HT), histamine, ACh, and dopamine (DA). The 5HT₃ receptor antagonists, ondansetron and dolasetron (see Chapters 13 and 46), are very effective in suppressing nausea and vomiting. Common treatments also include droperidol, metoclopramide, dexamethasone, and avoidance of N₂O. The use of propofol as an induction agent and the nonsteroidal anti-inflammatory drug ketorolac as a substitute for opioids may decrease the incidence and severity of postoperative nausea and vomiting.

**OTHER EMERGENCE AND POSTOPERATIVE PHENOMENA.** Hypertension and tachycardia are common as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or
worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5-30% of patients and is characterized by tachycardia, restlessness, crying, moaning, and thrashing. Neurologic signs, including delirium, spasticity, hyperreflexia, and Babinski sign, are often manifest in the patient emerging from anesthesia. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of meperidine (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all of these emergence phenomena is greatly reduced with opioids and $\alpha_2$ agonists (dexmedetomidine).

Airway obstruction may occur during the postoperative period because residual anesthetic effects. Pulmonary function is reduced following all types of anesthesia and surgery, and hypoxemia may occur. Pain control can be complicated in the immediate postoperative period and respiratory suppression associated with opioids can be problematic. Regional anesthetic techniques are an important part of a perioperative approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, $\alpha_2$ adrenergic receptor agonists, and NMDA receptor antagonists.

**ACTIONS AND MECHANISMS OF GENERAL ANESTHETICS**

**THE ANESTHETIC STATE**

The components of the anesthetic state include:

- **Amnesia**
- **Immobility** in response to noxious stimulation
- **Attenuation of autonomic responses** to noxious stimulation
- **Analgesia**
- **Unconsciousness**

The potency of general anesthetic agents is measured by determining the concentration of general anesthetic that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in *MAC units*, with 1 MAC defined as the minimum alveolar concentration that prevents movement in response to surgical stimulation in 50% of subjects. The
strengths of MAC as a measurement are that:

- Alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry.
- It provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the CNS.
- It is a simple-to-measure end point that reflects an important clinical goal.

End points other than immobilization also can be used to measure anesthetic potency. For example, the ability to respond to verbal commands (MAC\textsubscript{awake}) and the ability to form memories also have been correlated with alveolar anesthetic concentration. Verbal response and memory formation are suppressed at a fraction of MAC. The ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents (nitrous oxide versus isoflurane).

Generally, the potency of IV agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

**MECHANISMS OF ANESTHESIA**

**CELLULAR MECHANISMS OF ANESTHESIA.** General anesthetics produce 2 important physiologic effects at the cellular level:

- The inhalational anesthetics can hyperpolarize neurons. This may be an important effect on neurons serving a pacemaker role and on pattern-generating circuits.
- Both inhalational and IV anesthetics have substantial effects on synaptic transmission and much smaller effects on action-potential generation or propagation.

Inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. The inhalational anesthetic isoflurane clearly can inhibit neurotransmitter release, while the small reduction in presynaptic action potential amplitude produced by isoflurane (3% reduction at MAC
concentration) substantially inhibits neurotransmitter release. Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

Intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the IV agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

MOLECULAR ACTIONS OF GENERAL ANESTHETICS. Most IV general anesthetics act predominantly through GABA<sub>A</sub> receptors and perhaps through some interactions with other ligand-gated ion channels such as NMDA receptors and 2-pore K<sup>+</sup> channels.

Chloride channels gated by the inhibitory GABA<sub>A</sub> receptors (see Figures 14–3 and 14–6) are sensitive to a wide variety of anesthetics, including the halogenated inhalational agents and many IV agents (propofol, barbiturates, etomidate, and neurosteroids). At clinical concentrations, general anesthetics increase the sensitivity of the GABA<sub>A</sub> receptor to GABA, thus enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the GABA<sub>A</sub> receptor probably is mediated by binding of the anesthetics to specific sites on the GABA<sub>A</sub>-receptor protein (but they do not compete with GABA for its binding site on the receptor). The capacity of propofol and etomidate to inhibit the response to noxious stimuli is mediated by a specific site on the β<sub>3</sub> subunit of the GABA<sub>A</sub> receptor, whereas the sedative effects of these anesthetics are mediated by on the β<sub>2</sub> subunit.

Structurally related to the GABA<sub>A</sub> receptors are other ligand-gated ion channels including glycine receptors and neuronal nicotinic ACh receptors. Glycine receptors may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Inhalational anesthetics enhance the capacity of glycine to activate glycine-gated chloride channels (glycine receptors), which play an important role in inhibitory neurotransmission in the spinal cord and brainstem.
Propofol, neurosteroids, and barbiturates also potentiate glycine-activated currents, whereas etomidate and ketamine do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic ACh receptors, which seem to mediate other components of anesthesia such as analgesia or amnesia.

Ketamine, nitrous oxide, cyclopropane, and xenon are the only general anesthetics that do not have significant effects on GABA_A or glycine receptors. These agents inhibit a different type of ligand-gated ion channel, the NMDA receptor (see Figure 14–7 and Table 14–1). NMDA receptors are glutamate-gated cation channels that are somewhat selective for Ca^{++} and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity.

Halogenated inhalational anesthetics activate some members of a class of K^+ channels known as 2-pore domain channels; other 2-pore domain channel family members are activated by xenon, nitrous oxide, and cyclopropane. These channels are located in both presynaptic and postsynaptic sites. The postsynaptic channels may be the molecular locus through which these agents hyperpolarize neurons.

Anatomic Sites of Anesthetic Action. In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Most anesthetics cause, with some exceptions, a global reduction in cerebral metabolic rate (CMR) and in cerebral blood flow (CBF). A consistent feature of general anesthesia is a suppression of metabolism in the thalamus, which serves as a major relay by which sensory input from the periphery ascends to the cortex. Suppression of thalamic activity may serve as a switch between the awake and anesthetized states. General anesthesia also results in the suppression of activity in specific regions of the cortex, including the mesial parietal cortex, posterior cingulate cortex, precuneus, and inferior parietal cortex.

Similarities between natural sleep and the anesthetized state suggest that anesthetics might also modulate endogenous sleep regulating pathways, which include ventrolateral preoptic (VLPO) and tuberomammillary nuclei. VLPO projects inhibitory GABA-ergic fibers to ascending arousal nuclei, which in turn project to the cortex, forebrain, and subcortical areas; release of histamine, 5HT,
orexin, NE, and ACh mediate wakefulness. Intravenous and inhalational agents with activity at GABA_A receptors can increase the inhibitory effects of VLPO, thereby suppressing consciousness. Dexmedetomidine, an α_2 agonist, also increases VLPO-mediated inhibition by suppressing the inhibitory effect of locus ceruleus neurons on VLPO. Finally, both IV and inhalational anesthetics depress hippocampal neurotransmission, a probable locus for their amnestic effects.

PARENTERAL ANESTHETICS

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. These drugs ultimately accumulate in fatty tissue. Each anesthetic has its own unique set of properties and side effects (Tables 19–1 and 19–2). Propofol and thiopental are the 2 most commonly used parenteral agents. Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Thiopental has a long-established track record of safety. Etomidate usually is reserved for patients at risk for hypotension and/or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures.

PHARMACOKINETIC PRINCIPLES

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 19–1). Hydrophobicity is the key factor governing their pharmacokinetics. After a single IV bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord where they produce anesthesia within a single circulation time. Subsequently blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less perfused tissues such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (Figure 19–2).

**Figure 19–1** Structures of some parenteral anesthetics.
Thiopental serum levels after a single intravenous induction dose. Thiopental serum levels after a bolus can be described by two time constants, $t_{1/2} \alpha$ and $t_{1/2} \beta$. The initial fall is rapid ($t_{1/2} \alpha < 10$ min) and is due to redistribution of drug from the plasma and the highly perfused brain and spinal cord into less well-perfused tissues such as muscle and fat. During this redistribution phase, serum thiopental concentration falls to levels at which patients awaken (AL, awakening level; see inset—the average thiopental serum concentration in 12 patients after a 6-mg/kg intravenous bolus of thiopental). Subsequent metabolism and elimination is much slower and is characterized by a half-life ($t_{1/2} \beta$) of more than 10 hours. (Adapted with permission from Burch PG, and Stanski DR, The role of metabolism and protein binding in thiopental anesthesia. *Anesthesiology*, 1983, 58:146–152. Copyright Lippincott Williams & Wilkins. [http://lww.com](http://lww.com).)

After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-life
are “context-sensitive,” and the degree to which a $t_{1/2}$ is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Figure 19–3; see Table 19–1). For example, after a single bolus of thiopental, patients usually emerge from anesthesia within 10 min; however, a patient may require more than a day to awaken from a prolonged thiopental infusion. Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of the brain and the fraction of anesthetic dose delivered to the brain are higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of anesthetic. The elderly also typically require a smaller anesthetic dose, primarily because of a smaller initial volume of distribution.

$^a$MAC (minimum alveolar concentration) values are expressed as vol %, the percentage of the atmosphere that is anesthetic.

A value of MAC > 100% means that hyperbaric conditions would be required.

$^b$MAC$_{AWAKE}$ is the concentration at which appropriate responses to commands are lost.

$^c$EC$_{50}$ for memory suppression (vol %): isoflurane, 0.24; N$_2$O, 52.5; values not available for other agents.
Figure 19–3 Context-sensitive half-time of general anesthetics. The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites (see Figure 19–2). However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug’s metabolic rate. This phenomenon has been termed the context-sensitive half-time; that is, the $t_{1/2}$ of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as etomidate, propofol, and ketamine increase only modestly with prolonged infusions; others (e.g., diazepam and thiopental) increase dramatically. SPECIFIC PARENTERAL AGENTS

PROPOFOL, FOSPROPOFOL

Propofol is the most commonly used parenteral anesthetic in the U.S. Fospropofol is a prodrug form that is converted to propofol in vivo.
The clinical pharmacological properties of propofol are summarized in Table 19–1.

CHEMISTRY AND FORMULATIONS. The active ingredient in propofol, 2,6-diisopropylphenol, is an oil at room temperature and insoluble in aqueous solutions. Propofol is formulated for IV administration as a 1% (10 mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. In the U.S., disodium EDTA (0.05 mg/mL) or sodium metabisulfite (0.25 mg/mL) is added to inhibit bacterial growth. Propofol should be administered within 4 h of its removal from sterile packaging; unused drug should be discarded. The lipid emulsion formulation of propofol is associated with significant pain on injection and hyperlipidemia. A new aqueous formulation of propofol, fospropofol, which is not associated with these adverse effects, has recently been approved for use for sedation in patients undergoing diagnostic procedures. Fospropofol, which itself is inactive, is a phosphate ester prodrug of propofol that is hydrolyzed by endothelial alkaline phosphatases to yield propofol, phosphate, and formaldehyde. The formaldehyde is rapidly converted to formic acid, which then is metabolized by tetrahydrofolate dehydrogenase to CO₂ and water.

DOSAGE AND CLINICAL USE. The induction dose of propofol (DIPRIVAN, others) in a healthy adult is 2-2.5 mg/kg. Dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination t₁/₂, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10-50% of the induction dose) every 5 min or as needed are effective. An infusion of propofol produces a more stable drug level (100-300 µg/kg/min) and is better suited for longer-term anesthetic maintenance. Sedating doses of propofol are 20-50% of those required for general anesthesia. Fospropofol produces dose-dependent sedation and can be administered in otherwise healthy individuals at 2-8 mg/kg intravenously (delivered either as a bolus or by a short infusion over 5-10 min). The optimum dose for sedation is ~6.5 mg/kg. This results in a loss of consciousness in ~10 min. The duration of the sedative effect is ~45 min.

PHARMACOKINETICS AND METABOLISM. Onset and duration of anesthesia after a single bolus are similar to thiopental. Propofol has a context-
sensitive $t_{1/2}$ of 10 min with an infusion lasting 3 h and $\sim$40 min for infusions lasting up to 8 h (see Figure 19–3). Propofol’s shorter duration of action after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment.

Propofol is metabolized in the liver by conjugation to sulfate and glucuronide to less active metabolites that are renally excreted. Propofol is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels. Clearance of propofol is reduced in the elderly. In neonates, propofol clearance is also reduced. By contrast, in young children, a more rapid clearance in combination with a larger central volume may necessitate larger doses of propofol for induction and maintenance of anesthesia.

The $t_{1/2}$ for hydrolysis of fospropofol is 8 min; the drug has a small volume of distribution and a terminal $t_{1/2} \sim 46$ min.

**SIDE EFFECTS**

*Nervous System.* The sedation and hypnotic actions of propofol are mediated by its action on $\text{GABA}_A$ receptors; agonism at these receptors results in an increased chloride conduction and hyperpolarization of neurons. Propofol suppresses the EEG, and in sufficient doses, can produce burst suppression of the EEG. Propofol decreases cerebral metabolic rate of $O_2$ consumption ($\text{CMRO}_2$), CBF, and intracranial and intraocular pressures by about the same amount as thiopental. Like thiopental, propofol has been used in patients at risk for cerebral ischemia; however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant.

*Cardiovascular System.* Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental. The fall in blood pressure can be explained by both vasodilation and possibly mild depression of myocardial contractility. Propofol appears to blunt the baroreceptor reflex and reduce sympathetic nerve activity. As with thiopental, propofol should be used with caution in patients at risk for or intolerant of decreases in blood pressure.

*Respiratory System.* Propofol produces a slightly greater degree of respiratory
depression than thiopental. Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol appears to be less likely than barbiturates to provoke bronchospasm and may be the induction agent of choice in asthmatics. The bronchodilator properties of propofol may be attenuated by the metabisulfite preservative in some propofol formulations.

*Other Side Effects.* Propofol has a significant antiemetic action. Propofol elicits pain on injection that can be reduced with lidocaine and the use of larger arm and antecubital veins. A rare but potentially fatal complication, termed *propofol infusion syndrome* (PRIS), has been described primarily in prolonged, higher-dose infusions of propofol in young or head-injured patients. The syndrome is characterized by metabolic acidosis, hyperlipidemia, rhabdomyolysis, and an enlarged liver. The side-effect profile of fospropofol is similar to that of propofol.

**ETOMIDATE**

Etomidate is a substituted imidazole that is supplied as the active d-isomer. Etomidate is poorly soluble in water and is formulated as a 2 mg/mL solution in 35% propylene glycol. Unlike thiopental, etomidate does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction.

**DOSAGE AND CLINICAL USE.** Etomidate (Amidate, others) is primarily used for anesthetic induction of patients at risk for hypotension. Induction doses of etomidate (see Table 19–1) are accompanied by a high incidence of pain on injection and myoclonic movements. Lidocaine effectively reduces the pain of injection, while myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. Etomidate is pharmacokinetically suitable for off-label infusion for anesthetic maintenance (10 μg/kg/min) or sedation (5 μg/kg/min); however, long-term infusions are not recommended.

**PHARMACOKINETICS AND METABOLISM.** An induction dose of etomidate has a rapid onset; redistribution limits the duration of action. Metabolism occurs in the liver, primarily to inactive compounds. Elimination is both renal (78%) and biliary (22%). Compared to thiopental, the duration of action of etomidate increases less with repeated doses (see Figure 19–3).
SIDE EFFECTS

Nervous System. Etomidate produces hypnosis and has no analgesic effects. The effects of etomidate on CBF, metabolism, and intracranial and intraocular pressures are similar to those of thiopental (without dropping mean arterial blood pressure). Etomidate produces increased EEG activity in epileptogenic foci and has been associated with seizures.

Cardiovascular System. Cardiovascular stability after induction is a major advantage of etomidate over either barbiturates or propofol. Induction doses of etomidate typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output etomidate has little effect on coronary perfusion pressure while reducing myocardial O\textsubscript{2} consumption.

Respiratory and Other Side Effects. The degree of respiratory depression due to etomidate appears to be less than that due to thiopental. Like methohexital, etomidate may induce hiccups but does not significantly stimulate histamine release. Etomidate has been associated with nausea and vomiting. The drug also inhibits adrenal biosynthetic enzymes required for the production of cortisol and some other steroids. Thus, while etomidate is not recommended for long-term infusion, it appears safe for anesthetic induction and has some unique advantages in patients prone to hemodynamic instability.

KETAMINE

Ketamine is an arylcyclohexylamine, a congener of phencyclidine. Ketamine is supplied as a mixture of the R+ and S-isomers even though the S-isomer is more potent with fewer side effects. Although more lipophilic than thiopental, ketamine is water-soluble.

DOSAGE AND CLINICAL USE. Ketamine (KETALAR, others) is useful for anesthetizing patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. Ketamine rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia, but may have their eyes open, move their limbs involuntarily, and breathe spontaneously. This cataleptic state has been termed dissociative anesthesia. The administration of ketamine has been shown to reduce the
development of tolerance to long-term opioid use. Ketamine typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. Ketamine does not elicit pain on injection or true excitatory behavior as described for methohexital, although involuntary movements produced by ketamine can be mistaken for anesthetic excitement.

PHARMACOKINETICS AND METABOLISM. The onset and duration of an induction dose of ketamine are determined by the same distribution/redistribution mechanisms operant for all the other parenteral anesthetics. Ketamine is hepatically metabolized to norketamine, which has reduced CNS activity; norketamine is further metabolized and excreted in urine and bile. Ketamine has a large volume of distribution and rapid clearance that make it suitable for continuous infusion without the lengthening in duration of action seen with thiopental (see Table 19–1 and Figure 19–3). Protein binding is much lower with ketamine than with the other parenteral anesthetics.

SIDE EFFECTS

Nervous System. Ketamine has indirect sympathomimetic activity and produces distinct behavioral effects. The ketamine-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation, lacrimation, and spontaneous limb movements with increased overall muscle tone. Patients are amnestic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics. Unlike other parenteral anesthetics, ketamine increases CBF and intracranial pressure (ICP) with minimal alteration of cerebral metabolism. The effects of ketamine on CBF can be readily attenuated by the simultaneous administration of sedative-hypnotic agents.

Emergence delirium, characterized by hallucinations, vivid dreams, and delusions, is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management. Benzodiazepines reduce the incidence of emergence delirium.

Cardiovascular System. Unlike other anesthetics, induction doses of ketamine typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake. Ketamine has direct
negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action. Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. While not arrhythmogenic, ketamine increases myocardial O₂ consumption and is not an ideal drug for patients at risk for myocardial ischemia.

Respiratory System. The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other general anesthetics. Ketamine is a potent bronchodilator and is particularly well suited for anesthetizing patients at high risk for bronchospasm.

BARBITURATES

CHEMISTRY AND FORMULATIONS. Barbiturates are derivatives of barbituric acid with either an oxygen or a sulfur at the 2-position (see Figure 19–1 and Chapter 17). The 3 barbiturates most commonly used in clinical anesthesia are sodium thiopental, thiamylal, and methohexital. Sodium thiopental (PENTOTHAL, others) has been used most frequently for inducing anesthesia. Thiamylal (SURITAL) is licensed in the U.S. only for veterinary use. Barbiturates are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency. Barbiturates are formulated as the sodium salts with 6% sodium carbonate and reconstituted in water or isotonic saline to produce 2.5% (thiopental), 2% (thiamylal), or 1% (methohexital) alkaline solutions (10 ≤ pH ≤ 11). Mixing barbiturates with drugs in acidic solutions during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the IV tubing.

PHARMACOLOGICAL PROPERTIES. The pharmacological properties and other therapeutic uses of the barbiturates are presented in Chapter 17. Table 17–2 lists the common barbiturates with their clinical pharmacological properties.

DOSAGES AND CLINICAL USE. Recommended IV dosing for parenteral barbiturates in a healthy young adult is given in Table 19–1.

PHARMACOKINETICS AND METABOLISM. The principal mechanism limiting anesthetic duration after single doses is redistribution of these
hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances. See Table 19–1 for pharmacokinetic parameters.

Methohexital differs from the other two IV barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions. Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of thiopeptaltal and thiamylal can produce unconsciousness lasting several days. All 3 barbiturates are primarily eliminated by hepatic metabolism and renal excretion of inactive metabolites; a small fraction of thiopeptaltal undergoes desulfuration to the longer-acting hypnotic pentobarbital. These drugs are highly protein bound. Hepatic disease or other conditions that reduce serum protein concentration will increase the initial free concentration and hypnotic effect of an induction dose.

SIDE EFFECTS

Nervous System. Barbiturates suppress the EEG and can produce burst suppression of the EEG. They reduce the CMR, as measured by CMRO2, in a dose-dependent manner. As a consequence of the decrease in CMRO2, CBF and ICP are similarly reduced. Presumably in part due to their CNS depressant activity, barbiturates are effective anticonvulsants. Thiopental in particular is a proven medication in the treatment of status epilepticus. Methohexital can increase ictal activity, and seizures have been described in patients who received doses sufficient to produce burst suppression of the EEG. This property makes methohexital a good choice for anesthesia in patients who undergo electroconvulsive therapy.

Cardiovascular System. The anesthetic barbiturates produce dose-dependent decreases in blood pressure. The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex. Thiopental maintains the ratio of myocardial O2 supply to demand in patients with coronary artery disease within a normal blood pressure range. Hypotension can be severe in patients with an impaired ability to compensate for venodilation such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β adrenergic blockage. None of
the barbiturates has been shown to be arrhythmogenic.

**Respiratory System.** Barbiturates are respiratory depressants. Induction doses of thiopental decrease minute ventilation and tidal volume, with a smaller and inconsistent decrease in respiratory rate. Reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates; at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. Compared to propofol, barbiturates produce a higher incidence of wheezing in asthmatics, attributed to histamine release from mast cells, during induction of anesthesia.

**Other Side Effects.** Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. True allergies to barbiturates are rare; however, direct drug-induced histamine release is occasionally seen. Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. Methohexital can produce pain on injection to a greater degree than thiopental. Inadvertent intraarterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction that can threaten limb survival. Methohexital and to a lesser degree other barbiturates can produce excitatory symptoms on induction such as cough, hiccups, muscle tremors, twitching, and hypertonus.

**INHALATIONAL ANESTHETICS**

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 19–4. The inhalational anesthetics have therapeutic indices (LD$_{50}$/ED$_{50}$) that range from 2-4, making these among the most dangerous drugs in clinical use. The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on matching a patient’s pathophysiology with drug side-effect profiles.
Figure 19–4 Structures of inhalational general anesthetics. Note that all inhalational general anesthetic agents except nitrous oxide and halothane are ethers, and that fluorine progressively replaces other halogens in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.

Table 19–3 lists the widely varying physical properties of the inhalational agents in clinical use. Ideally, an inhalational agent would produce a rapid induction of anesthesia and a rapid recovery following discontinuation.

**PHARMACOKINETIC PRINCIPLES**

Inhalational agents behave as gases rather than as liquids and thus require different pharmacokinetic constructs to be used in analyzing their uptake and distribution. Inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the 2 tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. While the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different. Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in 2 tissues when the partial pressures of anesthetic are equal in the 2 tissues. Blood:gas, brain:blood, and fat:blood partition
coefficients for the various inhalational agents are listed in Table 19–3. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (e.g., fat) than they are in others (e.g., blood).

In clinical practice, equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 19–5. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs because fat represents a huge anesthetic reservoir that will be filled slowly because of the modest blood flow to fat. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC.

Figure 19–5 Uptake of inhalational general anesthetics. The rise in end-tidal
alveolar (FA) anesthetic concentration toward the inspired (FI) concentration is most rapid with the least soluble anesthetics, nitrous oxide and desflurane, and slowest with the most soluble anesthetic, halothane. All data are from human studies. (Reproduced with permission from Eger EI, II. Inhaled anesthetics: Uptake and distribution, in Miller RD et al, eds. Miller’s Anesthesia, 7th ed. Philadelphia: Churchill Livingstone, 2010, p 540. Copyright, Elsevier.)

Elimination of inhalational anesthetics is largely the reverse process of uptake. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts of anesthetic in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC_{awake}, a partial pressure somewhat lower than MAC (see Table 19–3).

**HALOTHANE**

Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is a light-sensitive compound, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with O₂ or air are neither flammable nor explosive.

**PHARMACOKINETICS.** Halothane has a relatively high blood:gas partition coefficient and high fat:blood partition coefficient. Induction with halothane is relatively slow, and the alveolar halothane concentration remains substantially lower than the inspired halothane concentration for many hours of administration. Because halothane is soluble in fat and other body tissues, it will accumulate during prolonged administration.

Approximately 60-80% of halothane taken up by the body is eliminated unchanged by the lungs in the first 24 h after its administration. A substantial amount of the halothane not eliminated in exhaled gas is biotransformed by hepatic CYPs. The major metabolite of halothane is trifluoroacetic acid, which is formed by removal of bromine and chlorine ions. Trifluoroacetic acid, bromine, and chlorine all can be detected in the urine. Trifluoroacetylchloride, an
intermediate in oxidative metabolism of halothane, can trifluoroacetylate several proteins in the liver. An immune reaction to these altered proteins may be responsible for the rare cases of fulminant halothane-induced hepatic necrosis.

**CLINICAL USE.** Halothane is used for maintenance of anesthesia. It is well tolerated for inhalation induction of anesthesia, most commonly in children. The use of halothane in the U.S. has diminished because of the introduction of newer inhalational agents with better pharmacokinetic and side-effect profiles. Halothane continues to be extensively used in children because it is well tolerated and its side effects appear to be diminished in children. Halothane has a low cost and is still widely used in developing countries.

**SIDE EFFECTS**

*Cardiovascular System.* Halothane induces a dose-dependent reduction in arterial blood pressure. Mean arterial pressure typically decreases ~20-25% at MAC concentrations of halothane, primarily as a result of direct myocardial depression leading to reduced cardiac output and attenuation of baroreceptor reflex function. Halothane-induced reductions in blood pressure and heart rate generally disappear after several hours of constant halothane administration, presumably because of progressive sympathetic stimulation. Halothane does not cause a significant change in systemic vascular resistance but does dilates the vascular beds of the skin and brain. Halothane inhibits autoregulation of renal, splanchnic, and CBF, leading to reduced perfusion of these organs in the face of reduced blood pressure. Coronary autoregulation is largely preserved during halothane anesthesia. Halothane inhibits hypoxic pulmonary vasoconstriction, leading to increased perfusion to poorly ventilated regions of the lung and an increased alveolar:arterial O₂ gradient. Sinus bradycardia and atrioventricular rhythms occur frequently during halothane anesthesia but usually are benign. These rhythms result mainly from a direct depressive effect of halothane on sinoatrial node discharge. Halothane also can sensitize the myocardium to the arrhythmogenic effects of epinephrine.

*Respiratory System.* Spontaneous respiration is rapid and shallow during halothane anesthesia. The decreased alveolar ventilation results in an elevation in arterial CO₂ tension from 40 mm Hg to >50 mm Hg at 1 MAC. The elevated CO₂ does not provoke a compensatory increase in ventilation, because halothane causes a concentration-dependent inhibition of the ventilatory response to CO₂.
This action of halothane is thought to be mediated by depression of central chemoreceptor mechanisms. Halothane also inhibits peripheral chemoreceptor responses to arterial hypoxemia. Thus, neither hemodynamic (tachycardia and hypertension) nor ventilatory responses to hypoxemia are observed during halothane anesthesia, making it prudent to monitor arterial O₂ directly.

**Nervous System.** Halothane dilates the cerebral vasculature, increasing CBF and cerebral blood volume. This can result in an increase in ICP, especially in patients with space-occupying intracranial masses, brain edema, or preexisting intracranial hypertension. Halothane attenuates autoregulation of CBF in a dose-dependent manner.

**Muscle.** Halothane causes some relaxation of skeletal muscle by its central depressant effects. Halothane also potentiates the actions of nondepolarizing muscle relaxants (curariform drugs; see Chapter 11), increasing both their duration of action and the magnitude of their effect. Halothane and the other halogenated inhalational anesthetics can trigger malignant hyperthermia. This syndrome frequently is fatal and is treated by immediate discontinuation of the anesthetic and administration of dantrolene. Halothane relaxes uterine smooth muscle, a useful property for manipulation of the fetus (version) in the prenatal period and for delivery of retained placenta.

**Kidney.** Patients anesthetized with halothane usually produce a small volume of concentrated urine. This is the consequence of halothane-induced reduction of renal blood flow and glomerular filtration rate, which may be reduced by 40-50% at 1 MAC. Halothane-induced changes in renal function are fully reversible and are not associated with long-term nephrotoxicity.

**Liver and GI Tract.** Halothane reduces splanchnic and hepatic blood flow. Halothane can produce fulminant hepatic necrosis (*halothane hepatitis*) in ~1 in 10,000 patients receiving halothane and is referred to as halothane hepatitis. This syndrome (with a 50% fatality rate) is characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia and can be accompanied by a rash and peripheral eosinophilia. Halothane hepatitis may be the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism.
**ISOFLURANE**

Isoflurane (FORANE, others) is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or oxygen.

**PHARMACOKINETICS.** Isoflurane has a blood:gas partition coefficient substantially lower than that of halothane or enflurane. Consequently, induction with isoﬂurane and recovery from isoﬂurane are relatively faster. More than 99% of inhaled isoﬂurane is excreted unchanged by the lungs. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen.

**CLINICAL USE.** Isoflurane is a commonly used inhalational anesthetic worldwide. It is typically used for maintenance of anesthesia after induction with other agents because of its pungent odor, but induction of anesthesia can be achieved in <10 min with an inhaled concentration of 3% isoﬂurane in O₂; this concentration is reduced to 1-2% (~1-2 MAC) for maintenance of anesthesia. The use of adjunct agents such as opioids or nitrous oxide reduces the concentration of isoﬂurane required for surgical anesthesia.

**SIDE EFFECTS**

*Cardiovascular System.* Isoflurane produces a concentration-dependent decrease in arterial blood pressure; cardiac output is well maintained; hypotension is the result of decreased systemic vascular resistance. Isoflurane produces vasodilation in most vascular beds, with particularly pronounced effects in skin and muscle. Isoflurane is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O₂ consumption. Isoflurane significantly attenuates baroreceptor function. Patients anesthetized with isoﬂurane generally have mildly elevated heart rates as a compensatory response to reduced blood pressure; however, rapid changes in isoﬂurane concentration can produce both transient tachycardia and hypertension due to isoﬂurane-induced sympathetic stimulation.

*Respiratory System.* Isoflurane produces concentration-dependent depression of ventilation. Isoflurane is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia. Although isoﬂurane is an effective bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.
Nervous System. Isoflurane dilates the cerebral vasculature, producing increased CBF; this vasodilating activity is less than that of either halothane or enflurane. There is a modest risk of an increase in ICP in patients with preexisting intracranial hypertension. Isoflurane reduces CMRO$_2$ in a dose-dependent manner.

Muscle. Isoflurane produces some relaxation of skeletal muscle by its central effects. It also enhances the effects of both depolarizing and nondepolarizing muscle relaxants. Like other halogenated inhalational anesthetics, isoflurane relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

Kidney. Isoflurane reduces renal blood flow and glomerular filtration rate, resulting in a small volume of concentrated urine.

Liver and GI Tract. Splanchnic and hepatic blood flows are reduced with increasing doses of isoflurane as systemic arterial pressure decreases. There are no reported incidences of hepatic toxicity.

ENFLURANE

Enflurane (ETHRANE, others) is a clear, colorless liquid at room temperature with a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen.

PHARMACOKINETICS. Because of its relatively high blood:gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow. Enflurane is metabolized to a modest extent, with 2-8% of absorbed enflurane undergoing oxidative metabolism in the liver by CYP2E1. Fluoride ions are a by-product of enflurane metabolism, but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with consequent elevation of serum fluoride.

CLINICAL USE. Isoflurane is primarily utilized for maintenance rather than induction of anesthesia. Surgical anesthesia can be induced with enflurane in <10 min with an inhaled concentration of 4% in oxygen, and maintained with concentrations from 1.5-3%. Enflurane concentrations required to produce
anesthesia are reduced when it is coadministered with nitrous oxide or opioids.

**SIDE EFFECTS**

*Cardiovascular System.* Enflurane causes a concentration-dependent decrease in arterial blood pressure, due in part, to depression of myocardial contractility, with some contribution from peripheral vasodilation. Enflurane has minimal effects on heart rate.

*Respiratory System.* The respiratory effects of enflurane are similar to those of halothane. Enflurane produces a greater depression of the ventilatory responses to hypoxia and hypercarbia than do either halothane or isoflurane. Enflurane, like other inhalational anesthetics, is an effective bronchodilator.

*Nervous System.* Enflurane is a cerebral vasodilator and can increase ICP in some patients; it also reduces CMRO<sub>2</sub>. High concentrations of enflurane or profound hypocarbia during enflurane anesthesia can result in electrical seizure activity that may be accompanied by peripheral motor manifestations. The seizures are self-limited and are not thought to produce permanent damage. Epileptic patients are not particularly susceptible to enflurane-induced seizures; nonetheless, enflurane generally is not used in patients with seizure disorders.

*Muscle.* Enflurane produces significant skeletal muscle relaxation in the absence of muscle relaxants. It also significantly enhances the effects of nondepolarizing muscle relaxants. As with other inhalational agents, enflurane relaxes uterine smooth muscle.

*Kidney.* Enflurane reduces renal blood flow, glomerular filtration rate, and urinary output. These effects are rapidly reversed upon drug discontinuation. There is scant evidence of long-term nephrotoxicity following enflurane use, and it is safe to use in patients with renal impairment, provided that the depth of enflurane anesthesia and the duration of administration are not excessive.

*Liver and GI Tract.* Enflurane reduces splanchnic and hepatic blood flow in proportion to reduced arterial blood pressure. Enflurane does not appear to alter liver function or to be hepatotoxic.

**DESFLURANE**
Desflurane (SUPRANE) is a highly volatile liquid at room temperature (vapor pressure = 681 mm Hg) and must be stored in tightly sealed bottles. Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O₂, air, or N₂O). Desflurane is nonflammable and nonexplosive in mixtures of air or O₂.

**PHARMACOKINETICS.** Desflurane has a very low blood:gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues. Thus, the alveolar and blood concentrations rapidly rise to the level of inspired concentration, providing rapid induction of anesthesia and rapid changes in depth of anesthesia following changes in the inspired concentration. Emergence from desflurane anesthesia also is very rapid. Desflurane is minimally metabolized; >99% of absorbed desflurane is eliminated unchanged through the lungs.

**CLINICAL USE.** Desflurane is a widely used anesthetic for outpatient surgery because of its rapid onset of action and rapid recovery. The drug irritates the tracheobronchial tree and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an IV agent, with desflurane subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6-8% (~1 MAC). Lower concentrations of desflurane are required if it is coadministered with nitrous oxide or opioids.

**SIDE EFFECTS**

*Cardiovascular System.* Desflurane produces hypotension primarily by decreasing systemic vascular resistance. Cardiac output is well preserved, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary). Transient tachycardia is often noted with abrupt increases in desflurane’s delivered concentration, a result of this desflurane-induced stimulation of the sympathetic nervous system. The hypotensive effects of desflurane do not wane with increasing duration of administration.

*Respiratory System.* Desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (<1 MAC)
the net effect is to preserve minute ventilation. Desflurane concentrations >1 MAC depress minute ventilation, resulting in elevated arterial CO₂ tension (Pa₇CO₂). Desflurane is a bronchodilator. However, it also is a strong airway irritant, and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. *Because of its irritant properties, desflurane is not used for induction of anesthesia.*

*Nervous System.* Desflurane decreases cerebral vascular resistance and CMRO₂. Burst suppression of the EEG is achieved with ~2 MAC desflurane; at this level, CMRO₂ is reduced by ~50%. Under conditions of normocapnia and normotension, desflurane produces an increase in CBF and can increase ICP in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in ICP thus can be prevented by hyperventilation.

*Muscle, Kidney, Liver and GI Tract.* Desflurane produces direct skeletal muscle relaxation as well as enhancing the effects of nondepolarizing and depolarizing neuromuscular blocking agents. Consistent with its minimal metabolic degradation, desflurane has no reported nephrotoxicity or hepatotoxicity.

*Desflurane and Carbon Monoxide.* Inhaled anesthetics are administered via a system that permits unidirectional flow of gas and rebreathing of exhaled gases. To prevent rebreathing of CO₂ (which can lead to hypercarbia), CO₂ absorbers are incorporated into the anesthesia delivery circuits. With almost complete desiccation of the CO₂ absorbents, substantial quantities of CO can be produced. This effect is greatest with desflurane and can be prevented by the use of well-hydrated, fresh CO₂ absorbent.

**SEVOFLURANE**

Sevoflurane (ULTANE, others) is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen. However, sevoflurane can undergo an exothermic reaction with desiccated CO₂ absorbent (BARALYME) to produce airway burns or spontaneous ignition, explosion, and fire.
Sevoflurane must not be used with an anesthesia machine in which the CO₂ absorbent has been dried by prolonged gas flow through the absorbent. The reaction of sevoflurane with desiccated CO₂ absorbent also can produce CO, which can result in serious patient injury.

**PHARMACOKINETICS.** The low solubility of sevoflurane in blood and other tissues provides for rapid induction of anesthesia and rapid changes in anesthetic depth following changes in delivered concentration. Approximately 3% of absorbed sevoflurane is metabolized in the liver by CYP2E1, with the predominant product being hexafluoroisopropanol. Hepatic metabolism of sevoflurane also produces inorganic fluoride. Interaction of sevoflurane with soda lime also produces decomposition products that may be toxic such as compound A, pentafluoroisopropenyl fluoromethyl ether (see “Kidney” under “Side Effects”).

**CLINICAL USE.** Sevoflurane is widely used, particularly for outpatient anesthesia, because of its rapid recovery profile, and because it is not irritating to the airway. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2-4% sevoflurane.

**SIDE EFFECTS**

*Cardiovascular System.* Sevoflurane produces concentration-dependent decreases in arterial blood pressure (due to systemic vasodilation) and cardiac output. Sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

*Respiratory System.* Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in PaCO₂. Sevoflurane is not irritating to the airway and is a potent bronchodilator. As a result, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics.

*Nervous System.* Sevoflurane produces effects on cerebral vascular resistance, CMRO₂, and CBF that are very similar to those produced by isoflurane and desflurane. Sevoflurane can increase ICP in patients with poor intracranial
compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in ICP can be prevented by hyperventilation. In children, sevoflurane is associated with delirium upon emergence from anesthesia. This delirium is short lived and without any reported adverse long-term sequelae.

**Muscle.** Sevoflurane produces skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents.

**Kidney.** Controversy has surrounded the potential nephrotoxicity of compound A, which is produced by interaction of sevoflurane with the CO$_2$-absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers. Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following sevoflurane administration. *The FDA recommends that sevoflurane be administered with fresh gas flows of at least 2 L/min to minimize accumulation of compound A.*

**Liver and GI Tract.** Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

**NITROUS OXIDE**

Nitrous oxide (N$_2$O) is a colorless, odorless gas at room temperature. N$_2$O is sold in steel cylinders and must be delivered through calibrated flow meters provided on all anesthesia machines. N$_2$O is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

**PHARMACOKINETICS.** N$_2$O is very insoluble in blood and other tissues. This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration. The rapid uptake of N$_2$O from alveolar gas serves to concentrate coadministered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N$_2$O administration, N$_2$O gas can diffuse from blood to the
alveoli, diluting O₂ in the lung. This can produce an effect called *diffusional hypoxia*. To avoid hypoxia, 100% O₂ rather than air should be administered when N₂O is discontinued.

Almost all (99.9%) of the absorbed N₂O is eliminated unchanged by the lungs. N₂O can interact with the cobalt of vitamin B₁₂, thereby preventing vitamin B₁₂ from acting as a cofactor for methionine synthase. Inactivation of methionine synthase can produce signs of vitamin B₁₂ deficiency, including megaloblastic anemia and peripheral neuropathy, a particular concern in patients with malnutrition, vitamin B₁₂ deficiency, or alcoholism. For this reason, N₂O is not used as a chronic analgesic or as a sedative in critical care settings.

**CLINICAL USE.** N₂O is a weak anesthetic agent that has significant analgesic effects. Surgical anesthetic depth is only achieved under hyperbaric conditions. By contrast, analgesia is produced at concentrations as low as 20%. The analgesic property of N₂O is a function of the activation of opioidergic neurons in the periaqueductal gray matter and the adrenergic neurons in the locus ceruleus. N₂O is frequently used in concentrations of ~50% to provide analgesia and mild sedation in outpatient dentistry. N₂O cannot be used at concentrations >80% because this limits the delivery of adequate O₂. Because of this limitation, N₂O is used primarily as an adjunct to other inhalational or IV anesthetics.

A major problem with N₂O is that it will exchange with N₂ in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, N₂O will enter the cavity faster than N₂ escapes, thereby increasing the volume and/or pressure in this cavity. Examples of air collections that can be expanded by N₂O include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. N₂O should be avoided in these clinical settings.

**SIDE EFFECTS**

*Cardiovascular System.* Although N₂O produces a negative inotropic effect on heart muscle in vitro, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of N₂O on the sympathetic nervous system. The cardiovascular effects of N₂O also are heavily influenced by the concomitant administration of other anesthetic agents. When
N$_2$O is coadministered with halogenated inhalational anesthetics, it produces an increase in heart rate, arterial blood pressure, and cardiac output. In contrast, when N$_2$O is coadministered with an opioid, it generally decreases arterial blood pressure and cardiac output. N$_2$O also increases venous tone in both the peripheral and pulmonary vasculature. The effects of N$_2$O on pulmonary vascular resistance can be exaggerated in patients with preexisting pulmonary hypertension; thus, the drug generally is not used in these patients.

Respiratory System. N$_2$O causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. Even modest concentrations of N$_2$O markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O$_2$ saturation directly in patients receiving or recovering from N$_2$O.

Nervous System. N$_2$O can significantly increase CBF and ICP. This cerebral vasodilatory capacity of N$_2$O is significantly attenuated by the simultaneous administration of IV agents such as opiates and propofol. By contrast, the combination of N$_2$O and inhaled agents results in greater vasodilation than the administration of the inhaled agent alone at equivalent anesthetic depth.

Muscle. N$_2$O does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs.

Kidney, Liver, and GI Tract. N$_2$O is not known have nephrotoxic or hepatotoxic effects.

**XENON**

Xenon (Xe), an inert gaseous element, is not approved for use in the U.S. and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air; thus, xenon is expensive and available in limited quantities. Xenon, unlike other anesthetic agents, has minimal cardiorespiratory and other side effects.

Xenon is extremely insoluble in blood and other tissues, providing for rapid
induction and emergence from anesthesia. It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. However, supplementation with an IV agent such as propofol appears to be required for clinical anesthesia. Xenon is well tolerated in patients of advanced age. No long-term side effects from xenon anesthesia have been reported.

ANESTHETIC ADJUNCTS

A general anesthetic is usually given with adjuncts to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects.

BENZODIAZEPINES

Benzodiazepines (see Chapter 17) can produce anesthesia similar to that of barbiturates, they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is midazolam followed distantly by diazepam (VALIUM, others), and lorazepam (ATIVAN, others).

Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation (as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis). Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of midazolam (0.01-0.05 mg/kg intravenously) reach peak effect in ~2 min and provide sedation for ~30 min. Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines. Midazolam is hepatically metabolized. Either for prolonged sedation or for general anesthetic maintenance, midazolam is more suitable for infusion than are other
benzodiazepines, although its duration of action does significantly increase with prolonged infusions (see Figure 19–3). Benzodiazepines reduce CBF and metabolism but at equianesthetic doses are less potent in this respect than are barbiturates. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea.

**α2 ADRENERGIC AGONISTS.** Dexmedetomidine (PRECEDEX) is a highly selective α2 adrenergic receptor agonist used for short-term (<24 h) sedation of critically ill adults and for sedation prior to and during surgical or other medical procedures in nonintubated patients. Activation of the α2A adrenergic receptor by dexmedetomidine produces both sedation and analgesia.

The recommended loading dose is 1 μg/kg given over 10 min, followed by infusion at a rate of 0.2-0.7 μg/kg/h. Reduced doses should be considered in patients with risk factors for severe hypotension. Dexmedetomidine is highly protein bound and is metabolized primarily in the liver; the glucuronide and methyl conjugates are excreted in the urine. Common side effects of dexmedetomidine include hypotension and bradycardia, attributed to decreased catecholamine release by activation peripherally and in the CNS of the α2A receptor. Nausea and dry mouth also are common untoward reactions. At higher drug concentrations, the α2B subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. Dexmedetomidine provides sedation and analgesia with minimal respiratory depression. However, dexmedetomidine does not appear to provide reliable amnesia and additional agents may be needed.

**ANALGESICS**

With the exception of ketamine, neither parenteral nor currently available inhalational anesthetics are effective analgesics. Analgesics typically are administered with general anesthetics to reduce anesthetic requirement and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, COX-2 inhibitors, and acetaminophen (see Chapter 34) sometimes provide
adequate analgesia for minor surgical procedures. However, opioids are the primary analgesics used during the perioperative period because of the rapid and profound analgesia they produce. Fentanyl (SUBLIMAZE, others), sufentanil (SUFENTA, others), alfentanil (ALFENTA, others), remifentanil (ULTIVA), meperidine (DEMEROL, others), and morphine are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ-opioid receptors (see Chapter 18).

The choice of a perioperative opioid is based primarily on duration of action, since, at appropriate doses, all produce similar analgesia and side effects. Remifentanil has an ultrashort duration of action (~10 min), accumulates minimally with repeated doses, and is particularly well suited for procedures that are briefly painful. Single doses of fentanyl, alfentanil, and sufentanil all have similar intermediate durations of action (30, 20, and 15 min, respectively), but recovery after prolonged administration varies considerably. Fentanyl’s duration of action lengthens the most with infusion, sufentanil’s much less so, and alfentanil’s the least.

The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia; other opioids are not as efficacious against shivering, perhaps due to less κ-receptor agonism. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain (see Chapter 18). Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

**NEUROMUSCULAR-BLOCKING AGENTS**

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 11.
Depolarizing (e.g., succinylcholine) and nondepolarizing muscle relaxants (e.g., vecuronium) often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the IV line prior to injection of a muscle relaxant. The action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as neostigmine or edrophonium (see Chapter 10), in combination with a muscarinic receptor antagonist (e.g., glycopyrrolate or atropine; see Chapter 9) to offset the muscarinic activation resulting from esterase inhibition. Other than histamine release by some agents, nondepolarizing muscle relaxants used in this manner have few side effects. However, succinylcholine has multiple serious side effects (bradycardia, hyperkalemia, and severe myalgia) including induction of malignant hyperthermia in susceptible individuals.

**Therapeutic Gases**

**OXYGEN**

Oxygen (O\(_2\)) is essential to life. Hypoxia is a life-threatening condition in which O\(_2\) delivery is inadequate to meet the metabolic demands of the tissues. Hypoxia may result from alterations in tissue perfusion, decreased O\(_2\) tension in the blood, or decreased O\(_2\) carrying capacity. In addition, hypoxia may result from restricted O\(_2\) transport from the microvasculature to cells or impaired utilization within the cell. An inadequate supply of O\(_2\) ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

**NORMAL OXYGENATION**

O\(_2\) makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mm Hg). While the fraction (percentage) of O\(_2\) remains constant regardless of atmospheric pressure, the partial
pressure of O₂ (PO₂) decreases with lower atmospheric pressure. Ascent to elevated altitude reduces the uptake and delivery of O₂ to the tissues, whereas, increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the PO₂ in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the PO₂ decreases by dilution with CO₂ and water vapor and by uptake into the blood.

Under ideal conditions, when ventilation and perfusion are well matched, the alveolar PO₂ will be ~14.6 kPa (110 mm Hg). The corresponding alveolar partial pressures of water and CO₂ are 6.2 kPa (47 mm Hg) and 5.3 kPa (40 mm Hg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and capillary blood, and the PO₂ in end-capillary blood is typically within a fraction of a kPa of that in the alveoli. The PO₂ in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a PO₂ of ~5.3 kPa (40 mm Hg). Together, the diffusional barrier, ventilation–perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial O₂ gradient, which is normally 1.3-1.6 kPa (10-12 mm Hg) when air is breathed and 4.0-6.6 kPa (30-50 mm Hg) when 100% O₂ is breathed. O₂ is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of O₂ typically reduces the PO₂ of venous blood by an additional 7.3 kPa (55 mm Hg). Although the PO₂ at the site of cellular O₂ utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a PO₂ of only a few mm Hg.

In the blood, O₂ is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of O₂ combined with hemoglobin depends on the PO₂, as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 19–6). Hemoglobin is ~98% saturated with O₂ when air is breathed under normal circumstances, and it binds 1.3 mL of O₂ per gram when fully saturated. The steep slope of this curve with falling PO₂ facilitates unloading of O₂ from hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing PCO₂, and decreasing pH, as is
found in metabolically active tissues, lowers the O₂ saturation for the same Pₒ₂ and thus delivers additional O₂ where and when it is most needed. However, the flattening of the curve with higher Pₒ₂ indicates that increasing blood Pₒ₂ by inspiring O₂-enriched mixtures can increase the amount of O₂ carried by hemoglobin only minimally. Because of the low solubility of O₂ (0.226 mL/L per kPa or 0.03 mL/L per mm Hg at 37°C), breathing 100% O₂ can increase the amount of O₂ dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired Pₒ₂ is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved O₂ is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 19–4).

Figure 19–6 Oxyhemoglobin dissociation curve for whole blood. The relationship between Pₒ₂ and hemoglobin (Hb) saturation is shown. The P₅₀, or the Pₒ₂ resulting in 50% saturation, is indicated. An increase in temperature or a decrease in pH (as in working muscle) shifts this relationship to the right, reducing the hemoglobin saturation at the same Pₒ₂ and thus aiding in the delivery of O₂ to the tissues.

*This table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial $O_2$ tension increases, the amount of dissolved $O_2$ increases in direct proportion to the $P_0_2$, but the amount of oxygen bound to hemoglobin reaches a maximum of 156 ml O$_2$/liter (100% saturation of hemoglobin at 15 g/dl). Further increase in $O_2$ content requires increase in dissolved oxygen. At 100% inspired $O_2$, dissolved $O_2$ still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the haemoglobin in the mixed venous blood remains fully saturated with $O_2$. The figures in this table are approximate and are based on the assumptions of 15 g/dl haemoglobin, 100 ml O$_2$/liter whole-body oxygen extractor, and constant cardiac output. When severe anaemia is present, arterial $Hb$ remains the same, but arterial content is lower when oxygen extraction is normal, resulting in lower $O_2$ content and tension in mixed venous blood. Similarly, when cardiac output falls significantly, the same oxygen saturation occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.*

**OXYGEN DEPRIVATION.** Hypoxemia generally implies a failure of the respiratory system to oxygenate arterial blood. Classically, there are 5 causes of hypoxemia:

- Low inspired $O_2$ fraction ($F_{O_2}$)
- Increased diffusion barrier
- Hypoventilation
- Ventilation–perfusion mismatch
- Shunt or venous admixture

The term hypoxia denotes insufficient oxygenation of the tissues. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of $O_2$ delivery and $O_2$ utilization. $O_2$ delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased $O_2$ carrying capacity of the blood likewise will reduce $O_2$ delivery, such as occurs with anemia, CO poisoning, or hemoglobinopathy. Finally, hypoxia may occur when transport of $O_2$ from the capillaries to the tissues is decreased (edema) or utilization of the $O_2$ by the cells is impaired (CN$^-$ toxicity). Hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia inducible factor-1α. The cellular consequences are discussed in Chapter 19 of the 12th edition of the parent text.
ADAPTATION TO HYPOXIA. Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce acute mountain sickness, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema. Mountain sickness is treated with rest and analgesics when mild or supplemental O₂, descent to lower altitude, or an increase in ambient pressure when more severe. Acetazolamide (a carbonic anhydrase inhibitor) and dexamethasone also may be helpful.

OXYGEN INHALATION

PHYSIOLOGICAL EFFECTS OF OXYGEN INHALATION. O₂ inhalation is used primarily to reverse or prevent the development of hypoxia. However, when O₂ is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

RESPIRATORY SYSTEM. Inhalation of O₂ at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of O₂ inhalation because of a paradoxical increase in the tension of CO₂ in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less efficient removal of carbon dioxide from the tissues. Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the airspaces while O₂ is absorbed. High O₂ concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis, occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of O₂ administration.
**CARDIOVASCULAR SYSTEM.** Heart rate and cardiac output are slightly reduced when 100% O$_2$ is breathed; blood pressure changes little. Elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with O$_2$ therapy or return to sea level. In neonates with congenital heart disease and left-to-right shunting of cardiac output, O$_2$ supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

**METABOLISM.** Inhalation of 100% O$_2$ does not produce detectable changes in O$_2$ consumption, CO$_2$ production, respiratory quotient, or glucose utilization.

**OXYGEN ADMINISTRATION**

O$_2$ is supplied as a compressed gas in steel cylinders; purity of 99% is *medical grade*. For safety, O$_2$ cylinders and piping are color-coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to O$_2$ systems.

O$_2$ is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. Only a closed delivery system with an airtight seal to the patient’s airway and complete separation of inspired from expired gases can precisely control F$_{1O_2}$. In all other systems, the actual delivered F$_{1O_2}$ will depend on the ventilatory pattern (i.e., rate, tidal volume, inspiratory–expiratory time ratio, and inspiratory flow) and delivery system characteristics.

**LOW-FLOW SYSTEMS.** Low-flow systems, in which the O$_2$ flow is lower than the inspiratory flow rate, have a limited ability to raise the F$_{1O_2}$ because they depend on entrained room air to make up the balance of the inspired gas. These devices typically deliver 24-28% F$_{1O_2}$ at 2-3 L/min. Up to 40% F$_{1O_2}$ is possible at higher flow rates, although this is poorly tolerated for more than brief periods because of mucosal drying.

**HIGH-FLOW SYSTEMS.** The most commonly used high-flow O$_2$ delivery
device is the Venturi-style mask, which uses a specially designed mask insert to entrain room air reliably in a fixed ratio and thus provides a relatively constant $\text{FiO}_2$ at relatively high flow rates. Typically, each insert is designed to operate at a specific $\text{O}_2$ flow rate, and different inserts are required to change the $\text{FiO}_2$. Lower delivered $\text{FiO}_2$ values use greater entrainment ratios, resulting in higher total ($\text{O}_2$ plus entrained air) flows to the patient, ranging from 80 L/min for 24% $\text{FiO}_2$ to 40 L/min at 50% $\text{FiO}_2$. $\text{O}_2$ nebulizers, another type of Venturi-style device, provide patients with humidified $\text{O}_2$ at 35-100% $\text{FiO}_2$ at high flow rates. Finally, $\text{O}_2$ blenders provide high inspired $\text{O}_2$ concentrations at very high flow rates. These devices mix high-pressure compressed air and $\text{O}_2$ to achieve any concentration of $\text{O}_2$ from 21-100% at flow rates of up to 100 L/min. Despite the high flows, the delivery of high $\text{FiO}_2$ to an individual patient also depends on maintaining a tight-fitting seal to the airway and/or the use of reservoirs to minimize entrainment of diluting room air.

**MONITORING OF OXYGENATION.** Monitoring and titration are required to meet the therapeutic goal of $\text{O}_2$ therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Noninvasive monitoring of arterial $\text{O}_2$ saturation can be achieved using transcutaneous pulse oximetry, in which $\text{O}_2$ saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Pulse oximetry measures hemoglobin saturation and not $\text{PO}_2$. It is not sensitive to increases in $\text{PO}_2$ that exceed levels required to saturate the blood fully. Pulse oximetry is very useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating $\text{O}_2$ therapy in situations where toxicity from $\text{O}_2$ or side effects of excess $\text{O}_2$ are of concern.

**COMPLICATIONS OF OXYGEN THERAPY.** In addition to the potential to promote absorption atelectasis and depress ventilation, high flows of dry $\text{O}_2$ can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified $\text{O}_2$ thus should be used when prolonged therapy (>1 h) is required. Finally, any $\text{O}_2$-
enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken. Hypoxemia can occur despite the administration of supplemental \( \text{O}_2 \). Therefore, it is essential that both \( \text{O}_2 \) saturation and adequacy of ventilation be assessed frequently.

**THERAPEUTIC USES OF OXYGEN**

**CORRECTION OF HYPOXIA.** The primary therapeutic use of \( \text{O}_2 \) is to correct hypoxia. Hypoxia is most commonly a manifestation of an underlying disease, and administration of \( \text{O}_2 \) thus should be viewed as temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. Hypoxia resulting from most pulmonary diseases can be alleviated at least partially by administration of \( \text{O}_2 \), allowing time for definitive therapy to reverse the primary process.

*Reduction of Partial Pressure of an Inert Gas.* Because nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In situations such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of air-filled spaces. Because nitrogen is relatively insoluble, inhalation of high concentrations of \( \text{O}_2 \) (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of \( \text{O}_2 \) for air embolism is additionally beneficial because it helps to relieve localized hypoxia distal to the vascular obstruction. In the case of *decompression sickness*, or *bends*, lowering the inert gas tension in blood and tissues by \( \text{O}_2 \) inhalation prior to or during a barometric decompression reduces the supersaturation that occurs after decompression so that bubbles do not form.

*Hyperbaric Oxygen Therapy.* \( \text{O}_2 \) can be administered at greater than atmospheric pressure in hyperbaric chambers. Clinical uses of hyperbaric \( \text{O}_2 \) therapy include the treatment of trauma, burns, radiation damage, infections, nonhealing ulcers, skin grafts, spasticity, and other neurological conditions. Hyperbaric \( \text{O}_2 \) may be useful in generalized hypoxia. In CO poisoning, hemoglobin (Hb) and myoglobin become unavailable for \( \text{O}_2 \) binding because of the high affinity of these proteins for CO. High \( \text{Po}_2 \) facilitates competition of \( \text{O}_2 \) for Hb binding
sites as CO is exchanged in the alveoli. In addition, hyperbaric O$_2$ increases the availability of dissolved O$_2$ in the blood (see Table 19–4). Adverse effects of hyperbaric O$_2$ therapy include middle ear barotrauma, CNS toxicity, seizures, lung toxicity, and aspiration pneumonia.

Hyperbaric O$_2$ therapy has 2 components: increased hydrostatic pressure and increased O$_2$ pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased O$_2$ pressure at the tissue is the primary therapeutic goal for other indications for hyperbaric O$_2$. A small increase in Po$_2$ in ischemic areas enhances the bactericidal activity of leukocytes and increases angiogenesis. Repetitive brief exposures to hyperbaric O$_2$ may enhance therapy for chronic refractory osteomyelitis, osteoradionecrosis, crush injury, or the recovery of compromised skin and tissue grafts. Increased O$_2$ tension can be bacteriostatic and useful in the treatment for the spread of infection with Clostridium perfringens and clostridial myonecrosis (gas gangrene).

**OXYGEN TOXICITY**

O$_2$ can have deleterious actions at the cellular level. O$_2$ toxicity may result from increased production of hydrogen peroxide and reactive intermediates such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.
RESPIRATORY TRACT. The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest O₂ tensions in the body. Subtle changes in pulmonary function can occur within 8-12 h of exposure to 100% O₂. Increases in capillary permeability, which will increase the alveolar/arterial O₂ gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 h of exposure. Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired O₂ tension, and concentrations of <0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli.

NERVOUS SYSTEM. Retinopathy of prematurity (ROP) is an eye disease in premature infants involving abnormal vascularization of the developing retina that can result from O₂ toxicity or relative hypoxia. CNS problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when O₂ tension is returned to normal. In premature neonates and those who have sustained in utero asphyxia, hyperoxia and hypocapnia are associated with worse neurologic outcomes.

CARBON DIOXIDE

CO₂ is produced by metabolism at approximately the same rate as O₂ is consumed. At rest, this value is ~3 mL/kg/min, but it may increase dramatically with exercise. CO₂ diffuses readily from the cells into the blood, where it is carried partly as bicarbonate ion (HCO₃⁻), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of ~6 kPa (46 mm Hg) in mixed venous blood. CO₂ is transported to the lung, where it is normally exhaled at the rate it is produced, leaving a partial pressure of ~5.2 kPa (40 mm Hg) in the alveoli and in arterial blood. An increase in PCO₂ results in a respiratory acidosis and may be due to decreased ventilation or the inhalation of CO₂, whereas an increase in ventilation results in decreased PCO₂ and a respiratory alkalosis. Since
CO₂ is freely diffusible, the changes in blood PCO₂ and pH soon are reflected by intracellular changes in PCO₂ and pH and by widespread effects in the body, especially on respiration, circulation, and the CNS.

**RESPIRATION.** CO₂ is a rapid, potent stimulus to ventilation in direct proportion to the inspired CO₂. CO₂ stimulates breathing by acidifying central chemoreceptors and the peripheral carotid bodies. Elevated Pco₂ causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion.

**CIRCULATION.** The circulatory effects of CO₂ result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of CO₂ on the heart, diminished contractility, results from pH changes and a decreased myofilament Ca²⁺ responsiveness. The direct effect on systemic blood vessels results in vasodilation. CO₂ causes widespread activation of the sympathetic nervous system. The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (see Chapter 12). The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to CO₂. The net effect of CO₂ inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of CO₂ appear more important, and total peripheral resistance decreases when the Pco₂ is increased. CO₂ also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased PCO₂ are due to the release of catecholamines.

*Hypocarbia* results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

**CNS.** Hypercarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hypoventilating from
narcotics or anesthetics, increasing Pco₂ may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can have lethal consequences.

**METHODS OF ADMINISTRATION.** CO₂ is marketed in gray metal cylinders as the pure gas or as CO₂ mixed with O₂. It usually is administered at a concentration of 5-10% in combination with O₂ by means of a face mask. Another method for the temporary administration of CO₂ is by rebreathing, such as from an anesthesia breathing circuit or from something as simple as a paper bag.

**THERAPEUTIC USES.** CO₂ is used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because it is highly soluble and does not support combustion. CO₂ can be used to flood the surgical field during cardiac surgery. Because of its density, CO₂ displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are CO₂ rather than insoluble N₂. It is used to adjust pH during cardiopulmonary bypass procedures when a patient is cooled.

Hypocarbia still has some uses in anesthesia; it constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. While short-term hypocarbia is effective for this purpose, sustained hypocarbia has been associated with worse outcomes in patients with head injury. Hypocarbia should be instituted with a clearly defined indication and normocarbia should be reestablished as soon the indication for hypocarbia no longer applies.

**NITRIC OXIDE**

Nitric oxide (NO) is a free-radical gas now known as a critical endogenous cell-signaling molecule with an increasing number of potential therapeutic applications.

Endogenous NO is produced from L-arginine by NO synthases (neural, inducible and endothelial) (see Chapter 3). In the vasculature, basal production of NO by endothelial cells is a primary determinant of resting vascular tone. NO causes vasodilation of smooth muscle cells and inhibition of platelet aggregation.
and adhesion. Impaired NO production is implicated in atherosclerosis, hypertension, cerebral and coronary vasospasm, ischemia–reperfusion injury, inflammation, and in mediating central nociceptive pathways. NO is rapidly inactivated in the circulation by oxyhemoglobin and by the reaction of NO with the heme iron, leading to the formation of nitrosyl-hemoglobin. Small quantities of methemoglobin are also produced and these are converted to the ferrous form of heme iron by cytochrome b5 reductase. The majority of inhaled NO is excreted in the urine in the form of nitrate.

THERAPEUTIC USES. Inhaled NO (iNO) selectively dilates the pulmonary vasculature and has potential as a therapy for numerous diseases associated with increased pulmonary vascular resistance. Inhaled NO is FDA-approved for only 1 indication, persistent pulmonary hypertension of the newborn.

DIAGNOSTIC USES. Inhaled NO can be used during cardiac catheterization to evaluate the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (DL) across the alveolar–capillary unit. NO is more effective than CO₂ in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature. NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of fractional exhaled NO (FeNO) is a noninvasive marker for airway inflammation with utility in the assessment of respiratory tract diseases including asthma, respiratory tract infection, and chronic lung disease.

TOXICITY. Administered at low concentrations (0.1-50 ppm), iNO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50-100 ppm. NO is an atmospheric pollutant; the Occupational Safety and Health Administration places the 7-h exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to nitrogen dioxide (NO₂) in the presence of high concentrations of O₂.

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation. Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding
complications have not been reported. In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation.

The most important requirements for safe NO inhalation therapy include:

- Continuous measurement of NO and NO\(_2\) concentrations using either chemiluminescence or electrochemical analyzers
- Frequent calibration of monitoring equipment
- Intermittent analysis of blood methemoglobin levels
- The use of certified tanks of NO
- Administration of the lowest NO concentration required for therapeutic effect

METHODS OF ADMINISTRATION. Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1-40 ppm in dose and for periods of a few hours to several weeks in duration. The determination of dose response relationship on a frequent basis should assist in the titration of the optimum dose of NO. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO\(_2\) concentrations.

HELIUM

Helium (He) is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium can be mixed with O\(_2\) and administered by mask or endotracheal tube. Under hyperbaric conditions, it can be substituted for the bulk of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, laser airway surgery, as a label in imaging studies, and for diving at depth. Helium is also suited for determinations of residual lung
volume, functional residual capacity, and related lung volumes. These measurements require a highly diffusible nontoxic gas that is insoluble and does not leave the lung by the bloodstream so that, by dilution, the lung volume can be measured. Helium can be added to O$_2$ to reduce turbulence due to airway obstruction since the density of helium is less than that of air and the viscosity of helium is greater than that of air. Mixtures of helium and O$_2$ reduce the work of breathing. Helium has high thermal conductivity, making it useful during laser surgery on the airway. Laser-polarized helium is used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Optical pumping of hyperpolarized helium increases the signal from the gas in the lung to permit detailed imaging of the airways and inspired airflow patterns.

**HYDROGEN SULFIDE**

Hydrogen sulfide (H$_2$S), which has a characteristic rotten egg smell, is a colorless, flammable, water-soluble gas that is primarily considered a toxic agent due to its ability to inhibit mitochondrial respiration through blockade of cytochrome c oxidase. Inhibition of respiration is potentially toxic; however, if depression of respiration occurs in a controlled manner, it may allow nonhibernating species exposed to inhaled H$_2$S to enter a state akin to suspended animation (i.e., a slowing of cellular activity to a point where metabolic processes are inhibited but not terminal) and thereby increase tolerance to stress. H$_2$S also may cause activation of ATP-dependent K$^+$ channels, cause vasodilation properties, and serve as a free radical scavenger. H$_2$S has been shown to protect against whole-body hypoxia, lethal hemorrhage, and ischemia-reperfusion injury in various organs including the kidney, lung, liver, and heart. Currently, effort is underway for development of gas-releasing molecules that could deliver H$_2$S and other therapeutic gases to diseased tissue. H$_2$S in low quantities may have the potential to limit cell death.
Local anesthetics bind reversibly to a specific receptor site within the pore of the Na\(^+\) channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction.

**CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIP.** The most widely used agents today are procaine, lidocaine, bupivacaine, and tetracaine (Figure 20–1). These agents were synthesized as substitutes for cocaine, preserving the local anesthetic effect of cocaine but avoiding its toxicity and addictive properties. The typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage. The hydrophilic group usually is a tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, local anesthetics with an ester link are hydrolyzed readily by plasma esterases. Hydrophobicity increases both the potency and the duration of action of the local anesthetics; association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na\(^+\) channels is thought to be hydrophobic, so that receptor affinity for anesthetic agents is greater for more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.
Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency- and voltage-dependence of their action.

**MECHANISM OF ACTION.** Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve
impulses. The major mechanism of action of local anesthetics involves their interaction with 1 or more specific binding sites within the Na\(^+\) channel (see Figure 14–1A).

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na\(^+\) that normally is produced by membrane depolarization. This action of local anesthetics is due to their direct interaction with voltage-gated Na\(^+\) channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse conduction slows, and nerve conduction fails. Local anesthetics can block K\(^+\) channels but this interaction requires higher concentrations of drug; thus, blockade of conduction is not accompanied by any large change in resting membrane potential.

**FREQUENCY- AND VOLTAGE-DEPENDENCE OF LOCAL ANESTHETIC ACTION.** A higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the local anesthetic molecule in its charged form, gains access to its binding site within the pore only when the Na\(^+\) channel is in an open state, and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na\(^+\) channel. The frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na\(^+\) channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between action potentials.

**DIFFERENTIAL SENSITIVITY OF NERVE FIBERS TO LOCAL ANESTHETICS.** For most patients treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 20–1).
In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated Aδ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated Aγ, Aβ, and Aα fibers (mediating postural, touch, pressure, and motor information). The precise mechanisms responsible for this apparent specificity of local anesthetic action on pain fibers are not known. The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.

**EFFECT OF pH.** Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Inasmuch as the local anesthetics are weak bases...
(typical pK_a values range from 8-9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and the catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

PROLONGATION OF ACTION BY VASOCONSTRICTORS. The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. In clinical practice, a vasoconstrictor, usually epinephrine, is often added to local anesthetics. The vasoconstrictor, by decreasing the rate of absorption, localizes the anesthetic at the desired site, and reduces systemic toxicity by allowing metabolism to keep pace with the rate at which it is absorbed into the circulation. It should be noted, however, that epinephrine also dilates skeletal muscle vascular beds through actions at β_2_ adrenergic receptors, and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

UNDESIRED EFFECTS OF LOCAL ANESTHETICS. Local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, they have important effects on the CNS, the autonomic ganglia, the neuromuscular junction, and all forms of muscle.

The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, in local anesthetics with chiral centers, the S-enantiomer is less toxic than the R-enantiomer.

CNS. Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. Central stimulation is followed by depression; death usually is caused by respiratory failure. Benzodiazepines or rapidly acting barbiturates administered intravenously are the drugs of choice for both the prevention and arrest of convulsions (see Chapter 17). Lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, both lidocaine and procaine may produce a loss of consciousness that is preceded only by symptoms of sedation.
Cardiovascular System. Following systemic absorption, local anesthetics act on the cardiovascular system, primarily on the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In addition, most local anesthetics cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and effects on the CNS are produced; on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. Untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if epinephrine also is present.

Smooth Muscle. Local anesthetics depress contractions in the bowel. They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction. Spinal and epidural anesthesia and instillation of local anesthetics into the peritoneal cavity cause sympathetic nervous system paralysis, which can result in increased tone of GI musculature. Local anesthetics seldom depress uterine contractions during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglionic Synapse. Local anesthetics also affect transmission at the neuromuscular junction. Procaine, e.g., can block the response of skeletal muscle to ACh at concentrations at which the muscle responds normally to direct electrical stimulation. Similar effects occur at autonomic ganglia. These effects are due to block of nicotinic ACh receptors by high concentrations of the local anesthetic.

HYPERSENSITIVITY TO LOCAL ANESTHETICS. Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant for the catecholamine/vasoconstrictor.

METABOLISM OF LOCAL ANESTHETICS. The metabolic fate of local anesthetics is of great practical importance, because their
toxicity depends largely on the balance between their rates of absorption and elimination. The rate of absorption of many anesthetics can be reduced considerably by the incorporation of a vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Because toxicity is related to the concentration of free drug, binding of the anesthetic to proteins in the serum and to tissues reduces the concentration of free drug in the systemic circulation, and consequently reduces toxicity.

Some of the common local anesthetics (e.g., tetracaine) are esters; they are inactivated primarily by a plasma esterase. The liver also participates in hydrolysis of local anesthetics. Because spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation. The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs the initial reactions involving N-dealkylation and subsequent hydrolysis. With prilocaine, the initial step is hydrolytic, forming o-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution. The amide-linked local anesthetics are extensively (55-95%) bound to plasma proteins, particularly α1-acid glycoprotein. Many factors increase (e.g., cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (e.g., oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics in the body. Reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives.

**COCAINÉ**

Cocaine, an ester of benzoic acid and methylecgonine, occurs in abundance in the leaves of the coca shrub.
PHARMACOLOGICAL ACTIONS AND PREPARATIONS. The clinically desired actions of cocaine are the blockade of nerve impulses, as a consequence of its local anesthetic properties, and local vasoconstriction, secondary to inhibition of local NE reuptake. Cocaine’s high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems. Its euphoric properties are due primarily to inhibition of catecholamine uptake, particularly DA, in the CNS. Cocaine is used primarily for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provide anesthesia and shrinking of the mucosa. Cocaine hydrochloride is provided as a 1%, 4%, or 10% solution for topical application. Because of its abuse potential, cocaine is listed as a schedule II controlled substance by the U.S. Drug Enforcement Agency.

LIDOCAINE

Lidocaine (XYLOCAINE, others), an aminoethylamide, is the prototypical amide local anesthetic.

PHARMACOLOGICAL ACTIONS; PREPARATIONS. Lidocaine produces faster, more intense, longer-lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics. Lidocaine is absorbed rapidly after parenteral administration and from the GI and respiratory tracts. Although it is effective when used without any vasoconstrictor, epinephrine decreases the rate of absorption, such that the toxicity is decreased and the duration of action usually is prolonged. In addition to preparations for injection, lidocaine is formulated for topical, ophthalmic, mucosal, and transdermal use.

A lidocaine transdermal patch (LIDODERM) is used for relief of pain associated with postherpetic neuralgia. An oral patch (DENTIPATCH) is available for application to accessible mucous membranes of the mouth prior to superficial dental procedures. The combination of lidocaine (2.5%) and prilocaine (2.5%) in an occlusive dressing (EMLA, others) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia. Lidocaine in combination with tetracaine (PLIAGLIS) in a formulation that generates a “peel” is approved for topical local analgesia prior to superficial dermatological procedures such as filler injections and laser-based treatments.
Lidocaine in combination with tetracaine is marketed in a formulation that generates heat upon exposure to air (SYNERA), which is used prior to venous access and superficial dermatological procedures such as excision, electrodessication, and shave biopsy of skin lesions. The mild warming is intended to increase skin temperature by up to 5°C for the purpose of enhancing delivery of local anesthetic into the skin. Lidocaine is dealkylated in the liver by CYPs and metabolized to monoethylglycine and xylidide. Both metabolites retain local anesthetic activity.

**TOXICITY.** The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum lidocaine levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

**CLINICAL USES.** Lidocaine has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an anti-arrhythmic agent (see Chapter 29).

**BUPIVACAINE**

**PHARMACOLOGICAL ACTIONS; PREPARATIONS.** Bupivacaine (MARCAINE, SENSORCAINE, others), is a widely used amide local anesthetic. Bupivacaine is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block make it popular for providing prolonged analgesia during labor or the postoperative period. With indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia.

**TOXICITY.** Bupivacaine is more cardiotoxic than equi-effective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration. Although lidocaine and bupivacaine both rapidly block cardiac Na⁺ channels during systole, bupivacaine dissociates much more slowly than does lidocaine during diastole, so a significant fraction of Na⁺ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole. Bupivacaine-induced
cardiac toxicity can be very difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia.

**OTHER SYNTHETIC LOCAL ANESTHETICS**

**LOCAL ANESTHETICS SUITABLE FOR INJECTION**

**ARTICaine.** Articaine (SeptoCaine) is an amide local anesthetic approved in the U.S. for dental and periodontal procedures. Articaine exhibits a rapid onset (1-6 min) and duration of action of ~1 h.

**CHLOROPROCAINE.** Chloroprocaine (Nesacaine, others) is a chlorinated derivative of procaine. It has rapid onset and short duration of action and reduced acute toxicity due to its rapid metabolism (plasma $t_{1/2} \sim 25$ seconds). A higher than expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine has also been reported. This back pain is thought to be due to tetany in the paraspinous muscles, which may be a consequence of $\text{Ca}^{2+}$ binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

**MEPIVACAINE.** Mepivacaine (Carbocaine, PoloCaine, others) is an intermediate-acting amino amide. Its pharmacological properties are similar to those of lidocaine. Mepivacaine is more toxic to the neonate and thus is not used in obstetrical anesthesia. Mepivacaine is not effective as a topical anesthetic.

**PRILOCAINE.** Prilocaine (CitaneSt) is an intermediate-acting amino amide. It has a pharmacological profile similar to that of lidocaine. It causes little vasodilation and thus can be used without a vasoconstrictor, and its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks. The use of prilocaine is largely limited to dentistry because the drug can cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to o-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg.

**ROPIVACAINE.** Ropivacaine (Naropin, others), an amino ethylamine, is
slightly less potent than bupivacaine in producing anesthesia. In clinical studies, ropivacaine appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of bupivacaine.

**PROCAINE.** Procaine (Novocain, others) is an amino ester. It is use now is confined to infiltration anesthesia and occasionally for diagnostic nerve blocks. This is because of its low potency, slow onset, and short duration of action. It is hydrolyzed in vivo to produce para-aminobenzoic acid, which inhibits the action of sulfonamides. Thus, large doses should not be administered to patients taking sulfonamide drugs.

**TETRACAINE.** Tetracaine (Pontocaine) is a long-acting amino ester. It is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. It is widely used in spinal anesthesia when a drug of long duration is needed. Tetracaine also is incorporated into several topical anesthetic preparations. Tetracaine is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

**LOCAL ANESTHETICS USED PRIMARILY TO ANESTHETIZE MUCOUS MEMBRANES AND SKIN**

Some anesthetics are either too irritating or too ineffective to be applied to the eye. However, they are useful as topical anesthetic agents on the skin and/or mucous membranes. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations.

**DIBUCAINE.** Dibucaine (Nupercainal, others) is a quinoline derivative. Its toxicity resulted in its removal from the U.S. market as an injectable preparation; it retains wide popularity outside the U.S. as a spinal anesthetic. It currently is available as an over-the-counter ointment for use on the skin.

**DYCLONINE.** Dyclonine hydrochloride has a rapid onset of action and duration
of effect comparable to that of procaine. It is absorbed through the skin and mucous membranes. Dyclonine is an active ingredient in a number of over-the-counter medications including sore throat lozenges (SUCRETS, others), a patch for cold sores (Orajel Overnight Cold Sore Patch), and a 0.75% solution (Skin Shield Liquid Bandage).

**PRAMOXINE.** Pramoxine hydrochloride (TRONOTHANE, others) is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. Pramoxine produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes.

**ANESTHETICS OF LOW SOLUBILITY**

Some local anesthetics are poorly soluble in water, and consequently are too slowly absorbed to be toxic. They can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained anesthetic action. The most important member of the series is **benzocaine** (ethyl aminobenzoate; HURRICaine, others). Benzocaine is incorporated into a large number of topical preparations. Benzocaine can cause methemoglobinemia; consequently, dosing recommendations must be followed carefully.

**LOCAL ANESTHETICS LARGELY RESTRICTED TO OPHTHALMOLOGICAL USE**

Most of the local anesthetics that have been described are too irritating for ophthalmological use. The 2 compounds used most frequently today are **proparacaine** (ALCAINE, OPHTHAINE, others) and tetracaine (see Figure 20–1). In addition to being less irritating during administration, proparacaine has the added advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics. For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is
incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus, it is longest in normal cornea and shortest in inflamed conjunctiva. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting, and sloughing of the corneal epithelium, and predisposition of the eye to inadvertent injury; see Chapter 64.

**CLINICAL USES OF LOCAL ANESTHETICS**

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers 2 major advantages. First, physiological perturbations associated with general anesthesia are avoided; second, neurophysiological responses to pain and stress can be modified beneficially. There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Peak plasma levels vary widely depending on the area of injection. Thus, recommended maximum doses serve only as general guidelines.

**TOPICAL ANESTHESIA**

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2-10%), and cocaine (1-4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia.

The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). *Maximal* safe total dosages for
topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine. Peak anesthetic effect following topical application of cocaine or lidocaine occurs within 2-5 min (3-8 min with tetracaine), and anesthesia lasts for 30-45 min (30-60 min with tetracaine).

*Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions.*

Use of eutectic mixtures of local anesthetics lidocaine (2.5%)/prilocaine (2.5%) (EMLA) and lidocaine (7%)/tetracaine (7%) (PLIAGLIS) bridges the gap between topical and infiltration anesthesia. The efficacy of each of these combinations lies in the fact that the mixture has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. These creams produce anesthesia to a maximum depth of 5 mm and are applied as a cream on intact skin under an occlusive dressing in advance (~30-60 min) of any procedure. These mixtures are effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). These mixtures must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

**INFLltrATION ANESTHESIA**

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves. Infiltration anesthesia can be so superficial as to include only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of epinephrine (5 μg/mL) to the injection solution. *Epinephrine-containing solutions should not, however, be injected into tissues supplied by end arteries (e.g., fingers and toes, ears, the nose, and the penis). The resulting vasoconstriction may cause gangrene.* The local anesthetics used most frequently for infiltration anesthesia are lidocaine (0.5-1%), procaine (0.5-1%), and bupivacaine (0.125-0.25%). When used without epinephrine, up to 4.5 mg/kg of lidocaine, 7 mg/kg of procaine, or 2 mg/kg of bupivacaine can be
employed in adults. When epinephrine is added, these amounts can be increased by one-third. The advantage of infiltration anesthesia and other regional anesthetic techniques is that it can provide satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas. The amount of anesthetic required to anesthetize an area can be reduced significantly and the duration of anesthesia increased markedly by specifically blocking the nerves that innervate the area of interest.

**FIELD BLOCK ANESTHESIA**

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic in order to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2-3 cm distal to the site of injection. The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used. Knowledge of the relevant neuroanatomy obviously is essential for successful field block anesthesia.

**NERVE BLOCK ANESTHESIA**

Injection of a solution of a local anesthetic into or about peripheral nerves or nerve plexuses produces greater areas of anesthesia than do the techniques already described. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection.

Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and
relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck. Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar at the elbow, and blocks of sensory cranial nerves.

Major determinants of the onset of sensory anesthesia following injection near a nerve are:

- Proximity of the injection to the nerve
- Concentration and volume of drug
- Degree of ionization of the drug
- Time

Local anesthetic is never intentionally injected into the nerve, as this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Thus, the local anesthetic must diffuse into the nerve where it acts. The rate of diffusion is determined by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. Local anesthetics with lower $pK_a$ values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding in tissue lipids. The amount of connective tissue that must be penetrated can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. It is useful to think of 3 categories:

- Those with a short (20-45 min) duration of action in mixed peripheral nerves, such as procaine
Those with an intermediate (60-120 min) duration of action, such as lidocaine and mepivacaine
Those with a long (400-450 min) duration of action, such as bupivacaine, ropivacaine, and tetracaine

Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 μg/mL).

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve-fiber size, internodal distance, and frequency and pattern of nerve-impulse transmission. Anatomical factors are similarly important. Nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, since removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2-4 h, lidocaine (1-1.5%) can be used in the amounts recommended earlier. Mepivacaine (up to 7 mg/kg of a 1-2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2-3 mg/kg of a 0.25-0.375% solution) can be used when a longer duration of action is required. The amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects.

**INTRAVENOUS REGIONAL ANESTHESIA (BIER BLOCK)**

This technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique,
an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100-150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5-10 min. Pain from the tourniquet and the potential for ischemic nerve injury limits tourniquet inflation to 2 h or less. However, the tourniquet should remain inflated for at least 15-30 min to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40-50 mL (0.5 mL/kg in children) of a 0.5% solution without epinephrine is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without epinephrine, the dose administered should not exceed 4 mg/kg. A few clinicians prefer prilocaine (0.5%) over lidocaine because of its higher therapeutic index. The attractiveness of this technique lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (e.g., 50 mL of 0.5% lidocaine contains 250 mg of lidocaine). The more cardiotoxic local anesthetic, bupivacaine, is not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand, but can be adapted for the foot and distal leg.

**SPINAL ANESTHESIA**

Spinal anesthesia follows the injection of local anesthetic into the cerebrospinal fluid (CSF) in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia is popular. In most adults, the spinal cord terminates above the second lumbar vertebra; between
that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. The consequences of sympathetic blockade vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be minimal in healthy children. The most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilation will occur. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. As the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Treatment of hypotension usually is warranted when the blood pressure decreases to $\sim 30\%$ of resting values. Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. Because the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential venoconstrictive and chronotropic properties are preferred. For this reason, ephedrine, 5-10 mg intravenously, often is the drug of choice. In addition, direct-acting $\alpha_1$ adrenergic receptor agonists such as phenylephrine (see Chapter 12) can be administered either by bolus or continuous infusion.

**PHARMACOLOGY OF SPINAL ANESTHESIA.** In the U.S., lidocaine, tetracaine, and bupivacaine are most commonly used in spinal anesthesia. Procaine occasionally is used for diagnostic blocks when a short duration of action is desired. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate to long procedures, and tetracaine for long procedures.

The factors contributing to the distribution of local anesthetics in the CSF determine the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. For a given preparation of local anesthetic, administration of increasing amounts
leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. Vasoconstrictors may prolong spinal anesthesia by decreasing spinal cord blood flow and thus decreasing clearance of local anesthetic from the CSF. Epinephrine and other α adrenergic agonists decrease nociceptive transmission in the spinal cord, an effect that may involve activation of α2A adrenergic receptors. Such actions may contribute to the beneficial effects of epinephrine, clonidine, and dexmedetomidine when these agents are added to spinal local anesthetics.

**DRUG BARICITY AND PATIENT POSITION.** The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures.

**COMPLICATIONS OF SPINAL ANESTHESIA.** Persistent neurological deficits following spinal anesthesia are extremely rare. Possible causes include introduction of foreign substances into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective. High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. It is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be very useful in patients with fixed, chronic spinal cord injury. A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be evaluated to exclude serious complications such as meningitis. Treatment usually is with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed.

**EVALUATION OF SPINAL ANESTHESIA.** Spinal anesthesia is a safe and
effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. Equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a “light” general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

**EPIDURAL ANESTHESIA**

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5-0.75%, is used when a long duration of surgical block is desired. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 μg/mL of fentanyl added, frequently are used to provide analgesia during labor. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. Addition of epinephrine prolongs duration of action, decreases systemic toxicity, and also makes inadvertent intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia. The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers.
A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection. The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic blockade with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Cardiovascular responses to epidural anesthesia might be expected to be less prominent; however, in practice the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when epinephrine is added to the epidural injection. The resulting concentration of epinephrine in blood is sufficient to produce significant $\beta_2$ adrenergic receptor-mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of epinephrine (see Chapter 12).

High concentrations of local anesthetics in blood during epidural anesthesia are especially important when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. These concerns have been lessened by the trend toward using more dilute solutions of bupivacaine for labor analgesia.

**EPIDURAL AND INTRATHECAL OPIATE ANALGESIA.** Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia. The analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection.

Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (see Chapter 18). Because conduction in autonomic, sensory, and motor nerves is
not affected by the opioids, blood pressure, motor function, and non-nociceptive sensory perception typically are not influenced by spinal opioids. Side effects include urinary retention, pruritus, nausea, and vomiting.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures but are used during surgical procedures and for the relief of postoperative and chronic pain. In selected patients, spinal or epidural opioids can provide excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months’ duration. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids.
Epileptic seizures often cause transient impairment of consciousness, leaving the individual at risk of bodily harm and often interfering with education and employment. Therapy is symptomatic: Available drugs inhibit seizures, but neither effective prophylaxis nor cure is available. The mechanisms of action of antiseizure drugs fall into 3 major categories:

1. Limiting the sustained, repetitive firing of neurons, an effect mediated by promoting the inactivated state of voltage-activated Na\(^+\) channels
2. Enhancing synaptic inhibition mediated \(\gamma\)-aminobutyric acid (GABA), a drug effect that may occur via presynaptic or postsynaptic action
3. Inhibition of voltage-activated Ca\(^{2+}\) channels responsible for T-type Ca\(^{2+}\) currents

Drugs effective against the most common forms of epileptic seizures, *partial and secondarily generalized tonic-clonic seizures*, appear to work by one of the first two mechanisms. Drugs effective against the less common *absence seizure* work by the third mechanism.

**TERMINOLOGY AND EPILEPTIC SEIZURE CLASSIFICATION**

The term *seizure* refers to a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. The term *epilepsy* refers to a disorder of brain function characterized by the periodic and unpredictable occurrence of seizures. Seizures are thought to arise from the cerebral cortex, not from other CNS structures. Epileptic seizures are classified as *partial* seizures, those beginning focally in a cortical site, and *generalized* seizures, those that involve both hemispheres widely from the outset. The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure
arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body part controlled by this region of cortex. A simple partial seizure is associated with preservation of consciousness. A complex partial seizure is associated with impairment of consciousness. The majority of complex partial seizures originate from the temporal lobe. Examples of generalized seizures include absence, myoclonic, and tonic-clonic. The type of epileptic seizure is one determinant of the drug selected for therapy. Table 21–1 presents more detailed information on the classification of seizures and available medications.

More than 50 distinct epileptic syndromes have been identified and categorized into partial versus generalized epilepsies. The partial epilepsies account for roughly 60% of all epilepsies. The etiology commonly consists of a lesion in some part of the cortex, such as a tumor, developmental malformation, or damage due to trauma or stroke. The generalized epilepsies account for ~40% of all epilepsies and the etiology is usually genetic. The most common generalized epilepsy, referred to as juvenile myoclonic epilepsy, accounts for ~10% of all epileptic syndromes. Like most of the generalized-onset epilepsies, juvenile myoclonic epilepsy is a complex genetic disorder that is probably due to
inheritance of multiple susceptibility genes.

**NATURE AND MECHANISMS OF SEIZURES AND ANTISEIZURE DRUGS**

**PARTIAL EPILEPSIES**

Either reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure; pharmacological studies of seizures support this notion. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with GABA and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively (see Chapter 14). Antagonists of the GABA_A receptor or agonists of different glutamate-receptor subtypes (NMDA, AMPA, or kainic acid) trigger seizures in experimental animals in vivo. Conversely, drugs that enhance GABA-mediated synaptic inhibition or glutamate-receptor antagonists inhibit seizures in diverse models.

Electrophysiological analyses of individual neurons during a partial seizure demonstrate that the neurons undergo depolarization and fire action potentials at high frequencies (Figure 21-1). This pattern of neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity. Thus, selective inhibition of this pattern of firing would be expected to reduce seizures with minimal unwanted effects. Inhibition of the high-frequency firing may be mediated by reducing the ability of Na+ channels to recover from inactivation (Figure 21-2). Depolarization-triggered opening of the Na+ channels in the axonal membrane of a neuron is required for an action potential; after opening, the channels spontaneously close, a process termed inactivation. This inactivation is thought to cause the refractory period during which it is not possible to evoke another action potential. Because firing at a slow rate permits sufficient time for Na+ channels to recover from inactivation, inactivation has little or no effect on low-frequency firing. However, reducing the rate of recovery of Na+ channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of carbamazepine, lamotrigine, phenytoin, topiramate, valproic acid, and
zonisamide against partial seizures.

Figure 21–1 Cortical EEG, extracellular, and intracellular recordings in a seizure focus induced by local application of a convulsant agent to mammalian cortex. The extracellular recording was made through a high-pass filter. Note the high-frequency firing of the neuron evident in both extracellular and intracellular recording during the paroxysmal depolarization shift (PDS). (Modified with permission from Ayala GF, Dichter M, Gummit RJ, et al. Genesis of epileptic interictal spikes. New knowledge of cortical feedback systems suggests a neurophysiological explanation of brief paroxysms. Brain Res, 1973;52:1–17. Copyright © Elsevier.)
Figure 21–2 Antiseizure drug-enhanced Na⁺ channel inactivation. Some antiseizure drugs (shown in blue text) prolong the inactivation of the Na⁺ channels, thereby reducing the ability of neurons to fire at high frequencies. Note that the inactivated channel itself appears to remain open, but is blocked by the inactivation gate I. A, activation gate.

Enhancing GABA-mediated synaptic inhibition would reduce neuronal excitability and raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse. The principal postsynaptic receptor of synaptically released GABA is termed the GABAₐ receptor (see Chapters 14 and 17). Activation of the GABAₐ receptor inhibits the postsynaptic cell by increasing the inflow of Cl⁻ ions into the cell, which tends to hyperpolarize the neuron. Clinically relevant concentrations of both benzodiazepines and barbiturates enhance GABAₐ receptor–mediated inhibition through distinct actions on the GABAₐ receptor (Figure 21–3), and this enhanced inhibition probably underlies the effectiveness of these compounds against partial and tonic-clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the antiseizure mechanism of tiagabine; tiagabine inhibits the GABA transporter, GAT-1, and reduces neuronal and glial uptake of GABA.
Enhanced GABA synaptic transmission. In the presence of GABA, the GABA_A receptor (structure on left) is opened, allowing an influx of Cl^−, which in turn increases membrane polarization. Some antiseizure drugs (show in larger blue text) act by reducing the metabolism of GABA. Others act at the GABA_A receptor, enhancing Cl^− influx in response to GABA. As outlined in the text, gabapentin acts presynaptically to promote GABA release; its molecular target is currently under investigation. GABA molecules; GABA-T, GABA transaminase; GAT-1, GABA transporter.

**GENERALIZED-ONSET EPILEPSIES: ABSENCE SEIZURES**
In contrast to partial seizures, which arise from localized regions of the cerebral cortex, generalized-onset seizures arise from the reciprocal firing of the thalamus and cerebral cortex. Among the diverse forms of generalized seizures, absence seizures have been studied most intensively. The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 per second (3 Hz). EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the neocortex and thalamus. One intrinsic property of thalamic neurons that is pivotally involved in the generation of the 3-Hz spike-and-wave discharges is the low threshold (“T-type”) Ca$^{2+}$ current. T-type currents amplify thalamic membrane potential oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Importantly, the principal mechanism by which anti–absence-seizure drugs (ethosuximide, valproic acid) are thought to act is by inhibition of the T-type Ca$^{2+}$ channels (Figure 21–4). Thus, inhibiting voltage-gated ion channels is a common mechanism of action among antiseizure drugs, with anti–partial-seizure drugs inhibiting voltage-activated Na$^+$ channels and anti–absence-seizure drugs inhibiting voltage-activated Ca$^{2+}$ channels.
Figure 21–4 Antiseizure drug-induced reduction of current through T-type Ca\textsuperscript{2+} channels. Some antiseizure drugs (shown in blue text) reduce the flow of Ca\textsuperscript{2+} through T-type Ca\textsuperscript{2+} channels, thereby reducing the pacemaker current that underlies the thalamic rhythm in spikes and waves seen in generalized absence seizures.

GENETIC APPROACHES TO THE EPILEPSIES. Genetic causes are solely responsible for rare epileptic forms inherited in an autosomal dominant or autosomal recessive manner. Genetic causes also are mainly responsible for more common forms such as juvenile myoclonic epilepsy (JME) or childhood absence epilepsy (CAE), the majority of which are likely due to inheritance of 2 or more susceptibility genes. Genetic determinants also may contribute some degree of risk to epilepsies caused by injury of the cerebral cortex. Because most patients with epilepsy are neurologically normal, elucidating the mutant genes underlying familial epilepsy in otherwise normal individuals is of particular interest. This has led to the identification of 25 distinct genes implicated in distinct idiopathic epilepsy syndromes that account for <1% of all of the human epilepsies. Almost all of the mutant genes encode voltage- or ligand-gated ion channels. Mutations have been identified in Na\textsuperscript{+}, K\textsuperscript{+}, Ca\textsuperscript{2+}, and Cl\textsuperscript{−} channels, in channels gated by GABA and acetylcholine, and most recently, in intracellular Ca\textsuperscript{2+} release channels (RyR2) activated by Ca\textsuperscript{2+}. The genotype-phenotype correlations of these genetic syndromes are complex. The cellular electrophysiological consequences of these mutations help describe the mechanisms of seizures and antiseizure drugs. For example, generalized epilepsy with febrile seizures (GEFS\textsuperscript{+}) is caused by a point mutation in the β subunit of a voltage-gated Na\textsuperscript{+} channel (SCN1B). The phenotype of the mutated Na\textsuperscript{+} channel appears to involve defective inactivation.

ANTISEIZURE DRUGS: GENERAL CONSIDERATIONS

Table 21–2 presents proposed mechanisms of action of antiseizure drugs, classified according to likely molecular target and activity. It is important to select the appropriate drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. As a general rule, complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. The degree of success varies as a function of
seizure type, cause, and other factors. Drugs used currently frequently cause unwanted effects that range in severity from minimal impairment of the CNS to ideation and attempt of suicide to death from aplastic anemia or hepatic failure. To minimize toxicity, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to the concurrent administration of another agent. However, multiple-drug therapy may be required, especially when 2 or more types of seizure occur in the same patient. Measurement of drug concentrations in plasma facilitates optimizing antiseizure medication. However, clinical effects of some drugs do not correlate well with their concentrations in plasma. The ultimate therapeutic regimen must be determined by clinical assessment of effect and toxicity. Many of these agents interact noticeably with other medications via induction or inhibition of hepatic CYPs and UGTs that are responsible for drug metabolism (Table 21–3).

HYDANTOINS

PHENYTOIN

Phenytoin (DILANTIN) is effective against all types of partial and tonic-clonic seizures but not absence seizures.

PHARMACOLOGICAL EFFECTS. Phenytoin exerts antiseizure activity without causing general depression of the CNS. In toxic doses, it may produce excitatory signs and at lethal levels a type of decerebrate rigidity. Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization. This effect is mediated by a slowing of the rate of recovery of voltage-activated Na\(^+\) channels from inactivation, an action that is both voltage- (greater effect if membrane is depolarized) and use-dependent. At therapeutic concentrations, the effects on Na\(^+\) channels are selective, and no changes of spontaneous activity or responses to iontophoretically applied GABA or glutamate are detected. At concentrations 5- to 10-fold higher, multiple effects of phenytoin are evident, including reduction of spontaneous activity and enhancement of responses to GABA; these effects may underlie some of the
unwanted toxicity associated with high levels of phenytoin.

**PHARMACOKINETIC PROPERTIES.** Phenytoin is available in 2 types of oral formulations that differ in their pharmacokinetics: rapid-release and extended-release forms. Once-daily dosing is possible only with the extended-release formulations, and due to differences in dissolution and other formulation-dependent factors, the plasma phenytoin level may change when converting from 1 formulation to another. Comparable doses can be approximated by considering “phenytoin equivalents,” but serum-level monitoring is necessary to assure therapeutic safety. Phenytoin is extensively bound (~90%) to serum proteins, mainly albumin. Increased proportions of free drug are evident in the neonate, in patients with hypoalbuminemia, and in uremic patients. Some agents can compete with phenytoin for binding sites on plasma proteins and increase free phenytoin. Valproate competes for protein binding sites and inhibits phenytoin metabolism, resulting in marked and sustained increases in free phenytoin. Measurement of free rather than total phenytoin permits direct assessment of this potential problem in patient management.

The plasma $t_{1/2}$ of phenytoin (6 to 24 h at plasma concentrations < 10 μg/mL) increases with higher concentrations; as a result, plasma drug concentration increases disproportionately as dosage is increased, even with small adjustments for levels near the therapeutic range. The majority (95%) of phenytoin is metabolized by hepatic CYP2C9/10 and to a lesser extent CYP2C19 (see Table 21–3). Other drugs that are metabolized by these enzymes can inhibit the metabolism of phenytoin and increase its plasma concentration. Conversely, the degradation rate of other drugs that are substrates for these enzymes can be inhibited by phenytoin; one such drug is warfarin, and addition of phenytoin to a patient receiving warfarin can lead to bleeding disorders (see Chapter 30). Phenytoin has the capacity to induce CYPs (see Chapter 6); coadministration of phenytoin and medications metabolized by CYPs can lead to an increased degradation of such medications. For example, treatment with phenytoin can enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. Phenyltoin also has potential teratogenic effects. Carbamazepine, oxcarbazepine, phenobarbital, and primidone also can induce CYP3A4 and likewise might increase degradation of oral contraceptives.

The low water solubility of phenytoin hindered its intravenous use and led to
production of fosphenytoin, a water-soluble prodrug. *Fosphenytoin* (Cerebyx, others) is converted into phenytoin by phosphatases in liver and red blood cells with a $t_{1/2}$ of 8-15 min. Fosphenytoin is extensively bound (95-99%) to human plasma proteins, primarily albumin. Fosphenytoin is useful for adults with partial or generalized seizures when IV or intramuscular administration is indicated.

**TOXICITY.** The toxic effects of phenytoin depend on the route of administration, the duration of exposure, and the dosage. When fosphenytoin, the water-soluble prodrug, is administered intravenously at an excessive rate in the emergency treatment of status epilepticus, the most notable toxic signs are cardiac arrhythmias with or without hypotension, and/or CNS depression. Cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease than young, healthy patients. These complications can be minimized by administering fosphenytoin at a rate of <150 mg of phenytoin sodium equivalents per minute. Acute oral overdosage results primarily in signs referable to the cerebellum and vestibular system; high doses have been associated with marked cerebellar atrophy. Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased frequency of seizures, GI symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is an annoying untoward effect in young females. Usually, these phenomena can be diminished by adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of rare drug allergy and necessitate withdrawal of the drug. Moderate elevation of the plasma concentrations of hepatic transaminases sometimes are observed.

Gingival hyperplasia occurs in ~20% of all patients during chronic therapy. The condition can be minimized by good oral hygiene. Inhibition of release of antidiuretic hormone (ADH) has been observed. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia, with hypocalcemia and elevated alkaline phosphatase activity, has been attributed to both altered metabolism of vitamin D and the attendant inhibition of intestinal absorption of Ca$^{2+}$. Phenytoin also increases the metabolism of vitamin K and reduces the concentration of vitamin K–dependent proteins that are important for normal Ca$^{2+}$ metabolism in bone. Hypersensitivity reactions include morbilliform rash in 2-5% of patients and occasionally more serious skin reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis.
Hematological reactions include neutropenia and leukopenia. A few cases of red-cell aplasia, agranulocytosis, and mild thrombocytopenia also have been reported. Lymphadenopathy, resembling Hodgkin disease and malignant lymphoma, is associated with reduced immunoglobulin A (IgA) production. Hypoprothrombinemia and hemorrhage have occurred in the newborns of mothers who received phenytoin during pregnancy; vitamin K is effective treatment or prophylaxis.

**PLASMA DRUG CONCENTRATIONS.** A good correlation usually is observed between the total concentration of phenytoin in plasma and its clinical effect. Control of seizures generally is obtained with total concentrations > 10 μg/mL: toxic effects such as nystagmus develop at total concentrations ~20 μg/mL. Control of seizures generally is obtained with free phenytoin concentrations of 0.75-1.25 μg/mL.

**DRUG INTERACTIONS.** Drugs metabolized by CYP2C9 or CYP2C10 can increase the plasma concentration of phenytoin by decreasing its rate of metabolism. Carbamazepine, which may enhance the metabolism of phenytoin, causes a decrease in phenytoin concentration. Conversely, phenytoin reduces the concentration of carbamazepine.

**THERAPEUTIC USES**

*Epilepsy.* Phenytoin is one of the more widely used antiseizure agents, and it is effective against partial and tonic-clonic but not absence seizures. Phenytoin preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to switch between products, care should be taken to select a therapeutically equivalent product and patients should be monitored for loss of seizure control or onset of new toxicities.

*Other Uses.* Trigeminal and related neuralgias occasionally respond to phenytoin, but carbamazepine may be preferable.

**ANTISEIZURE BARBITURATES**

The pharmacology of the barbiturates as a class is described in Chapter 17; discussion in this chapter is limited to phenobarbital.
PHENOBARBITAL

Phenobarbital (LUMINAL, others) was of the more effective organic antiseizure agent. It has relatively low toxicity, and is inexpensive.

MECHANISM OF ACTION. Phenobarbital likely inhibits seizures by potentiation of synaptic inhibition through an action on the GABA_A receptor. At therapeutic concentrations, phenobarbital increases the GABA_A receptor-mediated current by increasing the duration of bursts of GABA_A receptor-mediated currents without changing the frequency of bursts. At levels exceeding therapeutic concentrations, phenobarbital also limits sustained repetitive firing; this may underlie some of the antiseizure effects of higher concentrations of phenobarbital achieved during therapy of status epilepticus.

PHARMACOKINETIC PROPERTIES. Oral absorption of phenobarbital is complete but somewhat slow; peak concentrations in plasma occur several hours after a single dose. Phenobarbital is 40-60% bound to plasma and tissue proteins. Up to 25% of a dose is eliminated by pH-dependent renal excretion of the unchanged drug; the remainder is inactivated by hepatic CYPs. Phenobarbital induces UGTs as well as the CYP2C and CYP3A subfamilies, thereby stimulating degradation of drugs cleared by these mechanisms (oral contraceptives are metabolized by CYP3A4).

TOXICITY. Sedation, the most frequent undesired effect of phenobarbital, is apparent upon initiation of therapy, but tolerance develops during chronic medication. Nystagmus and ataxia occur at excessive dosage. Phenobarbital can produce irritability and hyperactivity in children, and agitation and confusion in the elderly. Scarlatiniform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1-2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received phenobarbital during pregnancy; vitamin K is effective for treatment or prophylaxis. As with phenytoin, megaloblastic anemia that responds to folate and osteomalacia that responds to high doses of vitamin D occur during chronic phenobarbital therapy. Other adverse
effects of phenobarbital are discussed in Chapter 17.

PLASMA DRUG CONCENTRATIONS. During long-term therapy, the plasma concentration of phenobarbital averages 10 μg/mL per daily dose of 1 mg/kg in adults and 5-7 μg/mL per 1 mg/kg in children. Plasma concentrations of 10-35 μg/mL are usually recommended for control of seizures. Sedation, nystagmus, and ataxia usually are absent at concentrations < 30 μg/mL during long-term therapy, but adverse effects may be apparent for several days at lower concentrations when therapy is initiated or whenever the dosage is increased. Concentrations > 60 μg/mL may be associated with marked intoxication in the nontolerant individual. The plasma phenobarbital concentration should be increased above 30-40 μg/mL only if the increment is adequately tolerated and only if it contributes significantly to control of seizures.

DRUG INTERACTIONS. Interactions between phenobarbital and other drugs usually involve induction of the hepatic CYPs by phenobarbital (see Table 21–3). The interaction between phenytoin and phenobarbital is variable. Concentrations of phenobarbital in plasma may be elevated by as much as 40% during concurrent administration of valproic acid.

THERAPEUTIC USES. Phenobarbital is an effective agent for generalized tonic-clonic and partial seizures. Its efficacy, low toxicity, and low cost make it an important agent for these types of epilepsy. However, its sedative effects and its tendency to disturb behavior in children have reduced its use as a primary agent.

IMINOSTILBENES

CARBAMAZEPINE

Carbamazepine (TEGRETOL, CARBATROL, others) is considered to be a primary drug for the treatment of partial and tonic-clonic seizures.

MECHANISM OF ACTION. Like phenytoin, carbamazepine limits the repetitive firing of action potentials evoked by a sustained depolarization by slowing the rate of recovery of voltage-activated Na+ channels from inactivation. At therapeutic drug levels, the effects of carbamazepine are selective in that
there are no effects on spontaneous activity or on responses to iontophoretically applied GABA or glutamate. The carbamazepine metabolite, 10,11-epoxycarbamazepine, also limits sustained repetitive firing at therapeutically relevant concentrations, suggesting that this metabolite may contribute to the antiseizure efficacy of carbamazepine.

**PHARMACOKINETIC PROPERTIES.** The pharmacokinetics of carbamazepine are complex. They are influenced by its limited aqueous solubility and by the capacity of carbamazepine to increase its conversion to active metabolites by hepatic CYPs (see Table 21–3). Carbamazepine is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually are observed 4-8 h after oral ingestion, but may be delayed by as much as 24 h, especially following the administration of a large dose. The drug distributes rapidly into all tissues. Approximately 75% of carbamazepine binds to plasma proteins and concentrations in the CSF appear to correspond to the concentration of free drug in plasma. Hepatic CYP3A4 is primarily responsible for biotransformation of carbamazepine to the 10, 11-epoxide. This metabolite is as active as the parent compound; its concentrations in plasma and brain may reach 50% of those of carbamazepine, especially during the concurrent administration of phenytoin or phenobarbital. The 10, 11-epoxide is metabolized further to inactive compounds that are excreted in the urine. Carbamazepine induces CYPs, and UGTs.

**TOXICITY.** Acute intoxication with carbamazepine can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, the more frequent untoward effects of the drug include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may increase, especially with overdosage. Other adverse effects include nausea, vomiting, serious hematological toxicity (aplastic anemia, agranulocytosis), and hypersensitivity reactions (dangerous skin reactions, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with carbamazepine is retention of water, with decreased osmolality and concentration of Na⁺ in plasma, especially in elderly patients with cardiac disease. Some tolerance develops to the neurotoxic effects of carbamazepine, and they can be minimized by gradual increase in dosage or adjustment of maintenance dosage. Various hepatic or pancreatic abnormalities have been reported during therapy with carbamazepine, most commonly a transient
elevation of hepatic transaminases in plasma in 5-10% of patients. A transient, mild leukopenia occurs in ~10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. A persistent leukopenia may develop that requires withdrawal of the drug. Aplastic anemia occurs in ~1 in 200,000 patients. Possible teratogenic effects are discussed later in the chapter.

**PLASMA DRUG CONCENTRATIONS.** There is no simple relationship between the dose of carbamazepine and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6-12 μg/mL, although considerable variation occurs. Side effects referable to the CNS are frequent at concentrations > 9 μg/mL.

**DRUG INTERACTIONS.** Phenobarbital, phenytoin, and valproate may increase the metabolism of carbamazepine by inducing CYP3A4; carbamazepine may enhance the biotransformation of phenytoin. Concurrent administration of carbamazepine may lower concentrations of valproate, lamotrigine, tiagabine, and topiramate. Carbamazepine reduces both the plasma concentration and therapeutic effect of haloperidol. The metabolism of carbamazepine may be inhibited by propoxyphene, erythromycin, cimetidine, fluoxetine, and isoniazid.

**THERAPEUTIC USES.** Carbamazepine is useful in patients with generalized tonic-clonic and both simple and complex partial seizures (see Table 21–1). When it is used, renal and hepatic function and hematological parameters should be monitored. Carbamazepine is the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightning-type (“tabetic”) pain associated with bodily wasting. About 70% of patients with neuralgia obtain continuing relief. Adverse effects require discontinuation of medication in 5-20% of patients. Carbamazepine is also used in the treatment of bipolar affective disorders (see Chapter 16).

**OXCARBAZEPINE**

*Oxcarbazepine* (TRILEPTAL, others) is a keto analog of carbamazepine. Oxcarbazepine is a prodrug that is almost immediately converted to its main active metabolite, a 10-monohydroxy derivative, which is inactivated by glucuronide
conjugation and eliminated by renal excretion. Its mechanism of action is similar to that of carbamazepine. Oxcarbazepine is a less potent enzyme inducer than carbamazepine. Substitution of oxcarbazepine for carbamazepine is associated with increased levels of phenytoin and valproic acid, presumably because of reduced induction of hepatic enzymes. Oxcarbazepine does not induce the hepatic enzymes involved in its own degradation. Although oxcarbazepine does not appear to reduce the anticoagulant effect of warfarin, it does induce CYP3A and thus reduces plasma levels of steroid oral contraceptives. It is approved for monotherapy or adjunct therapy for partial seizures in adults, as monotherapy for partial seizures in children ages 4-16, and as adjunctive therapy in children 2 years of age and older with epilepsy.

**SUCINIMIDES**

**ETHOSUXIMIDE**

Ethosuximide (ZARONTIN, others) is a primary agent for the treatment of absence seizures. Ethosuximide reduces low threshold Ca$^{2+}$ currents (T-type currents) in thalamic neurons. At therapeutic concentrations, ethosuximide inhibits the T-type current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. Ethosuximide does not inhibit sustained repetitive firing or enhance GABA responses at clinically relevant concentrations.

**PHARMACOKINETIC PROPERTIES.** Absorption of ethosuximide is complete, with peak plasma concentrations occurring ~3 h after a single oral dose. Ethosuximide is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. About 25% of the drug is excreted unchanged in the urine; the remainder is metabolized by hepatic enzymes. The plasma $t_{1/2}$ is 40-50 h in adults and ~30 h in children.
**TOXICITY.** The most common dose-related side effects are GI complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccough) to which some tolerance develops. Parkinson-like symptoms and photophobia also have been reported. Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a prior history of psychiatric disturbance. Urticaria and other skin reactions, including Stevens-Johnson syndrome, as well as systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia also have been attributed to the drug.

**THERAPEUTIC USES AND PLASMA DRUG CONCENTRATIONS.** Ethosuximide is effective against absence seizures but not tonic-clonic seizures. An initial daily dose of 250 mg in children (3-6 years old) and 500 mg in older children and adults is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to prevent nausea or drowsiness associated with once-daily dosing. The usual maintenance dose is 20 mg/kg per day. Increased caution is required if the daily dose exceeds 1500 mg in adults or 750-1000 mg in children. The plasma concentration of ethosuximide averages ~2 μg/mL per daily dose of 1 mg/kg. A plasma concentration of 40-100 μg/mL usually is required for satisfactory control of absence seizures.

**VALPROIC ACID**

Valproic acid (DEPAKENE, others) produces effects on isolated neurons similar to those of phenytoin and ethosuximide (see Table 21–2). At therapeutically relevant concentrations, valproate inhibits sustained repetitive firing induced by depolarization of cortical or spinal cord neurons. The action appears to be mediated by a prolonged recovery of voltage-activated Na\(^+\) channels from inactivation. Valproate also produces small reductions of T-type Ca\(^{2+}\) currents. These actions of limiting sustained repetitive firing and reducing T-type currents may contribute to the effectiveness of valproic acid against partial and tonic-clonic seizures and absence seizures, respectively. In vitro, valproate can stimulate GABA synthesis and
inhibit GABA degradation.

**PHARMACOKINETIC PROPERTIES.** Valproic acid is absorbed rapidly and completely after oral administration. Peak concentration in plasma is observed in 1-4 h (delayed by several hours if the drug is ingested with food or taken as enteric-coated tablets). Its extent of binding to plasma proteins is ~90%, but the fraction bound is reduced as the total concentration of valproate is increased through the therapeutic range. The majority of valproate (95%) is cleared by hepatic metabolism, mainly by UGTs and β-oxidation. Two of the drug’s metabolites, 2-propyl-2-pentenoic acid and 2-propyl-4-pentenoic acid, are nearly as potent antiseizure agents as the parent molecule. The $t_{1/2}$ of valproate is ~15 h but is reduced in patients taking other antiepileptic drugs.

**TOXICITY.** The most common side effects are transient GI symptoms, including anorexia, nausea, and vomiting in ~16% of patients. Effects on the CNS include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally; weight gain has been seen with chronic valproic acid treatment in some patients. Elevation of hepatic transaminases in plasma is observed in up to 40% of patients. A rare complication is a fulminant hepatitis that is frequently fatal. Children < 2 years of age with other medical conditions who were given multiple antiseizure agents were especially likely to suffer fatal hepatic injury. Acute pancreatitis and hyperammonemia also have been frequently associated with the use of valproic acid. Valproic acid can also produce teratogenic effects.

**DRUG INTERACTIONS.** Valproate inhibits the metabolism of drugs that are substrates for CYP2C9, including phenytoin and phenobarbital. Valproate also inhibits UGT and thus inhibits the metabolism of lamotrigine and lorazepam. A high proportion of valproate is bound to albumin, and the high molar concentrations of valproate result in valproate’s displacing phenytoin and other drugs from albumin.

**THERAPEUTIC USES AND PLASMA DRUG CONCENTRATIONS.** Valproate is a broad-spectrum antiseizure drug effective in the treatment of absence, myoclonic, partial, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5-10 mg/kg/day to a
maximum daily dose of 60 mg/kg. Plasma concentrations associated with therapeutic effects are ~30-100 μg/mL, with a threshold at ~30-50 μg/mL. However, there is a poor correlation between the plasma concentration and efficacy.

**BENZODIAZEPINES**

The benzodiazepines are used primarily as sedative-antianxiety drugs; their pharmacology is described in Chapters 14 and 17. A large number of benzodiazepines have broad antiseizure properties, but only clonazepam (KLONOPIN, others) and clorazepate (TRANXENE, others) have been approved in the U.S. for the long-term treatment of certain seizures. Midazolam was designated an orphan drug for intermittent treatment of bouts of increased seizure activity in refractory patients with epilepsy who are on stable regimens of antiseizure drugs. Diazepam (VALIUM, DIASTAT; others) and lorazepam (ATIVAN, others) have well-defined roles in the management of status epilepticus.

**MECHANISM OF ACTION.** The antiseizure actions of the benzodiazepines result in large part from their ability to enhance GABA-mediated synaptic inhibition. The benzodiazepine receptor is an integral part of the GABA_A receptor (see Figure 14–6). Benzodiazepines act at subsets of GABA_A receptors and increase the frequency, but not duration, of openings at GABA-activated Cl– channels. At high concentrations, diazepam and many other benzodiazepines can reduce sustained high-frequency firing of neurons, similar to the effects of phenytoin, carbamazepine, and valproate. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with diazepam, they are considerably higher than those associated with antiseizure or anxiolytic effects in ambulatory patients.

**PHARMACOKINETIC PROPERTIES.** Benzodiazepines are well absorbed after oral administration. Concentrations in plasma peak within 1-4 h. After intravenous administration, central effects develop promptly but wane rapidly as the drugs redistribute to other tissues. Diazepam has a $t_{1/2}$ of redistribution of ~1 h. The extent of binding of benzodiazepines to plasma proteins correlates with
lipid solubility, ranging from ~99% for diazepam to ~85% for clonazepam. The major metabolite of diazepam, N-desmethyl-diazepam, is somewhat less active than the parent drug and may behave as a partial agonist. The $t_{1/2}$ of diazepam in plasma is between 1 and 2 days, while that of N-desmethyl-diazepam is ~60 h. Clonazepam is metabolized to produce inactive 7 amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The $t_{1/2}$ of clonazepam in plasma is ~23 h. Lorazepam is metabolized chiefly by conjugation with glucuronic acid; its $t_{1/2}$ in plasma is ~14 h.

TOXICITY. The principal side effects of long-term oral therapy with clonazepam are drowsiness and lethargy. These occur in ~50% of patients initially, but tolerance often develops with continued administration. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation. Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances, especially in children, may include aggression, hyperactivity, irritability, and difficulty in concentration. Both anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated, and status epilepticus may be precipitated if the drug is discontinued abruptly. Cardiovascular and respiratory depression may occur after the intravenous administration of diazepam, clonazepam, or lorazepam, particularly if administered after other antiseizure agents or central depressants.

PLASMA DRUG CONCENTRATIONS. Because tolerance affects the relationship between drug concentration and drug antiseizure effect, plasma concentrations of benzodiazepines are of limited value.

THERAPEUTIC USES. Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in children. Tolerance to its antiseizure effects usually develops after 1-6 months of administration, after which some patients will no longer respond to clonazepam at any dosage. The initial dose of clonazepam for adults should not exceed 1.5 mg per day and for children 0.01-0.03 mg/kg per day. The dose-dependent side effects are reduced if 2 or 3 divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25-0.5 mg per day in children and 0.5-1 mg per day in adults. The maximal recommended dose is 20 mg per day for adults and 0.2 mg/kg per day.
Clonazepam intranasal spray is designated as an orphan drug for recurrent acute repetitive seizures.

While diazepam is an effective agent for treatment of status epilepticus, its short duration of action is a disadvantage, leading to the more frequent use of lorazepam. Clorazepate is effective in combination with certain other drugs in the treatment of partial seizures. The maximal initial dose of clorazepate is 22.5 mg per day in 3 portions for adults and children > 12 years and 15 mg per day in 2 divided doses in children 9-12 years of age. Clorazepate is not recommended for children < 9 years. Clobazam (ONFI, others) is recently FDA-approved for the adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in children > 2 years of age. Starting dose is 5 mg in children < 30 kg in body weight, maximal dose is 20 mg. Starting dose for > 30 kg body weight is 10 mg and maximal dose is 40 mg.

OTHER ANTISEIZURE DRUGS

GABAPENTIN AND PREGABALIN

Gabapentin (NEURONTIN, others) and pregabalin (LYRICA) are antiseizure drugs that consist of a GABA molecule covalently bound to a lipophilic cyclohexane ring or isobutane, respectively. Gabapentin was designed to be a centrally active GABA agonist, with its high lipid solubility aimed at facilitating its transfer across the blood-brain barrier.

\[
\text{H}_2\text{N} - \text{COOH} \quad \text{H}_2\text{N} - \text{COOH}
\]

\text{GABAPENTIN} \quad \text{PREGABALIN}

MECHANISMS OF ACTION. Gabapentin inhibits tonic hind-limb extension in the electroshock seizure model and clonic seizures induced by pentylenetetrazol. Its efficacy in both these tests parallels that of valproic acid and distinguishes it from phenytoin and carbamazepine. Despite their design as GABA agonists, neither gabapentin nor pregabalin mimics GABA when applied to neurons in primary culture. These compounds bind with high affinity to a protein in cortical
membranes with an amino acid sequence identical to that of the Ca\(^{2+}\) channel subunit \(\alpha 2\delta-1\) but their molecular mechanism of action remains unknown, providing job security for researchers in this area. These compounds also have analgesic properties; the analgesic efficacy of pregabalin is eliminated in mice carrying a mutation in the \(\alpha 2\delta-1\) protein.

**PHARMACOKINETICS.** Gabapentin and pregabalin are absorbed after oral administration and are not metabolized in humans. These compounds are not bound to plasma proteins and are excreted unchanged in the urine. Their half-lives approximate 6 h. These compounds have no known interactions with other antiseizure drugs.

**THERAPEUTIC USES AND TOXICITY.** Gabapentin and pregabalin are effective for partial seizures, with and without secondary generalization, when used in addition to other antiseizure drugs. Pregabalin is approved for treatment of neuropathic pain associated with spinal cord injury. Gabapentin also is used for the treatment of migraine, chronic pain, bipolar disorder, and restless leg syndrome. Gabapentin usually is effective in doses of 900-1800 mg daily in 3 doses, although 3600 mg may be required in some patients. Therapy usually is begun with a low dose (300 mg/day), which is increased by 300 mg/day until an effective dose is reached. Gabapentin is well tolerated. Common adverse effects include mild to moderate somnolence, dizziness, ataxia, and fatigue that resolve within 2 weeks of onset during continued treatment. Gabapentin and pregabalin are listed in pregnancy category C.

**LAMOTRIGINE**

Lamotrigine (LAMICTAL, others) is a phenyltriazine derivative initially developed as an antifolate agent but the drug’s effectiveness as an antiseizure medication is unrelated to its antifolate properties.

**MECHANISMS OF ACTION.** Lamotrigine blocks sustained repetitive firing of mouse spinal cord neurons and delays the recovery from inactivation of recombinant Na\(^+\) channels, mechanisms similar to those of phenytoin and carbamazepine. Lamotrigine is effective against a broader spectrum of seizures than phenytoin and carbamazepine, suggesting that lamotrigine may have actions in addition to regulating recovery from inactivation of Na\(^+\) channels. The
mechanisms underlying its broad spectrum of actions may involve inhibiting synaptic release of glutamate.

PHARMACOKINETICS. Lamotrigine is completely absorbed from the GI tract and is metabolized primarily by glucuronidation. The plasma $t_{1/2}$ of a single dose is 24-30 h. Administration of phenytoin, carbamazepine, or phenobarbital reduces the $t_{1/2}$ and plasma concentrations of lamotrigine. Addition of valproate markedly increases plasma concentrations of lamotrigine, likely by inhibiting glucuronidation. Addition of lamotrigine to valproic acid produces a reduction of valproate concentrations by $\sim$25% over a few weeks. Concurrent use of lamotrigine and carbamazepine is associated with increases of the 10,11-epoxide of carbamazepine and clinical toxicity.

THERAPEUTIC USE. Lamotrigine is useful for monotherapy and add-on therapy of partial and secondarily generalized tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults. Patients already taking a hepatic enzyme–inducing antiseizure drug (such as carbamazepine, phenytoin, phenobarbital, or primidone, but not valproate) should be given lamotrigine initially at 50 mg/day for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/day each week up to a maintenance dose of 300-500 mg/day divided into 2 doses. For patients taking valproate in addition to an enzyme-inducing antiseizure drug, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/day for 2 weeks; the dose then can be increased by 25-50 mg/day every 1-2 weeks up to a maintenance dose of 100-150 mg/day divided into 2 doses.

TOXICITY. The most common adverse effects are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash when lamotrigine was added to another antiseizure drug. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in pediatric patients ($\sim$0.8%) is higher than in the adult population (0.3%).

LEVETIRACETAM

Levetiracetam (KEPPRA, others) is FDA-approved for adjunctive therapy for myoclonic, partial-onset, and primary generalized tonic-
clonic seizures in adults and children as young as 4 years old. The mechanism by which levetiracetam exerts these antiseizure effects is unknown.

**PHARMACOKINETICS.** Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% as unchanged drug; the main metabolite results from hydrolysis of the acetamide group. Levetiracetam is devoid of known interactions with other antiseizure drugs, oral contraceptives, or anticoagulants.

**THERAPEUTIC USE AND TOXICITY.** In clinical trials, levetiracetam given in addition to other antiseizure medications in adults with either refractory partial seizures or uncontrolled generalized tonic-clonic seizures was superior to placebo. Levetiracetam also has efficacy as adjunctive therapy for refractory generalized myoclonic seizures. Insufficient evidence is available about its use as monotherapy for partial or generalized epilepsy. Levetiracetam is well tolerated. Adverse effects include somnolence, asthenia, and dizziness.

**TIAGABINE**

Tiagabine (GABITRIL) is used for partial seizures in adults. Tiagabine inhibits the GABA transporter, GAT-1, and thereby reduces GABA uptake into neurons and glia, thereby prolonging the dwell time of GABA at inhibitory synapses.

**PHARMACOKINETICS.** Tiagabine is rapidly absorbed after oral administration, extensively bound to serum or plasma proteins, and metabolized mainly by hepatic CYP3A. Its $t_{1/2}$ of ~8 h is shortened by 2-3 h when coadministered with hepatic enzyme–inducing drugs such as phenobarbital, phenytoin, or carbamazepine.

**THERAPEUTIC USE AND TOXICITY.** Tiagabine is effective as add-on therapy of refractory partial seizures with or without secondary generalization. Its efficacy as monotherapy for newly diagnosed or refractory partial and generalized epilepsy has not been established. Adverse effects include dizziness, somnolence, and tremor that are mild to moderate in severity and appear shortly
after initiation of therapy. Tiagabine-enhanced effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures. Case reports suggest that tiagabine treatment of patients with a history of spike-and-wave discharges causes exacerbations of their EEG abnormalities. Thus, tiagabine may be contraindicated in patients with generalized absence epilepsy. Paradoxically, tiagabine has been associated with the occurrence of seizures in patients without epilepsy and off-label use of the drug is discouraged.

**TOPIRAMATE**

Topiramate (TOPAMAX, others) is FDA-approved as initial monotherapy (in patients at least 10 years old) and as adjunctive therapy (for patients as young as 2 years of age) for partial-onset or primary generalized tonic-clonic seizures, for Lennox-Gastaut syndrome in patients 2 years of age and older, and for migraine headache prophylaxis in adults.

**MECHANISMS OF ACTION.** Topiramate reduces voltage-gated Na$^+$ currents in cerebellar granule cells and may act on the inactivated state of the channel similar to phenytoin. In addition, topiramate activates a hyperpolarizing K$^+$ current, enhances postsynaptic GABA$_A$ receptor currents, and limits activation of AMPA-kainate receptors (see Table 14–1 and Figures 14–6, 14–7, and 14–8). Topiramate is a weak carbonic anhydrase inhibitor.

**PHARMACOKINETICS.** Topiramate is rapidly absorbed after oral administration, exhibits little (10-20%) binding to plasma proteins, and is mainly excreted unchanged in the urine. The remainder undergoes metabolism by hydroxylation, hydrolysis, and glucuronidation with no single metabolite accounting for > 5% of an oral dose. Its $t_{1/2}$ is ~1 day. Reduced estradiol plasma concentrations occur with concurrent topiramate, suggesting the need for higher doses of oral contraceptives when coadministered with topiramate.

**THERAPEUTIC USE AND TOXICITY.** Topiramate is equivalent to valproate and carbamazepine in children and adults with newly diagnosed partial and primary generalized epilepsy. It is effective as monotherapy for refractory partial epilepsy and refractory generalized tonic-clonic seizures. Topiramate is also effective as adjunctive therapy (against both drop attacks and tonic-clonic
seizures in patients with Lennox-Gastaut syndrome, and for migraine headache prophylaxis in adults). Topiramate is well tolerated. Common adverse effects are somnolence, fatigue, weight loss, and nervousness. It can precipitate renal calculi, which is most likely due to inhibition of carbonic anhydrase. Topiramate has been associated with cognitive impairment and patients may complain about a change in the taste of carbonated beverages.

ZONISAMIDE

Zonisamide (ZONEGRAN, others) is a sulfonamide derivative used as adjunctive therapy of partial seizures in adults. Zonisamide inhibits the T-type Ca\(^{2+}\) currents. In addition, zonisamide inhibits the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na\(^+\) channels in a manner similar to actions of phenytoin and carbamazepine.

PHARMACOKINETICS. Zonisamide is almost completely absorbed after oral administration, has a long t\(_1/2\) (~63 h), and is ~40% bound to plasma protein. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized zonisamide and a glucuronide of a metabolite formed by CYP3A4. Phenobarbital, phenytoin, and carbamazepine decrease the plasma concentration/dose ratio of zonisamide, whereas lamotrigine increases this ratio. Zonisamide has little effect on the plasma concentrations of other antiseizure drugs.

THERAPEUTIC USE AND TOXICITY. In clinical trials, the addition of zonisamide to other drugs in patients with refractory partial seizures was superior to placebo. There is insufficient evidence for its efficacy as monotherapy for newly diagnosed or refractory epilepsy. Zonisamide is well tolerated. Common adverse effects include somnolence, ataxia, anorexia, nervousness, and fatigue. Approximately 1% of individuals develop renal calculi, which may relate to its ability to inhibit carbonic anhydrase. Zonisamide can cause metabolic acidosis, which is more frequent in younger patients. Patients with predisposing conditions (e.g., renal disease, severe respiratory disorders, diarrhea, surgery, ketogenic diet) may be at greater risk. Measurement of serum bicarbonate prior to initiating therapy and periodically thereafter is recommended.
**LACOSAMIDE**

Lacosamide (VIMPAT) is approved as adjunctive therapy for partial-onset seizures in patients 17 years of age and older.

Lacosamide enhances slow inactivation of voltage-gated Na⁺ channels and limits sustained repetitive firing, the neuronal firing pattern characteristic of partial seizures. Lacosamide also binds collapsin response mediator protein 2 (crmp-2), a phosphoprotein involved in neuronal differentiation and axon outgrowth. Its antiseizure mechanism of action is more likely mediated by its enhancing slow inactivation of Na⁺ channels. Clinical studies of adults with refractory partial seizures demonstrated that addition of lacosamide to other drugs was superior to placebo.

**RUFINAMIDE**

Rufinamide (BANZEL) is a triazole derivative approved for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome. Rufinamide enhances slow inactivation of voltage-gated Na⁺ channels and limits sustained repetitive firing, the firing pattern characteristic of partial seizures. Whether this is the mechanism by which rufinamide suppresses seizures is presently unclear.

**VIGABATRIN**

Vigabatrin (SABRIL) is used as adjunctive therapy of refractory partial complex seizures in adults. In addition, vigabatrin is designated as an orphan drug for treatment of infantile spasms. Due to progressive and permanent bilateral vision loss, vigabatrin must be reserved for patients who have failed several alternative therapies.

Vigabatrin is a structural analog of GABA that irreversibly inhibits GABA degradation, thereby leading to increased concentrations of GABA in the brain. A 2-week, randomized, clinical trial of vigabatrin for infantile spasms in children < 2 years old revealed time- and dose-dependent increases in responders, evident as freedom from spasms for 7 consecutive days. The subset of children in whom infantile spasms were caused by tuberous sclerosis was particularly responsive to
vigabatrin.

**EZOGABINE**

Ezogabine (POTIGA) is a carbamate ethyl ester and K⁺- channel activator approved by the FDA for the treatment of partial-onset seizures.

Ezogabine is administered orally. Starting dose is 100 mg 3 times daily that is increased gradually to a maximal dose of 1200 mg/day. Ezogabine is metabolized primarily via glucuronidation and eliminated mainly through renal excretion. Its $t_{1/2}$ is ~8-11 h. Serious adverse effects are dose related and include difficulty in urination, hallucination, suicidal thoughts, and QT prolongation. Less serious side effects include drowsiness, dizziness, fatigue, blurred vision, tremor, memory impairment, asthenia, gait disturbance and balance disorder, and slurred speech.

**PERAMPANEL**

Perampanel (FYCOMPA) is a selective noncompetitive antagonist of the AMPA glutamate receptor. It is approved for the treatment of partial-onset seizures with or without secondarily generalized seizures.

Recommended starting oral dose is 2 mg once daily titrated to a maximal dose of 4-12 mg once daily taken at bedtime. The drug is rapidly absorbed after oral administration. The $t_{1/2}$ is ~105 h. It is 95% bound to plasma protein, mainly albumin. It is metabolized by oxidation followed by glucuronidation. Adverse effects include aggressive behavior, suicidal thoughts, sleepiness, vertigo, dizziness, nausea, problems with walking and muscle coordination, and weight gain.

**ACETAZOLAMIDE**

Acetazolamide, the prototype for the carbonic anhydrase inhibitors (see Chapter 25), is sometimes effective against absence seizures but its usefulness is limited by the rapid development of tolerance.
FELBAMATE

Felbamate (FELBATOL) is a dicarbamate. An association between felbamate and aplastic anemia resulted in the withdrawal of most patients from treatment with this drug. Postmarketing experience revealed an association between felbamate exposure and liver failure.

GENERAL PRINCIPLES AND CHOICE OF DRUGS FOR THE THERAPY OF THE EPILEPSIES

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity. An attempt should be made to determine the cause of the epilepsy with the hope of discovering a correctable lesion, either structural or metabolic. The drugs commonly used for distinct seizure types are listed in Table 21–1. The efficacy combined with the unwanted effects of a given drug determine which particular drug is optimal for a given patient.

In the absence of extenuating circumstances such as status epilepticus, only monotherapy should be initiated. Initial dosing should be low and should target steady-state plasma drug concentrations within the lower range associated with clinical efficacy. Dosage is increased and monitored at appropriate intervals as required for control of seizures or as limited by toxicity. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in ~50% of patients. If compliance has been confirmed yet seizures persist, another drug should be substituted. Unless serious adverse effects of the drug dictate otherwise, dosage always should be reduced gradually to minimize risk of seizure recurrence. The literature suggests that among previously untreated patients, 47% become seizure-free with the first drug and an additional 14% become seizure-free with a second or third agent. If therapy with a second single drug is inadequate, combination therapy is warranted; the decision to use combination therapy should not be made lightly, because most patients obtain optimal seizure control with fewest unwanted effects when taking a single drug. In choosing a combination, it seems wise to select 2 drugs that act by distinct mechanisms (e.g., one that promotes Na+ channel inactivation and
another that enhances GABA-mediated synaptic inhibition) (see Table 21–2). Side effects of each drug and the potential drug interactions also should be considered.

**DURATION OF THERAPY**

Antiseizure drugs are typically continued for at least 2 years. Tapering and discontinuing therapy should be considered, if the patient is seizure-free after 2 years. Factors associated with high risk for recurrent seizures following discontinuation of therapy include EEG abnormalities, known structural lesions, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. Typically, 80% of recurrences will occur within 4 months of discontinuing therapy. Clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (e.g., loss of driving privileges) against the various implications of continuing medication including cost, unwanted effects, implications of diagnosis of epilepsy, etc. Medications should be tapered slowly over a period of several months.

**SIMPLE AND COMPLEX PARTIAL AND SECONDARILY GENERALIZED TONIC-CLONIC SEIZURES**

The efficacy and toxicity of carbamazepine, phenobarbital, and phenytoin for treatment of partial and secondarily generalized tonic-clonic seizures in adults have been compared. Carbamazepine and phenytoin were the most effective agents.

**ABSENCE SEIZURES**

Ethosuximide and valproate are considered equally effective in the treatment of absence seizures. Between 50% and 75% of newly
diagnosed patients are free of seizures following therapy with either drug. If tonic-clonic seizures are present or emerge during therapy, valproate is the agent of first choice. Lamotrigine is also effective for newly diagnosed absence epilepsy although it is not FDA-approved for this indication.

**MYOCLONIC SEIZURES**

Valproic acid is the drug of choice for myoclonic seizures in the syndrome of juvenile myoclonic epilepsy, in which myoclonic seizures often coexist with tonic-clonic and absence seizures. Levetiracetam also has demonstrated efficacy as adjunctive therapy for refractory generalized myoclonic seizures.

**FEBRILE CONVULSIONS**

Two to 4% of children experience a convulsion associated with a febrile illness. From 25-33% of these children will have another febrile convolution. Only 2-3% become epileptic in later years. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (i.e., the febrile seizure lasted > 15 min, was one-sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is ~10%. Uncertainties regarding the efficacy of prophylaxis for reducing epilepsy combined with substantial side effects of phenobarbital prophylaxis argue against the use of chronic therapy for prophylactic purposes in these cases. For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered diazepam at the time of fever may prevent recurrent seizures and avoid side effects of chronic therapy.

**SEIZURES IN INFANTS AND YOUNG CHILDREN**

Infantile spasms with hypsarrhythmia are refractory to the usual
antiseizure agents. Corticotropin or glucocorticoids are commonly used. Vigabatrin (γ-vinyl GABA; SABRIL) is efficacious in comparison to placebo. The potential for progressive and permanent vision loss has resulted in vigabatrin being labeled with a black box warning and marketed under a restrictive distribution program. The drug has an orphan drug status for the treatment of infantile spasms. Lennox-Gastaut syndrome is a severe form of epilepsy, which usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Lamotrigine is an effective and well-tolerated additive drug for this treatment-resistant form of epilepsy. Felbamate also is effective for seizures in this syndrome, but the occasional occurrence of aplastic anemia and hepatic failure have limited its use. Topiramate has also been demonstrated to be effective.

**STATUS EPILEPTICUS AND OTHER CONVULSIVE EMERGENCIES**

Status epilepticus is a neurological emergency. Mortality for adults approximates 20%. The goal of treatment is rapid termination of behavioral and electrical seizure activity due to the risk of permanent brain damage. Prompt treatment is essential with effective drugs in adequate doses, and attention to hypoventilation and hypotension. Because hypoventilation may result from high doses of drugs used, it may be necessary to assist respiration temporarily. Drugs should be administered by the IV route only. Four IV treatments: diazepam followed by phenytoin; lorazepam; phenobarbital; and phenytoin alone seem to have similar efficacies, with success rates ranging from 44-65%. Lorazepam alone was found to be significantly better than phenytoin alone. No significant differences were found with respect to recurrences or adverse reactions.

**ANTISEIZURE THERAPY AND PREGNANCY**
The effectiveness of oral contraceptives appears to be reduced by concomitant use of antiseizure drugs. This may be caused by the increased rate of oral contraceptive metabolism by antiseizure drugs that induce CYPs (see Table 21–3). Antiseizure drugs that induce CYPs have been associated with vitamin K deficiency in the newborn, which can result in a coagulopathy and intracerebral hemorrhage. Treatment with vitamin K$_1$, 10 mg/day during the last month of gestation, has been recommended for prophylaxis.

**TERATOGENICITY.** Antiseizure drugs have teratogenic effects. The malformations include congenital heart defects, neural tube defects, cleft lip, cleft palate, and others. Phenytoin, carbamazepine, valproate, lamotrigine, and phenobarbital all have been associated with teratogenic effects. One consideration for a woman with epilepsy who wishes to become pregnant is a trial free of antiseizure drug; monotherapy with careful attention to drug levels is another alternative. Polytherapy with toxic levels should be avoided. Folate supplementation (0.4 mg/day) is recommended for all women of childbearing age to reduce the likelihood of neural tube defects.
Neurodegenerative disorders are characterized by progressive and irreversible loss of neurons from specific regions of the brain. Prototypical neurodegenerative disorders include Parkinson disease (PD) and Huntington disease (HD), where loss of neurons from structures of the basal ganglia results in abnormalities in the control of movement; Alzheimer disease (AD), where the loss of hippocampal and cortical neurons leads to impairment of memory and cognitive ability; and amyotrophic lateral sclerosis (ALS), where muscular weakness results from the degeneration of spinal, bulbar, and cortical motor neurons. Currently available therapies for neurodegenerative disorders alleviate the disease symptoms but do not alter the underlying neurodegenerative process.

SELECTIVE VULNERABILITY AND NEUROPROTECTIVE STRATEGIES

SELECTIVE VULNERABILITY. A striking feature of neurodegenerative disorders is the exquisite specificity of the disease processes for particular types of neurons. For example, in PD there is extensive destruction of the dopaminergic neurons of the substantia nigra, whereas neurons in the cortex and many other areas of the brain are unaffected. In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even within the cortex, the loss of neurons is not uniform but varies dramatically in different functional regions. In HD the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum. In ALS, there is loss of spinal motor neurons and the cortical neurons that provide their descending input. The diversity of these patterns of
neural degeneration suggests that the process of neural injury results from the interaction of genetic and environmental influences.

GENETICS AND ENVIRONMENT. Each of the major neurodegenerative disorders may be familial in nature. HD is exclusively familial; it is transmitted by autosomal dominant inheritance, and the molecular mechanism of the genetic defect has been defined. Nevertheless, environmental factors importantly influence the age of onset and rate of progression of HD symptoms. PD, AD, and ALS are mostly sporadic without clear pattern of inheritance. But for each there are well-recognized genetic forms. For example, there are both dominant (α-synuclein, LRRK2) and recessive (parkin, DJ-1, PINK1) gene mutations that may give rise to PD. In AD, mutations in the genes coding for the amyloid precursor protein (APP) and proteins known as the presenilins (involved in APP processing) lead to inherited forms of the disease. Mutations in the gene coding for copper-zinc superoxide dismutase (SOD1) account for about 2% of the cases of adult-onset ALS. There are also genetic risk factors that influence the probability of disease onset and modify the phenotype. For example, the apolipoprotein E (apoE) genotype constitutes an important risk factor for AD. Three distinct isoforms of this protein exist. Although all isoforms carry out their primary role in lipid metabolism equally well, individuals who are homozygous for the apoE4 allele (“4/4”) have a much higher lifetime risk of AD than do those homozygous for the apoE2 allele (“2/2”).

Environmental factors including infectious agents, environmental toxins, and acquired brain injury have been proposed in the etiology of neurodegenerative disorders. Traumatic brain injury has been suggested as a trigger for neurodegenerative disorders. At least one toxin, N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), can induce a condition closely resembling PD. More recently, evidence has linked pesticide exposure with PD. Exposure of soldiers to neurotoxic chemicals has been implicated in ALS (as part of “Gulf War syndrome”).

COMMON CELLULAR MECHANISMS OF NEURODEGENERATION. Despite their varied phenotypes, the neurodegenerative disorders share some common features. For example, misfolded and aggregated proteins are found in every major neurodegenerative disorder: alpha-synuclein, in PD; amyloid-β (Aβ)
and tau in AD; huntingtin in HD; and SOD and TDP-43 in ALS. The accumulation of misfolded proteins may result from either genetic mutations producing abnormal structure, or from impaired cellular clearance.

The term excitotoxicity describes the neural injury that results from the presence of excess glutamate in the brain. Glutamate is used as a neurotransmitter to mediate most excitatory synaptic transmission in the mammalian brain (see Table 14–1). The presence of excessive amounts of glutamate can lead to excitotoxic cell death (see Figure 14–8). The destructive effects of glutamate are mediated by glutamate receptors, particularly those of the N-methyl-d-aspartate (NMDA) type. Excitotoxic injury contributes to the neuronal death that occurs in acute processes such as stroke and head trauma. The role of excitotoxicity is less certain in the chronic neurodegenerative disorders; nevertheless, regional and cellular differences in susceptibility to excitotoxic injury, conveyed, e.g., by differences in types of glutamate receptors, may contribute to selective vulnerability. This has led to the development of glutamate antagonists as neuroprotective therapies, with 2 such agents (memantine and riluzole, described later) currently in clinical use.

Aging is associated with a progressive impairment in the capacity of neurons for oxidative metabolism with consequent production of reactive compounds such as hydrogen peroxide and oxygen radicals. These reactive species can lead to DNA damage, peroxidation of membrane lipids, and neuronal death. This has led to pursuit of drugs that can enhance cellular metabolism (such as the mitochondrial cofactor coenzyme Q10) and antioxidant strategies as treatments to prevent or retard degenerative diseases.

**PARKINSON DISEASE (PD)**

**CLINICAL OVERVIEW.** Parkinsonism is a clinical syndrome with 4 cardinal features:

- Bradykinesia (slowness and poverty of movement)
- Muscular rigidity
- Resting tremor (which usually abates during voluntary movement)
• An impairment of postural balance leading to disturbances of gait and to falling

The most common form of parkinsonism is idiopathic PD, first described by James Parkinson in 1817 as *paralysis agitans*, or the “shaking palsy.” The pathological hallmark of PD is the loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta, with the appearance of intracellular inclusions known as *Lewy bodies*. A loss of 70-80% of these dopamine-containing neurons accompanies symptomatic PD.

Without treatment, PD progresses over 5-10 years to a rigid, akinetic state in which patients are incapable of caring for themselves. Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has radically altered the prognosis of PD; in most cases, good functional mobility can be maintained for many years. Life expectancy of adequately treated patients is increased substantially, but overall mortality remains higher than that of the general population. In addition, while DA neuron loss is the most prominent feature of the disease, the disorder affects a wide range of other brain structures, including the brainstem, hippocampus, and cerebral cortex. This pathology is likely responsible for the “non-motor” features of PD, which include sleep disorders, depression, and memory impairment.

Several disorders other than idiopathic PD also may produce parkinsonism, including some relatively rare neurodegenerative disorders, stroke, and intoxication with DA-receptor antagonists. Drugs that may cause parkinsonism include antipsychotics such as haloperidol and chlorpromazine (see Chapter 16) and antiemetics such as prochlorperazine and metoclopramide (see Chapter 46). The distinction between idiopathic PD and other causes of parkinsonism is important because parkinsonism arising from other causes usually is refractory to all forms of treatment.

**PATHOPHYSIOLOGY.** The dopaminergic deficit in PD arises from a loss of the neurons in the substantia nigra pars compacta that provide innervation to the striatum (caudate and putamen). The current understanding of the pathophysiology of PD is based on the finding that the striatal DA content is
reduced in excess of 80%, with a parallel loss of neurons from the substantia nigra, suggesting that replacement of DA could restore function. We now have a model of the function of the basal ganglia that, while incomplete, is still useful.

DOPAMINE SYNTHESIS, METABOLISM, AND RECEPTORS. DA, a catecholamine, is synthesized in the terminals of dopaminergic neurons from tyrosine and stored, released, reaccumulated, and metabolized by processes described in Chapter 13 and summarized in Figure 22–1. The actions of DA in the brain are mediated by DA receptor, of which there are 2 broad classes. D1 and D2, with 5 distinct subtypes, D1-D5 (see Figure 13–6). All the DA receptors are G protein–coupled receptors (GPCRs). Receptors of the D1 group (D1 and D5 subtypes) couple to Gs and thence to activation of the cyclic AMP pathway. The D2 group (D2, D3, and D4 receptors) couple to Gi to reduce the adenylyl cyclase activity and voltage-gated Ca2+ currents while activating K+ currents (see Chapters 3 and 13 for details). Each of the 5 DA receptors has a distinct anatomical pattern of expression in the brain (see Figure 13–6). D1 and D2 proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D4 and D5 proteins are largely extrastriatal, whereas D3 expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.
Figure 22–1 Dopaminergic nerve terminal. Dopamine (DA) is synthesized from tyrosine in the nerve terminal by the sequential actions of tyrosine hydrolase (TH) and aromatic amino acid decarboxylase (AADC). DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET), or removed by postsynaptic uptake via OCT3 transporters. Cytosolic DA is subject to degradation by monoamine oxidase (MAO) and aldehyde dehydrogenase (ALDH) in the neuron, and by catechol-O-methyl transferase (COMT) and MAO/ALDH in non-neuronal cells; the final metabolic product is homovanillic acid (HVA). See structures in Figure 22–4. PH, phenylalanine hydroxylase.
NEURAL MECHANISM OF PARKINSONISM: A MODEL OF BASAL GANGLIA FUNCTION. Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD. The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Figure 22–2).

Figure 22–2 Schematic wiring diagram of the basal ganglia. The striatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of cerebral cortex. The striatum contains projection neurons expressing predominantly D₁ or D₂ dopamine receptors, as well as interneurons that use ACh as a neurotransmitter. Outflow from the striatum proceeds along 2 routes. The direct pathway, from the striatum to the substantia nigra pars reticulata (SNpr) and globus pallidus interna (GPi), uses the inhibitory transmitter GABA. The indirect pathway, from the striatum through the globus pallidus externa (GPe) and the subthalamic nucleus (STN) to the SNpr and GPi, consists of 2 inhibitory GABA-ergic links and 1 excitatory
glutamatergic projection (Glu). The substantia nigra pars compacta (SNpc) provides dopaminergic innervation to the striatal neurons, giving rise to both the direct and indirect pathways, and regulates the relative activity of these 2 paths. The SNpr and GPi are the output structures of the basal ganglia and provide feedback to the cerebral cortex through the ventroanterior and ventrolateral nuclei of the thalamus (VA/VL).

The neostriatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of the cortex. Most neurons within the striatum are projection neurons that innervate other basal ganglia structures. A small but important subgroup of striatal neurons consists of interneurons that connect neurons within the striatum but do not project beyond its borders. Acetylcholine (ACh) and neuropeptides are used as transmitters by these striatal interneurons.

The outflow of the striatum proceeds along 2 distinct routes, termed the direct and indirect pathways. The direct pathway is formed by neurons in the striatum that project directly to the output stages of the basal ganglia, the substantia nigra pars reticulata (SNpr) and the globus pallidus interna (GPi); these, in turn, relay to the ventroanterior and ventrolateral thalamus, which provides excitatory input to the cortex. The neurotransmitter of both links of the direct pathway is γ-aminobutyric acid (GABA), which is inhibitory, so that the net effect of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex.

The indirect pathway is composed of striatal neurons that project to the globus pallidus externa (GPe). This structure, in turn, innervates the subthalamic nucleus (STN), which provides outflow to the SNpr and GPi output stage. The first 2 links—the projections from striatum to GPe and GPe to STN—use the inhibitory transmitter GABA; however, the final link—the projection from STN to SNpr and GPi—is an excitatory glutamatergic pathway. Thus, the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex. The key feature of this model of basal ganglia function, which accounts for the symptoms observed in PD as a result of loss of dopaminergic neurons, is the differential effect of DA on the direct and indirect pathways (Figure 22–3).
The basal ganglia in Parkinson disease. The primary defect is destruction of the dopaminergic neurons of the SNpc. The striatal neurons that form the direct pathway from the striatum to the SNpr and GPi express primarily the excitatory D₁ DA receptor, whereas the striatal neurons that project to the GPe and form the indirect pathway express the inhibitory D₂ dopamine receptor. Thus, loss of the dopaminergic input to the striatum has a differential effect on the 2 outflow pathways; the direct pathway to the SNpr and GPi is less active (structures in purple), whereas the activity in the indirect pathway is increased (structures in red). The net effect is that neurons in the SNpr and GPi become more active. This leads to increased inhibition of the VA/VL thalamus and reduced excitatory input to the cortex. *Light blue lines* indicate primary pathways with reduced activity. (See legend to Figure 22–2 for definitions of anatomical abbreviations.)

The dopaminergic neurons of the substantia nigra pars compacta (SNpc) innervate all parts of the striatum; however, the target striatal neurons express distinct types of DA receptors. The striatal neurons giving rise to the direct pathway express primarily the excitatory D₁ dopamine receptor protein, whereas the striatal neurons forming the indirect pathway express primarily the inhibitory D₂ type. Thus, DA released in the striatum tends to increase the activity of the
direct pathway and reduce the activity of the indirect pathway, whereas the depletion that occurs in PD has the opposite effect. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and GPi to the thalamus and reduce excitation of the motor cortex. There are several limitations of this model of basal ganglia function. The anatomical connections are considerably more complex and many of the pathways involved use several neurotransmitters. Nevertheless, the model is useful and has important implications for the rational design and use of pharmacological agents in PD.

TREATMENT OF PARKINSON DISEASE

Table 22–1 summarizes commonly used medications for the treatment of PD.

Table 22–1

Commonly Used Medications for the Treatment of Parkinson Disease
LEVODOPA. Levodopa (L-dopa, LARODOPA, L-3,4-dihydroxyphenylalanine), the metabolic precursor of DA, is the single most effective agent in the treatment of PD.

The effects of levodopa result from its decarboxylation to DA. When administered orally, levodopa is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the drug in plasma usually peak between 0.5 and 2 h after an oral dose. The $t_{1/2}$ in plasma is short (1-3 h). The rate and extent of absorption of levodopa depends on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa.
Administration of levodopa with high-protein meals delays absorption and reduces peak plasma concentrations. Entry of the drug into the CNS across the blood-brain barrier is mediated by a membrane transporter for aromatic amino acids. In the brain, levodopa is converted to DA by decarboxylation primarily within the presynaptic terminals of dopaminergic neurons in the striatum. The DA produced is responsible for the therapeutic effectiveness of the drug in PD; after release, it is either transported back into dopaminergic terminals by the presynaptic uptake mechanism or metabolized by the actions of MAO and catechol-O-methyltransferase (COMT) (Figure 22–4).

![Figure 22–4 Metabolism of levodopa (l-dopa). AADC, aromatic l-amino acid decarboxylase; ALDH, aldehyde dehydrogenase; COMT, catechol-O-methyltransferase; DβH, dopamine-β-hydroxylase; MAO, monoamine oxidase.](image)

In clinical practice, levodopa is almost always administered in combination with a peripherally acting inhibitor of aromatic l-amino acid decarboxylase, such as carbidopa or benserazide (available outside the U.S.), drugs that do not penetrate well into the CNS. If levodopa is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so
that relatively little unchanged drug reaches the cerebral circulation and probably < 1% penetrates the CNS. In addition, DA release into the circulation by peripheral conversion of levodopa produces undesirable effects, particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood-brain barrier (Figure 22–5) and reduces the incidence of GI side effects.

Figure 22–5 Pharmacological preservation of L-DOPA and striatal dopamine. The principal site of action of inhibitors of COMT (e.g., tolcapone and entacapone) is in the peripheral circulation. They block the O-methylation of L-dopa and increase the fraction of the drug available for delivery to the brain. Tolcapone also has effects in the CNS. Inhibitors of MAO-B, such as low-dose selegiline and rasagiline, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores. AADC, aromatic L-amino acid decarboxylase; DA, dopamine; DOPAC, 3,4-dihydroxyphenylacetic acid; MAO, monoamine oxidase; 3MT, 3-methoxyltyramine; 3-OMD, 3-O-methyl DOPA.

A daily dose of 75 mg carbidopa is generally sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of carbidopa/levodopa (Sinemet, Atamet, others) is the 25/100 form, containing 25 mg carbidopa and 100 mg levodopa. With this formulation, dosage schedules of 3 or more tablets daily provide acceptable inhibition of decarboxylase in most individuals.

Levodopa therapy can have a dramatic effect on all the signs and symptoms of PD. Early in the course of the disease, the degree of
improvement in tremor, rigidity, and bradykinesia may be nearly complete. With long-term levodopa therapy, the “buffering” capacity is lost, and the patient’s motor state may fluctuate dramatically with each dose of levodopa, producing the motor complications of levodopa.

A common problem is the development of the “wearing off” phenomenon: Each dose of levodopa effectively improves mobility for a period of time, perhaps 1-2 h, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of dyskinesias, excessive and abnormal involuntary movements. In the later stages of PD, patients may fluctuate rapidly between being “off,” having no beneficial effects from their medications, and being “on” but with disabling dyskinesias (the on/off phenomenon). A sustained-release formulation consisting of carbidopa/levodopa in an erodable wax matrix (Sinemet CR) is helpful in some cases, but absorption of the sustained-release formulation is not entirely predictable.

Does levodopa alter the course of the underlying disease or merely modify the symptoms? A recent randomized trial has provided evidence that levodopa does not have an adverse effect on the course of the underlying disease, but has also confirmed that high doses of levodopa are associated with early onset of dyskinesias. Most practitioners have adopted a pragmatic approach, using levodopa only when the symptoms of PD cause functional impairment and other treatments are inadequate or not well tolerated.

A frequent and troubling adverse effect is the induction of hallucinations and confusion, especially in elderly patients or in patients with preexisting cognitive dysfunction. Conventional antipsychotic agents, such as the phenothiazines, are effective against levodopa-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D2 DA receptor. An alternative approach has been to use “atypical” antipsychotic agents (see Chapter 16). The 2 drugs that are most effective and best tolerated in patients with advanced PD are clozapine and quetiapine. Peripheral decarboxylation of levodopa and release of DA into the circulation may activate vascular DA receptors and produce orthostatic hypotension. Administration of levodopa with nonspecific inhibitors of MAO accentuates the actions of levodopa and may precipitate life-threatening
hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors always should be discontinued at least 14 days before levodopa is administered [note that this prohibition does not include the MAO-B subtype-specific inhibitors selegiline and rasagiline (Azilect)]. Abrupt withdrawal of levodopa or other dopaminergic medications may precipitate the neuroleptic malignant syndrome of confusion, rigidity, and hyperthermia, a potentially lethal adverse effect.

**DOPAMINE RECEPTOR AGONISTS.** The DA receptor agonists in clinical use have durations of action substantially longer than that of levodopa; they are often used in the management of dose-related fluctuations in motor state, and may be helpful in preventing motor complications. It has been suggested that DA receptor agonists may have the potential to modify the course of PD by reducing endogenous release of DA as well as the need for exogenous levodopa, thereby reducing free radical formation.

Two orally administered DA receptor agonists are commonly used for treatment of PD: ropinirole (Requip) and pramipexole (Mirapex). Ropinirole and pramipexole have selective activity at D2 class sites (specifically at the D2 and D3 receptor) and little or no activity at D1 class sites. Both are well absorbed orally and have similar therapeutic actions. Like levodopa, they can relieve the clinical symptoms of PD. The duration of action of the DA agonists (8-24 h) often is longer than that of levodopa (6-8 h), and they are particularly effective in the treatment of patients who have developed on/off phenomena. Ropinirole is also available in a once-daily sustained-release formulation (Requip XL), which is more convenient and may reduce adverse effects related to intermittent dosing. Both pramipexole and ropinirole may produce hallucinosis or confusion, similar to that observed with levodopa, and may cause nausea and orthostatic hypotension. They should be initiated at low dose and titrated slowly to minimize these effects. The DA agonists, as well as levodopa itself, are also associated with fatigue and somnolence. Practitioners prefer a DA agonist as initial therapy in younger patients in order to reduce the occurrence of motor complications. In older patients or those with substantial comorbidity, levodopa/carbidopa is generally better tolerated.

**APOMORPHINE.** Apomorphine (ApoKyn) is a dopaminergic
agonist that can be administered by subcutaneous injection. It has high affinity for D₄ receptors; moderate affinity for D₂, D₃, D₅, and adrenergic α₁D, α₂B, and α₂C receptors; and low affinity for D₁ receptors. Apomorphine is FDA-approved as a “rescue therapy” for the acute intermittent treatment of “off” episodes in patients with a fluctuating response to dopaminergic therapy.

Apomorphine has the same side effects as the oral DA agonists. Apomorphine is highly emetogenic and requires pre- and posttreatment antiemetic therapy. Oral trimethobenzamid (TIGAN), at a dose of 300 mg 3 times daily, should be started 3 days prior to the initial dose of apomorphine and continued at least during the first 2 months of therapy. Profound hypotension and loss of consciousness have occurred when apomorphine was administered with ondansetron; hence, the concomitant use of apomorphine with antiemetic drugs of the 5-HT₃ antagonist class is contraindicated. Other potentially serious side effects of apomorphine include QT prolongation, injection-site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior. Because of these potential adverse effects, use of apomorphine is appropriate only when other measures, such as oral DA agonists or COMT inhibitors, have failed to control the “off” episodes. Apomorphine therapy should be initiated with a 2-mg test dose in a setting where the patient can be monitored carefully. If tolerated, it can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require 3 or more injections daily.

**CATECHOL-O-METHYLTRANSFERASE INHIBITORS.** When levodopa is administered orally, most is converted by aromatic L-amino acid decarboxylase (AADC) to DA (see Figure 22–5), which causes nausea and hypotension. Addition of an AADC inhibitor such as carbidopa reduces the formation of DA but increases the fraction of levodopa that is methylated by COMT. COMT inhibitors block this peripheral conversion of levodopa to 3-O-methyl DOPA, increasing both the plasma $t_{1/2}$ of levodopa as well as the fraction of each dose that reaches the CNS.
The COMT inhibitors tolcapone (TASMAR) and entacapone (COMTAN) reportedly reduce significantly the “wearing off” symptoms in patients treated with levodopa/carbidopa. The 2 drugs differ only in their pharmacokinetic properties and adverse effects: tolcapone has a relatively long duration of action, and appears to act by both central and peripheral inhibition of COMT. Entacapone has a short duration of action (2 h) and principally inhibits peripheral COMT. Common adverse effects of these agents include nausea, orthostatic hypotension, vivid dreams, confusion, and hallucinations. An important adverse effect associated with tolcapone is hepatotoxicity. At least 3 fatal cases of fulminant hepatic failure in patients taking tolcapone have been observed, leading to addition of a black box warning to the label. Tolcapone should be used only in patients who have not responded to other therapies and with appropriate monitoring for hepatic injury. Entacapone has not been associated with hepatotoxicity. Entacapone also is available in fixed-dose combinations with levodopa/carbidopa (STALEVO).

**SELECTIVE MAO-B INHIBITORS.** Two isoenzymes of MAO oxidize catecholamines: MAO-A and MAO-B. MAO-B is the predominant form in the striatum and is responsible for most of the oxidative metabolism of DA in the brain.Selective MAO-B inhibitors are used for the treatment of PD: selegiline (ELDEPRYL, EMSAM, ZELAPAR) and rasagiline (AZILECT). These agents selectively and irreversibly inactivate MAO-B. Both agents exert modest beneficial effects on the symptoms of PD. The basis of this efficacy is, presumably, inhibition of breakdown of DA in the striatum.

Selective MAO-B inhibitors do not substantially inhibit the peripheral metabolism of catecholamines and can be taken safely with levodopa. These agents also do not exhibit the “cheese effect,” the potentially lethal potentiation of catecholamine action observed when patients on nonspecific MAO inhibitors ingest indirectly acting sympathomimetic amines such as the tyramine found in certain cheeses and wine.

Selegiline is generally well tolerated in younger patients for symptomatic treatment of early or mild PD. In patients with more advanced PD or underlying cognitive impairment, selegiline may accentuate the adverse motor and cognitive
effects of levodopa therapy. Metabolites of selegiline include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. Selegiline has become available in an orally disintegrating tablet (ZELAPAR) as well as a transdermal patch (EMSAM). Both of these delivery routes are intended to reduce hepatic first-pass metabolism and limit the formation of the amphetamine metabolites.

Unlike selegiline, rasagiline does not give rise to undesirable amphetamine metabolites. Rasagiline monotherapy is effective in early PD. Adjunctive therapy with rasagiline significantly reduces levodopa-related “wearing off” symptoms in advanced PD. Although selective MAO-B inhibitors are generally well tolerated, drug interactions can be troublesome. Similar to the nonspecific MAO inhibitors, selegiline can lead to the development of stupor, rigidity, agitation, and hyperthermia when administered with the analgesic meperidine. Although the mechanics of this interaction is uncertain, selegiline or rasagiline should not be given in combination with meperidine. Adverse effects, although uncommon, have been reported from coadministration of MAO-B inhibitors with tricyclic antidepressants or with serotonin-reuptake inhibitors.

**MUSCARINIC RECEPTOR ANTAGONISTS.** Antimuscarinic drugs currently used in the treatment of PD include trihexyphenidyl and benztropine mesylate, as well as the antihistaminic diphenhydramine hydrochloride, which also interacts at central muscarinic receptors. The biological basis for the therapeutic actions of muscarinic antagonists is not completely understood. They may act within the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons.

These drugs have relatively modest antiparkinsonian activity and are used only in the treatment of early PD or as an adjunct to dopaminergic therapy. Adverse effects result from their anticholinergic properties. Most troublesome are sedation and mental confusion. All anticholinergic drugs must be used with caution in patients with narrow-angle glaucoma (see Chapter 64). The pharmacology and signaling mechanisms of muscarinic receptors are thoroughly covered in Chapter 9.
**AMANTADINE.** Amantadine (Symmetrel), an antiviral agent used for the prophylaxis and treatment of influenza A (see Chapter 58), has antiparkinsonian activity. Amantadine appears to alter DA release in the striatum, has anticholinergic properties, and blocks NMDA glutamate receptors. It is used as initial therapy of mild PD. It also may be helpful as an adjunct in patients on levodopa with dose-related fluctuations and dyskinesias. Amantadine is usually administered at a dose of 100 mg twice a day and is well tolerated. Dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, these effects are mild and reversible.

**NEUROPROTECTIVE TREATMENTS FOR PARKINSON DISEASE.** Inhibition of MAO-B in the brain reduces the overall catabolism of DA, which may decrease the formation of potentially toxic-free radicals and consequently the rate of neurodegeneration in PD. In a recent study, rasagiline has been reported to have a neuroprotective effect. Another strategy under study is the use of compounds that augment cellular energy metabolism such coenzyme Q10, a cofactor required for the mitochondrial electron-transport chain. A small study has demonstrated that this drug is well tolerated in PD and has suggested that coenzyme Q10 may slow the course of the disease.

**CLINICAL SUMMARY.** Pharmacological treatment of PD should be tailored to the individual patient. Drug therapy is not obligatory in early PD; many patients can be managed for a time with exercise and lifestyle interventions. For patients with mild symptoms, MAO-B inhibitors, amantadine, or (in younger patients) anticholinergics are reasonable choices. In most patients, treatment with a dopaminergic drug, either levodopa or a DA agonist, is eventually required. Practitioners prefer DA agonist as initial therapy in younger patients in order to reduce the occurrence of motor complications. In older patients or those with substantial comorbidity, levodopa/carbidopa is generally better tolerated.

**ALZHEIMER DISEASE (AD)**

**CLINICAL OVERVIEW.** The brain region most vulnerable to neuronal dysfunction and cell loss in AD is the medial temporal lobe, including entorhinal cortex and hippocampus. Typical early AD symptoms are due to dysfunction of these structures resulting in anterograde episodic memory loss: repeated questions, misplaced
items, missed appointments, and forgotten details of daily life. A typical patient presents with memory dysfunction that is noticeable but not severe enough to impair daily function. Because current diagnostic criteria for AD require the presence of dementia (i.e., cognitive impairments sufficient to reduce function), these patients are generally given a diagnosis of mild cognitive impairment (MCI). Patients with MCI progress at a rate of about 10% per year to AD, although not all MCI patients will develop AD. Gradual but relentless progression in AD involves other cognitive domains including visuospatial and executive function. The later stages of the disease are characterized by increasing dependence and progression toward the akinetic-mute state that typifies end-stage neurologic disease. Death, most often from a complication of immobility such as pneumonia or pulmonary embolism, usually ensues within 6-12 years of onset.

**GENETICS.** Mutations in 3 genes have been identified as causes of autosomal dominant, early onset AD: APP, which encodes amyloid-β, precursor protein, and PSEN1 and PSEN2, encoding presenilin 1 and 2. All 3 genes are involved in the production of amyloid-β peptides (Aβ). Aβ is generated by sequential proteolytic cleavage of APP by 2 enzymes, βsecretase and γ-secretase; the presenilins form the catalytic core of γ-secretase. The genetic evidence, combined with the fact that Aβ accumulates in the brain in the form of soluble oligomers and amyloid plaques, and is toxic when applied to neurons, forms the basis for the amyloid hypothesis of AD pathogenesis. Many genes have been identified as having alleles that increase AD risk. By far the most important of these is APOE, which encodes the lipid carrier protein apoE. Individuals inheriting the ε4 allele of APOE have a more than 3-fold higher risk of developing AD. While they make up less than one-fourth of the population, they account for more than half of all AD cases.

**PATHOPHYSIOLOGY.** The pathological hallmarks of AD are amyloid plaques, which are extracellular accumulations of Aβ, and intracellular neurofibrillary tangles composed of the microtubule-associated protein tau. While the development of amyloid plaques is an early and invariant feature of AD, tangle burden accrues over time in a manner that correlates more closely with the development of cognitive impairment. In autosomal dominant AD, Aβ
accumulates due to mutations that cause its overproduction. Aggregation of Aβ is an important event in AD pathogenesis. While plaques consist of highly ordered fibrils of Aβ, it appears that soluble Aβ oligomers, perhaps as small as dimers, are more highly pathogenic. Tau also aggregates to form the paired helical filaments that make up neurofibrillary tangles. Posttranslational modifications of tau including phosphorylation, proteolysis, and other changes cause loss of tau’s normal functions and increase its propensity to aggregate. Mechanisms by which Aβ and tau induce neuronal dysfunction and death may include direct impairment of synaptic transmission and plasticity, excitotoxicity, oxidative stress, and neuroinflammation.

NEUROCHEMISTRY. The most striking neurochemical disturbance in AD is a deficiency of acetylcholine. The anatomical basis of the cholinergic deficit is atrophy and degeneration of subcortical cholinergic neurons. The selective deficiency of ACh in AD and the observation that central cholinergic antagonists (e.g., atropine) can induce a confusional state resembling the dementia of AD, have given rise to the “-cholinergic hypothesis” that a deficiency of ACh is critical in the genesis of the AD symptoms. AD, however, is complex and also involves multiple neurotransmitter systems, including glutamate, 5-HT, and neuropeptides, and there is destruction of not only cholinergic neurons but also the cortical and hippocampal targets that receive cholinergic input.

TREATMENT OF ALZHEIMER DISEASE

At present, no disease-modifying therapy for AD is available; current treatment is aimed at alleviating symptoms.

TREATMENT OF COGNITIVE SYMPTOMS. Augmentation of the cholinergic transmission is currently the mainstay of AD treatment. Three drugs, donepezil, rivastigmine, and galantamine, are widely used for this purpose; a fourth, tacrine, is rarely used now because of its extensive side effects compared to the newer agents (Table 22–2). All 4 agents are reversible antagonists of cholinesterases (see Chapter 10). Cholinesterase inhibitors are the usual first-line therapy for symptomatic treatment of cognitive impairments in mild or moderate AD. They are also widely used to treat other neurodegenerative diseases with cholinergic deficits, including dementia with Lewy bodies and vascular dementia. The drugs are usually well tolerated, with the most common side
effects being GI distress, muscle cramping, and abnormal dreams. They should be use with caution in patients with bradycardia or syncope.

\n\n\n\n
Memantine (NAMENDA) is used either as an adjunct or an alternative to cholinesterase inhibitors in AD, and is also commonly used to treat other neurodegenerative dementias. Memantine is a noncompetitive antagonist of the NMDA-type glutamate receptor. Memantine significantly reduces the rate of clinical deterioration in patients with moderate to severe AD. Adverse effects of memantine include mild headache or dizziness. The drug is excreted by the kidneys, and dosage should be reduced in patients with severe renal impairment.

TREATMENT OF BEHAVIORAL SYMPTOMS. In addition to cognitive decline, behavioral and psychiatric symptoms in dementia (BPSD) are common, particularly in middle stages of the disease. These symptoms include irritability and agitation, paranoia and delusional thinking, wandering, anxiety, and depression. Treatment can be difficult, and nonpharmacological approaches should generally be first-line.

A variety of pharmacological options are also available. Both cholinesterase inhibitors and memantine reduce some BPSD. However, their effects are modest,
and they do not treat some of the most troublesome symptoms, such as agitation. Atypical antipsychotics, such as risperidone, olanzapine, and quetiapine (see Chapter 16), are the most efficacious therapy for agitation and psychosis in AD. Risperidone and olanzapine are effective, but their use is often limited by adverse effects, including parkinsonism, sedation, and falls. In addition, the use of atypical antipsychotics in elderly patients with dementia-related psychosis has been associated with a higher risk of stroke and overall mortality. Benzodiazepines (see Chapter 17) can be used for occasional control of acute agitation, but are not recommended for long-term management because of their adverse effects on cognition and other risks in the elderly population. The typical antipsychotic haloperidol (see Chapter 16) may be useful for aggression, but sedation and extrapyramidal symptoms limit its use to control of acute episodes. Antidepressants (see Chapter 15) can be useful for BPSD, particularly when depression or anxiety contribute. Trazodone has modest benefits, but for the most part, selective serotonin reuptake inhibitors (SSRIs) are the preferred class of drugs.

**CLINICAL SUMMARY.** The typical AD patient presenting in early stages of disease should probably be treated with a cholinesterase inhibitor. Patients and families should be counseled that a realistic goal of therapy is to induce a temporary reprieve from progression, or at least a reduction in the rate of decline, rather than long-term recovery of cognition. As the disease progresses, memantine can be added to the regimen. Behavioral symptoms are often treated with a serotonergic antidepressant or, if they are severe enough to warrant the risk of higher mortality, an atypical antipsychotic. Eliminating drugs likely to aggravate cognitive impairments, particularly anticholinergics, benzodiazepines, and other sedative/hypnotics, from the patient’s regimen is another important aspect of AD pharmacotherapy.

**HUNTINGTON DISEASE (HD)**

HD is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in midlife. Symptoms develop insidiously, either as a movement disorder manifest by brief, jerk-like movements of the extremities, trunk, face, and neck (chorea) or as personality changes or both. Fine-motor incoordination and impairment of rapid eye movements are early
features. As the disorder progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is impaired, but affected persons rarely lose their memory of family, friends, and the immediate situation. Such persons often become irritable, anxious, and depressed. The outcome of HD is invariably fatal; over a course of 15-30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility.

**PATHOLOGY AND PATHOPHYSIOLOGY.** HD is characterized by prominent neuronal loss in the striatum (caudate/putamen) of the brain. Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to ventrolateral. Other areas of the brain also are affected. Interneurons and afferent terminals are largely spared, whereas the striatal projection neurons (the medium spiny neurons) are severely affected. This leads to large decreases in striatal GABA concentrations, whereas somatostatin and DA concentrations are relatively preserved.

Selective vulnerability also appears to underlie the development of chorea. In most adult-onset cases, the medium spiny neurons that project to the GPi and SNpr (the indirect pathway) appear to be affected earlier than those projecting to the GPe (the direct pathway; see Figure 22–2). The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements (Figure 22–6). In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset cases. Here, the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.
The basal ganglia in Huntington disease. HD is characterized by loss of neurons from the striatum. The neurons that project from the striatum to the GPe and form the indirect pathway are affected earlier in the course of the disease than those that project to the GPi. This leads to a loss of inhibition of the GPe. The increased activity in this structure, in turn, inhibits the STN, SNpr, and GPi, resulting in a loss of inhibition to the VA/VL thalamus and increased thalamocortical excitatory drive. 

*Structures in purple* have reduced activity in HD, whereas structures in red have increased activity. *Light blue lines* indicate primary pathways of reduced activity. (See legend to Figure 22–2 for definitions of anatomical abbreviations.)

**GENETICS.** HD is an autosomal dominant disorder with nearly complete penetrance. The average age of onset is between 35 and 45 years, but the range varies from as early as age 2 to as late as the middle 80s. Although the disease is inherited equally from mother and father, more than 80% of those developing symptoms before age 20 inherit the defect from the father. Known homozygotes for HD show clinical characteristics identical to the typical HD heterozygote, indicating that the unaffected chromosome does not attenuate the disease symptomatology.

A region near the end of the short arm of chromosome 4 contains a polymorphic (CAG)$_n$ trinucleotide repeat that is significantly expanded in all individuals with HD. The expansion of this trinucleotide repeat is the genetic alteration responsible for HD. The range of CAG repeat length in normal individuals is between 9 and 34 triplets, with a median repeat length on normal chromosomes
of 19. The repeat length in HD varies from 40 to over 100. Repeat length is correlated inversely with age of onset of HD. The younger the age of onset, the higher the probability of a large repeat number. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a large gene (10 kilobases) designated IT15. It encodes a protein of ~348,000 Da. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5′ end of IT15 and is followed directly by a second, shorter repeat of (CCG)$_n$ that encodes proline. The protein, huntingtin, does not resemble any other known protein, and the normal function of the protein has not been identified.

**TREATMENT OF HUNTINGTON DISEASE**

**SYMPTOMATIC TREATMENT.** None of the currently available medications slows the progression of the disease.

Symptomatic treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. Fluoxetine (see Chapter 15) is effective treatment for both the depression and the irritability manifest in symptomatic HD. Carbamazepine (see Chapter 21) also has been found to be effective for depression. Paranoia, delusional states, and psychosis are treated with antipsychotic drugs, but usually at lower doses than those used in primary psychiatric disorders (see Chapter 16). These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, clozapine, quetiapine (see Chapter 16), or carbamazepine may be more effective for treatment of paranoia and psychosis.

Tetrabenazine (XENAZINE, Nitoman) is available for the treatment of large-amplitude chorea associated with HD. Tetrabenazine, and the related drug reserpine, are inhibitors of the vesicular monoamine transporter 2 (VMAT2), and cause presynaptic depletion of catecholamines. Tetrabenazine is a reversible inhibitor; inhibition by reserpine is irreversible and may lead to long-lasting effects. Both drugs may cause hypotension and depression with suicidality; the
shorter duration of effect of tetrabenazine greatly simplifies the clinical management. Many HD patients exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious use of sedative or anxiolytic benzodiazepines can be very helpful. In juvenile-onset cases where rigidity rather than chorea predominates, DA agonists have had variable success in the improvement of rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to clonazepam, valproic acid, and other anticonvulsants (see Chapter 21).

**AMYOTROPHIC LATERAL SCLEROSIS (ALS)**

ALS (or Lou Gehrig disease) is a disorder of the motor neurons of the ventral horn of the spinal cord (lower motor neurons) and the cortical neurons that provide their afferent input (upper motor neurons). The disorder is characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Many ALS patients exhibit behavioral changes and cognitive dysfunction, and there is clinical, genetic, and neuropathological overlap between ALS and frontotemporal dementia spectrum disorders. ALS usually is progressive and fatal. Most patients die of respiratory compromise and pneumonia after 2-3 years, although some survive for many years.

**ETIOLOGY.** About 10% of ALS cases are familial (FALS), usually with an autosomal dominant pattern of inheritance. An important subset of FALS patients are families with a mutation in the gene for the enzyme SOD1. Mutations in this protein account for about 20% of cases of FALS. Mutations in the TARDBP gene encoding TAR DNA-binding protein (TDP-43) and in the FUS/TLS gene have been identified as causes of FALS. Both TDP-43 and FUS/TLS bind DNA and RNA, and regulate transcription and alternative splicing. More than 90% of ALS cases are sporadic. Of these, a few are caused by de novo mutations in SOD1, TDP-43, FUS/TLS, or other genes, but for the majority of sporadic cases the etiology remains unclear. There is evidence that glutamate reuptake may be abnormal in the disease, leading to accumulation of glutamate and excitotoxic injury. The only currently approved therapy for ALS, riluzole, is based on these observations.
TREATMENT OF ALS

Riluzole. Riluzole (2-amino-6-[trifluoromethoxy] benzothiazole; RILUTEK) is an agent with complex actions in the nervous system.

Riluzole is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by both CYP–mediated hydroxylation and glucuronidation. Its $t_{1/2}$ is 12 h. In vitro studies have shown that riluzole has both presynaptic and postsynaptic effects. It inhibits glutamate release, but it also blocks postsynaptic NMDA- and kainate-type glutamate receptors and inhibits voltage-dependent Na$^+$ channels. The recommended dose is 50 mg twice daily, taken 1 h before or 2 h after a meal. Riluzole usually is well tolerated, although nausea or diarrhea may occur. Rarely, riluzole may produce hepatic injury with elevations of serum transaminases, and periodic monitoring of these is recommended. Meta-analyses of the available clinical trials indicate that riluzole extends survival by 2-3 months. Although the magnitude of the effect of riluzole on ALS is small, it represents a significant therapeutic milestone in the treatment of a disease refractory to all previous treatments.

SYMPTOMATIC THERAPY OF ALS: SPASTICITY. Spasticity is an important component of the clinical features of ALS and the feature most amenable to present forms of treatment. Spasticity is defined as an increase in muscle tone characterized by an initial resistance to passive displacement of a limb at a joint, followed by a sudden relaxation (the so-called clasped-knife phenomenon). Spasticity results from loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected.

Baclofen. The best agent for the symptomatic treatment of spasticity in ALS is baclofen (Lioresal), a GABA$_B$ receptor agonist. Initial doses of 5-10 mg/day are recommended, which can be increased to as much as 200 mg/day if necessary. Alternatively, baclofen can be delivered directly into the space around the spinal cord using a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression.

Tizanidine. Tizanidine (Zanaflex) is an agonist of $\alpha_2$ adrenergic receptors in the CNS. It reduces muscle spasticity, probably by increasing presynaptic inhibition
of motor neurons. Tizanidine is primarily used in the treatment of spasticity in multiple sclerosis or after stroke, but it also may be effective in patients with ALS. Treatment should be initiated at a low dose of 2-4 mg at bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit the dose that can be administered.

**Other Agents.** Benzodiazepines (see Chapter 17) such as clonazepam (KLONOPIN) are effective antispasticity agents, but they may contribute to respiratory depression in patients with advanced ALS.

Dantrolene (DANTRIUM), approved in the U.S. for the treatment of muscle spasm, is not used in ALS because it can exacerbate muscular weakness. Dantrolene acts directly on skeletal muscle fibers, impairing Ca\(^{2+}\) release from the sarcoplasmic reticulum. It is effective in treating spasticity associated with stroke or spinal cord injury and in treating malignant hyperthermia (see Chapter 11). Dantrolene may cause hepatotoxicity, so it is important to monitor liver associated enzymes before and during therapy with the drug.
chapter 23
Ethanol and Methanol

The 2-carbon alcohol ethanol (CH₃CH₂OH), or beverage alcohol, is one of the most versatile drugs known to man, with multiple direct effects on a diverse range of neurochemical systems. Produced in nature, rewarding in its effects, and easy to manufacture, it has been taken by humans since the beginning of recorded history, is consumed by a large majority of people in the Western world, and is likely to contribute to more morbidity, mortality, and public health costs than all of the illicit drugs combined.

ETHANOL CONSUMPTION. Compared with other drugs, surprisingly large amounts of alcohol are required for physiological effects, resulting in its consumption more as a food than a drug. The alcohol content of beverages typically ranges from 4-6% (volume/volume) for beer, 10-15% for wine, and 40% and higher for distilled spirits (the “proof” of an alcoholic beverage is twice its percentage of alcohol; e.g., 40% alcohol is 80 proof). A glass of beer or wine, a mixed drink, or a shot of spirits contains ~14 g alcohol, or ~0.3 mol ethanol. Thus, alcohol is consumed in gram quantities, whereas most other drugs are taken in milligram or microgram doses.

Because the ratio of ethanol in end-expiratory alveolar air and ethanol in the blood is relatively consistent, blood ethanol concentrations (BECs) in humans can be estimated readily by the measurement of alcohol levels in expired air; the partition coefficient for ethanol between blood and alveolar air is approximately 2000:1. Because of the causal relationship between excessive alcohol consumption and vehicular accidents, there has been a near-universal adoption of laws attempting to limit the operation of vehicles while under the influence of alcohol. Legally allowed BECs in the U.S. typically are set at or below 80 mg% (80 mg ethanol per 100 mL blood; 0.08% w/v), which is equivalent to a concentration of 17 mM ethanol in blood. A 12-oz bottle of beer, a 5-oz glass of
wine, and a 1.5-oz “shot” of 40% liquor each contains approximately 14 g ethanol, and the consumption of 1 of these beverages by a 70-kg person would produce a BEC of ~30 mg%. However, it is important to note that this is approximate because the BEC is determined by a number of factors, including the rate of drinking, gender, body weight and water percentage, and the rates of metabolism and stomach emptying (see “Acute Ethanol Intoxication” later in the chapter).

PHARMACOLOGICAL PROPERTIES

ETHANOL

**ABSORPTION.** After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total-body water (0.5-0.7 L/kg). Peak blood levels occur about 30 min after ingestion of ethanol when the stomach is empty. Because absorption occurs more rapidly from the small intestine than from the stomach, delays in gastric emptying (owing, e.g., to the presence of food) slow ethanol absorption. Because of first-pass metabolism by gastric and liver alcohol dehydrogenase (ADH), oral ingestion of ethanol leads to lower BECs than would be obtained if the same quantity were administered intravenously. Gastric metabolism of ethanol is lower in women than in men, which may contribute to the greater susceptibility of women to ethanol. **Aspirin** increases ethanol bioavailability by inhibiting gastric ADH.

**METABOLISM.** Ethanol is metabolized largely (90-98%) by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by aldehyde dehydrogenase (ALDH) (Figure 23–1). Each metabolic step requires NAD⁺; this greatly exceeds the supply of NAD⁺ in the liver and NAD⁺ availability limits ethanol metabolism to ~8 g or 10 mL (~170 mmol) per hour in a 70-kg adult, or ~120 mg/kg/h. Thus, hepatic ethanol metabolism functionally saturates at relatively low blood levels compared with the high BECs achieved,
and ethanol metabolism is a zero-order process (constant amount per unit time). Small amounts of ethanol are excreted in urine, sweat, and breath.

Figure 23–1 *Metabolism of ethanol and methanol.*

CYP2E1 also can contribute, especially at higher ethanol concentrations. CYP2E1 is induced by chronic consumption of ethanol, increasing the clearance of its substrates and the activation of certain toxins such as CCl₄. There can be decreased clearance of the same drugs, however, after acute consumption of ethanol because ethanol competes with them for oxidation by the enzyme system
The large increase in the hepatic NADH:NAD+ ratio during ethanol oxidation has profound consequences in addition to limiting the rate of ethanol metabolism. Enzymes requiring NAD+ are inhibited; thus, lactate accumulates, activity of the tricarboxylic acid cycle is reduced, and acetyl coenzyme A (acetyl CoA) accumulates (and it is produced in quantity from ethanol-derived acetic acid; see Figure 23–1). The combination of increased NADH and elevated–acetyl CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides; ketone bodies accrue, exacerbating lactic acidosis. Ethanol metabolism by the CYP2E1 pathway produces elevated NADP+, limiting the availability of NADPH for the regeneration of reduced glutathione (GSH), thereby enhancing oxidative stress.

Genetic Variation in Ethanol Metabolism. The enzymes involved in ethanol metabolism are mainly ADH and ALDH, and secondarily, catalase and CYP2E1. CYPs 1A2 and 3A4 may also participate. Several of these enzymes have genetic variants that alter alcohol metabolism and susceptibility to its effects.

The genetics of the ADH isoforms are important for understanding risk factors for severe repetitive ethanol problems. The 3 relevant forms are ADH1A, 1B, and 1C. These class I ADHs have $K_m<34$ mmol (0.15 g/dL) and are responsible for 70% of the ethanol metabolizing capacity at BECs of 22 mM (i.e., ~0.10 g/dL). These ADH forms are the rate-limiting step in ethanol metabolism, reducing the BECs by ~4-5 mM (0.015-0.020 g/dL) per hour, the approximate levels of alcohol resulting from the consumption of 1 standard drink.

The ADH1A gene has no polymorphisms known to significantly affect the rate of alcohol metabolism. The ADH1B gene has a polymorphism, ADH1B*2, with arginine 47 replaced by histidine to produce a variant form of ADH with a 40-fold higher $V_{max}$ than ADH1B. This polymorphism is seen in 30-45% of Chinese, Japanese, and Koreans, less than 10% of most Europeans, but in 50-90% of Russians and Jews. The potential faster metabolism of ethanol may result in a transient slightly higher blood level of acetaldehyde and is reported to be associated with a lower risk for heavy drinking and ethanol-related problems. A second polymorphism for ADH1B, ADH1B*3 (arginine 269 replaced by cysteine), has a 30-fold higher $V_{max}$. ADH1B*3 is seen in about 30% of Africans (e.g., phenytoin and warfarin).
and also is associated with lower risk of heavy drinking and ethanol problems.

Acetaldehyde is produced from the breakdown of ethanol at the rate of approximately 1 standard drink per hour. As shown in Figure 23–1, the acetaldehyde is then rapidly broken down through the actions of ALDH2, primarily in the mitochondria of liver cells. The actions of ALDH2 are important because low levels of acetaldehyde may be perceived as rewarding and stimulating, while high blood levels of this substance produce severe adverse reactions that can include vomiting, diarrhea, and unstable blood pressure. There is a mutation in the ALDH2 gene (12q24), ALDH2*2 (resulting from a substitution of glycine 487 with lysine). Homozygotes with a nonfunctional ALDH2*2 occur in 5-10% of Japanese, Chinese, and Korean individuals, for whom severe adverse reactions occur after consumption of 1 drink or less. This reaction operates through the same mechanism that occurs with drinking after taking the ALDH2 inhibitor, disulfiram. Heterozygotes for this polymorphism (ALDH2*2, 2*1) make up 30-40% of Asian individuals who, after consuming ethanol experience a facial flush and an enhanced sensitivity to beverage alcohol, but who do not necessarily report an overall adverse response to the drug. A number of these polymorphisms affect risk for alcohol use disorder (Table 23–1).

METHANOL
Methanol (CH$_3$OH), is also known as methyl and wood alcohol. It is an important industrial reagent and solvent found in products such as paint removers, shellac, and antifreeze; methanol is added to industrial-use ethanol to mark it unsafe for human consumption.

**Absorption and Metabolism.** Methanol is rapidly absorbed via the oral route, inhalation, and through the skin, with the latter 2 routes most relevant to industrial settings. Methanol is metabolized by ADH and ALDH. Competition between methanol and ethanol for ADH forms the basis of the use of ethanol in methanol poisoning. Several drugs inhibit alcohol metabolism, including fomepizole (4-methylpyrazole), an ADH inhibitor useful in ethylene glycol poisoning, and *disulfiram*, an ALDH inhibitor used in treating alcoholism.

Feelings of intoxication from methanol, while similar in many ways to those with ethanol, are less intense, and often delayed by 8 or more hours from ingestion, progressing even more slowly if methanol is taken along with ethanol. As little as 15 mL of methanol can produce toxicity, including blindness, with doses in excess of 70 mL capable of producing death. Methanol poisoning consists of headache, GI distress, and pain (partially related to pancreatic injury), difficulty breathing, restlessness, and blurred vision associated with hyperemic optic disks. Severe metabolic acidosis can develop due to the accumulation of formic acid, and the respiratory depression can be severe, especially in the context of coma. The visual disturbances occur as a consequence of injury to ganglion cells of the retina by the metabolite, formic acid, with subsequent inflammation, atrophy, and potential bilateral blindness. The clinical picture can also include necrosis of the pancreas.

**EFFECTS OF ETHANOL ON PHYSIOLOGICAL SYSTEMS**

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring overconfidence with physical impairment:
Porter: … and drink, sir, is a great provoker of three things.

Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [cutaneous vasodilation], sleep [CNS depression], and urine [a consequence of the inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading]. Lechery, sir, it provokes and unprovokes: it provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and disheartens him, makes him stand to and not stand to [the imagination desires what the corpus cavernosum cannot deliver]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

More recent research has added details to Shakespeare’s enumeration—see the bracketed additions to the Porter’s words in the preceding paragraph and the section on organ systems later in the chapter—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates frequently observed influences of modest concentrations of ethanol on the CNS.

CENTRAL NERVOUS SYSTEM

Although the public often views alcoholic drinks as stimulating, ethanol primarily is a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other depressants such as barbiturates and benzodiazepines, can have antianxiety actions and produce behavioral disinhibition at a wide range of dosages. Individual signs of intoxication vary from expansive and vivacious affect to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function generally is impaired, and a condition of general anesthesia ultimately prevails. However, there is little margin between the anesthetic actions and lethal effects (usually owing to respiratory depression).

Chronic alcohol abuse is accompanied by tolerance, dependence, and craving for the drug. Alcoholism is characterized by compulsive use despite clearly
deleterious social and medical consequences. Alcoholism is a progressive illness, and brain damage from chronic alcohol abuse contributes to the deficits in cognitive functioning and judgment seen in alcoholics. Alcoholism is a leading cause of dementia in the U.S. Chronic alcohol abuse results in shrinkage of the brain owing to loss of both white and gray matter. In addition to loss of brain tissue, alcohol abuse also reduces brain metabolism, and this hypometabolic state rebounds to a level of increased metabolism during detoxification. The magnitude of decrease in metabolic state is determined by the number of years of alcohol use and the age of the patients.

**Actions of Ethanol on Neurochemical Pathways and Signaling.** Ethanol affects almost all brain systems. The changes across neural pathways occur simultaneously and the alterations often interact. An additional complication in describing CNS effects is the rapid adaptation to ethanol observed in the brain, with the result that the acute effects of the first dose of ethanol are often the opposite of the neurochemical consequences from repeated administration and those observed during falling blood ethanol levels and withdrawal syndromes. Alcohol perturbs the balance between excitatory and inhibitory influences in the brain, resulting in anxiolysis, ataxia, and sedation. This is accomplished by either enhancing inhibitory or antagonizing excitatory neurotransmission. The 12th edition of the parent text summarizes research supporting effects of ethanol on a number of ion channels and neurotransmitter signal transducing systems that alter neuronal excitability within the CNS.

**Ethanol Consumption and CNS Function.** Large doses of ethanol can interfere with encoding of memories, producing anterograde amnesias, commonly referred to as *alcoholic blackouts*; affected individuals are unable to recall all or part of experiences during the period of heavy intake. Perhaps reflecting the effect of ethanol on respirations as well as the muscle-relaxant effects of this drug, heavier drinking can be associated with sleep apnea, especially in older alcohol-dependent subjects. The transient CNS effects of heavy ethanol consumption that produce a hangover—the “next morning” syndrome of headache, thirst, nausea, and cognitive impairment—may reflect mechanisms similar to mild alcohol withdrawal, dehydration, and/or mild acidosis.

Chronic heavy drinking reportedly increases the probability of developing *alcoholic dementia*. The signs of cognitive deficits and brain atrophy observed soon after a heavy drinking period often reverse over the subsequent several
weeks to months following abstinence. The thiamine depletion that can accompany heavy ethanol consumption contributes to Wernicke-Korsakoff syndromes. Perhaps 3% of alcohol-dependent men and women report experiencing temporary auditory hallucinations and paranoid delusions that resemble schizophrenia beginning during periods of heavy intoxication; all of these psychiatric syndromes are likely to markedly improve within several days to a month of abstinence.

CARDIOVASCULAR SYSTEM

Ethanol intake greater than 3 standard drinks per day elevates the risk for heart attacks and bleeding-related strokes. The risk includes a 6-fold increased risk for coronary artery disease, a heightened risk for cardiac arrhythmias, and an elevated rate of congestive heart failure. The causes are complex and observations are complicated by certain positive effects of small amounts of ethanol.

Serum Lipoproteins and Cardiovascular Effects. In France, the risk of mortality due to coronary heart disease (CHD) is relatively low despite the consumption of high quantities of saturated fats (the “French paradox”). Epidemiological studies suggest that widespread wine consumption (20-30 g ethanol per day) is 1 of the factors conferring a cardioprotective effect, resulting in a 10-40% decreased risk of coronary heart disease compared with abstainers. In contrast, daily consumption of greater amounts of alcohol leads to an increased incidence of non-coronary causes of cardiovascular failure, such as arrhythmias, cardiomyopathy, and hemorrhagic stroke, offsetting the beneficial effects of alcohol on coronary arteries.

One possible mechanism by which alcohol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in high-density lipoprotein (HDL; see Chapter 31), have been associated with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol levels. Ethanol-induced increases in HDL-cholesterol thus could antagonize cholesterol accumulation in arterial walls, lessening the risk of infarction. HDL is found as 2 subfractions, named HDL₂ and HDL₃. Increased levels of HDL₂ (and possibly also HDL₃) are associated with reduced risk of
myocardial infarction. Levels of both subfractions are increased following alcohol consumption and decrease when alcohol consumption ceases. Apolipoproteins A-I and A-II are constituents of HDL. Increased levels of both apolipoproteins A-I and A-II are associated with individuals who are daily heavy drinkers. In contrast, there are reports of decreased serum apolipoprotein(a) levels following acute alcohol consumption. Elevated apolipoprotein(a) levels have been associated with an increased risk for the development of atherosclerosis.

All forms of alcoholic beverages confer cardio-protection. The flavonoids found in red wine (and purple grape juice) may have an additional anti-atherogenic role by protecting low-density lipoprotein (LDL) from oxidative damage. Alcohol consumption also is linked to elevated levels of tissue plasminogen activator (a clot-dissolving enzyme), decreased fibrinogen concentrations, and inhibition of platelet activation.

**Hypertension.** Heavy alcohol use can raise diastolic and systolic blood pressure. Consumption >30 g alcohol per day (>2 standard drinks) is associated with a 1.5-2.3 mm Hg rise in diastolic and systolic blood pressure.

**Cardiac Arrhythmias.** Alcohol prolongs the QT interval, prolongs ventricular repolarization, and enhances sympathetic stimulation. Atrial arrhythmias associated with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Some 15-20% of idiopathic cases of atrial fibrillation may be induced by chronic ethanol use.

**Cardiomyopathy.** Alcohol can depress cardiac contractility and lead to cardiomyopathy. Echocardiography demonstrates global hypokinesis. Approximately half of all patients with idiopathic cardiomyopathy are alcohol-dependent. Alcohol-induced cardiomyopathy has a better prognosis if patients are able to stop drinking. Women are at greater risk of alcohol-induced cardiomyopathy than are men.

**Stroke.** Clinical studies indicate an increased incidence of hemorrhagic and ischemic stroke in persons who drink >40-60 g alcohol per day. Proposed etiological factors include:

- Alcohol-induced cardiac arrhythmias and associated thrombus formation
• High blood pressure from chronic alcohol consumption and subsequent cerebral artery degeneration
• Acute increases in systolic blood pressure and alterations in cerebral artery tone
• Head trauma

SKELETAL MUSCLE

Chronic, heavy, daily alcohol consumption is associated with decreased muscle strength, even when adjusted for other factors such as age, nicotine use, and chronic illness. Heavy doses of alcohol also can cause irreversible damage to muscle, reflected by a marked increase in the activity of creatine kinase in plasma. Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity. Approximately 50% of chronic heavy drinkers have evidence of type II fiber atrophy. Most patients with chronic alcoholism show evidence of a skeletal myopathy similar to alcoholic cardiomyopathy.

BODY TEMPERATURE

Ingestion of ethanol causes a feeling of warmth because alcohol enhances cutaneous and gastric blood flow. Increased sweating also may occur. Heat, therefore, is lost more rapidly, and the internal body temperature falls. After consumption of large amounts of ethanol, the central temperature-regulating mechanism becomes depressed, and the fall in body temperature may become pronounced. The action of alcohol in lowering body temperature is greater and more dangerous when the ambient environmental temperature is low. Studies of deaths from hypothermia suggest that alcohol is a major risk factor in these events.

DIURESIS

Alcohol inhibits the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland, resulting in enhanced diuresis. Alcoholics withdrawing from alcohol exhibit increased vasopressin release and a consequent retention of water, as well as dilutional hyponatremia.
GI SYSTEM

**Esophagus.** Alcohol is 1 of multiple factors associated with esophageal dysfunction. Ethanol also is associated with the development of esophageal reflux, Barrett esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer. Compared with nonalcoholic nonsmokers, alcohol-dependent patients who smoke have a 10-fold increased risk of developing cancer of the esophagus. There is little change in esophageal function at low blood alcohol concentrations, but at higher blood alcohol concentrations, a decrease in peristalsis and decreased lower esophageal sphincter pressure occur. Patients with chronic reflux esophagitis may respond to proton pump inhibitors and abstinence from alcohol.

**Stomach.** Heavy alcohol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol appears to stimulate gastric secretions by exciting sensory nerves in the buccal and gastric mucosa and promoting the release of gastrin and histamine. Beverages containing more than 40% alcohol also have a direct toxic effect on gastric mucosa. Clinical symptoms include acute epigastric pain that is relieved with antacids or histamine H₂ receptor antagonists. Alcohol exacerbates the clinical course and severity of ulcer symptoms. It appears to act synergistically with *Helicobacter pylori* to delay healing.

**Intestines.** Many alcoholics have chronic diarrhea as a result of malabsorption in the small intestine. The rectal fissures and *pruritus ani* that frequently are associated with heavy drinking probably are related to chronic diarrhea. The diarrhea is caused by structural and functional changes in the small intestine; the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes frequently are reversible after a period of abstinence.

**Pancreas.** Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. Acute alcoholic pancreatitis is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Management usually involves intravenous fluid replacement—often with nasogastric suction—and opioid pain medication. The etiology of acute pancreatitis probably is related to a direct toxic metabolic effect of alcohol on pancreatic acinar cells. Chronic pancreatitis is treated by replacing the endocrine and exocrine deficiencies that result from pancreatic
insufficiency. The development of hyperglycemia often requires insulin for control of blood-sugar levels (see Chapter 43). Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (see Chapter 46).

**Liver.** Ethanol produces dose-related deleterious effects in the liver that include fatty infiltration of the liver, hepatitis, and cirrhosis. The accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. This accumulation results from inhibition of both the tricarboxylic acid cycle and the oxidation of fat, in part owing to the generation of excess NADH produced by the actions of ADH and ALDH (see Figure 23–1). Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. Alcohol can affect stellate cells in the liver directly; chronic alcohol use is associated with transformation of stellate cells into collagen-producing, myofibroblast-like cells, resulting in deposition of collagen around terminal hepatic venules. The histological hallmark of alcoholic cirrhosis is the formation of Mallory bodies, which are thought to be related to an altered intermediate cytoskeleton. Acetaminophen-induced hepatic toxicity (see Chapters 4, 6, and 34) has been associated with alcoholic cirrhosis as a result of alcohol-induced increases in microsomal production of toxic acetaminophen metabolites.

**VITAMINS AND MINERALS**

Alcoholics often present with nutritional deficiencies owing to decreased intake, decreased absorption, or impaired utilization of nutrients. The peripheral neuropathy, Korsakoff psychosis, and Wernicke encephalopathy seen in alcoholics probably are caused by deficiencies of the B complex of vitamins (particularly thiamine). Retinol and ethanol compete for metabolism by ADH; vitamin A supplementation therefore should be monitored carefully in alcoholics when they are consuming alcohol to avoid retinol-induced hepatotoxicity. The chronic consumption of alcohol inflicts an oxidative stress on the liver owing to the generation of free radicals, contributing to ethanol-induced liver injury. The antioxidant effects of α-tocopherol (vitamin E) may ameliorate some of this ethanol-induced toxicity in the liver. Chronic alcohol consumption has been implicated in osteoporosis. Acute administration of ethanol produces an initial reduction in serum parathyroid hormone (PTH) and Ca\(^2+\) levels, followed by a
rebound increase in PTH that does not restore Ca\(^{2+}\) levels to normal.

**SEXUAL FUNCTION**

Despite the widespread belief that alcohol can enhance sexual activities, the opposite effect is generally noted. Many drugs of abuse, including alcohol, have disinhibiting effects that may lead initially to increased libido. Both acute and chronic alcohol use can lead to impotence in men. Increased blood ethanol concentrations lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. The incidence of impotence may be as high as 50% in patients with chronic alcoholism. Additionally, many chronic alcoholics develop testicular atrophy and decreased fertility. Gynecomastia is associated with alcoholic liver disease and is related to increased cellular response to estrogen and to accelerated metabolism of testosterone. Many female alcoholics complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development. Some data suggest that fertility rates are lower for alcoholic women.

**HEMATOLOGICAL AND IMMUNOLOGICAL EFFECTS**

Chronic alcohol use is associated with a number of anemias including microcytic anemias, macrocytic anemias, normochromic anemias, and alcohol-induced sideroblastic anemia. Alcohol-induced sideroblastic anemia may respond to vitamin B\(_6\) replacement. Alcohol use also is associated with reversible thrombocytopenia, although platelet counts <20,000/mm\(^3\) are rare. Alcohol also affects granulocytes and lymphocytes. Effects include leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. In some patients, depressed leukocyte migration into inflamed areas may account in part for the poor resistance of alcoholics to some types of infection (e.g., *Klebsiella* pneumonia, listeriosis, and tuberculosis). In vitro studies with human lymphocytes suggest that alcohol can suppress CD4 T-lymphocyte function.

**ACUTE ETHANOL INTOXICATION**

Signs of intoxication typical of CNS depression are seen in most people following 2-3 drinks, with the most prominent effect seen at
the times of peak BEC, ~30-60 min following consumption on an empty stomach. These symptoms include an initial feeling of stimulation (perhaps due to inhibition of CNS inhibitory systems), giddiness, muscle relaxation, and impaired judgment. Higher blood levels (~80 mg/dL or ~17 mM) are associated with slurred speech, incoordination, unsteady gait, and potential impairments of attention; levels between 80 and 200 mg/dL (~17-43 mM) are associated with more intense mood lability, and greater cognitive deficits, potentially accompanied by aggressiveness, and anterograde amnesia (an alcoholic blackout). Blood ethanol levels >200 mg/dL can produce nystagmus and unwanted falling asleep; levels of 300 mg/dL (~65 mM) and higher can produce failing vital signs, coma, and death. All of these symptoms are likely to be exacerbated and occur at a lower BEC when ethanol is taken along with other CNS depressants (e.g., diazepam or similar benzodiazepines), or with any drug or medication for which sleepiness and uncoordination are likely.

Many factors, such as body weight and composition and the rate of absorption from the GI tract, determine the concentration of ethanol in the blood after ingestion of a given amount of ethanol. On average, the ingestion of 3 standard drinks (42 g ethanol) on an empty stomach results in a maximum blood concentration of 67-92 mg/dL in men. After a mixed meal, the maximal blood concentration from 3 drinks is 30-53 mg/dL in men. For individuals with normal hepatic function, ethanol is metabolized at a rate of 1 standard drink every 60-90 min. In women with smaller body size and a lower leaner body mass (lower volume of distribution for ethanol), the equivalent consumption could produce levels about 30-50% higher, on average.

Diabetic coma, drug intoxication, cardiovascular accidents, and skull fractures may be confused with alcohol intoxication. Breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that after alcohol consumption. Blood alcohol levels are necessary to confirm the presence or absence of alcohol intoxication.

The treatment of acute alcohol intoxication is based on the severity of respiratory and CNS depression. Patients with evidence of respiratory depression should be
intubated to protect the airway and to provide ventilatory assistance. The stomach may be lavaged. Because ethanol is freely miscible with water, ethanol can be removed from blood by hemodialysis. Acute alcohol intoxication is not always associated with coma, and careful observation is the primary treatment. Usual care involves observing the patient in the emergency room for 4-6 h while the patient metabolizes the ingested ethanol. Blood ethanol levels will be reduced by 15 mg/dL/h. Great care must be taken, however, when using sedatives to treat patients who have ingested an excessive amount of another CNS depressant, such as, ethanol, because of synergistic effects.

**CLINICAL USES OF ETHANOL**

Systemically administered ethanol is confined to the treatment of poisoning by methyl alcohol and ethylene glycol. Methanol ingestion results in formation of methanol’s metabolites, formaldehyde and formic acid (see Figure 23–1). Formic acid causes nerve damage; its effects on the retina and optic nerve can cause blindness. Treatment consists of sodium bicarbonate to combat acidosis, hemodialysis, and the administration of ethanol, which slows formate production by competing with methanol for metabolism by alcohol dehydrogenase.

Dehydrated alcohol may be injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol also have been employed for inoperable pain. For example, lumbar paravertebral injections of ethanol may destroy sympathetic ganglia and thereby produce vasodilation, relieve pain, and promote healing of lesions in patients with vascular disease of the lower extremities.

**TOLERANCE, DEPENDENCE, AND CHRONIC ETHANOL USE**

*Tolerance* is defined as a reduced behavioral or physiological response to the same dose of ethanol (see Chapter 24). There is a marked acute tolerance that is detectable soon after administration of ethanol. Acute tolerance can be demonstrated by measuring behavioral impairment at the same BECs on the ascending limb of the absorption phase of the BEC–time curve (minutes after
ingestion of alcohol) and on the descending limb of the curve as BECs are lowered by metabolism (1 or more hours after ingestion). Behavioral impairment and subjective feelings of intoxication are much greater at a given BEC on the ascending than on the descending limb. There also is a chronic tolerance that develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance often has a metabolic component owing to induction of alcohol-metabolizing enzymes.

*Physical dependence* is demonstrated by the elicitation of a withdrawal syndrome when alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of alcohol consumption and include sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and in severe cases, seizures. In addition, 2 or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, fever, and tachycardia. Another aspect of dependence is craving and drug-seeking behavior, often termed *psychological dependence*.

**ETIOLOGY OF ALCOHOL USE DISORDERS AND THE ROLE OF GENES**

Environmental and cultural factors that contribute to alcohol use include stress, drinking patterns within one’s culture and peer group, availability of alcohol, and attitudes toward drunkenness. These nonbiological forces contribute to perhaps 70-80% of the initial decision to drink and at least 40% of the transition from drinking to alcohol-related problems and alcohol use disorders. Correspondingly, ~60% of the susceptibility to alcohol use disorders results from heritable factors (see Table 23–1).

Polymorphisms in the enzymes of ethanol metabolism seem to explain why some populations (mainly Asian) are protected from alcoholism. This has been attributed to genetic differences in alcohol- and aldehyde-metabolizing enzymes. Specifically, genetic variants of ADH that exhibit high activity and variants of ALDH that exhibit low activity protect against heavy drinking, probably because alcohol consumption by individuals who have these variants results in accumulation of acetaldehyde, which produces a variety of unpleasant effects. In contrast to these protective genetic variants, there are few consistent data about
genes responsible for increased risk for alcoholism. A genetic mechanism associated with an enhanced risk for both alcohol and other drug use disorders operates through the intermediate characteristic (or phenotype) of impulsivity and disinhibition. The identified polymorphisms include 2 variations of the GABA_A receptors, a variation in ADH4 hypothesized to be related to personality characteristics, and a muscarinic cholinergic receptor gene, CHRM2.

Another phenotype is associated with a low level of response to ethanol. Genetic contributions to the level of response have been tentatively identified for 2 GABA_A subunits, a polymorphism in the promoter region of the 5HT transporter that is associated with lower levels of 5HT in the synaptic space, a polymorphism of the p subunit of K+ channel KCNMA1, and a variant nicotinic ACh receptor that is also related to an increased risk for heavy smoking and related consequences. Antisocial alcoholism has been linked with polymorphisms of several 5HT receptors.

**TERATOGENIC EFFECTS: FETAL ALCOHOL SYNDROME**

Children born to alcoholic mothers display a common pattern of distinct dysmorphology known as *fetal alcohol syndrome* (FAS). The diagnosis of FAS typically is based on the observance of a triad of abnormalities in the newborn, including:

- A cluster of craniofacial abnormalities
- CNS dysfunction
- Pre- and/or postnatal stunting of growth

Hearing, language, and speech disorders also may become evident as the child ages. Children who do not meet all the criteria for a diagnosis of FAS still may show physical and mental deficits consistent with a partial phenotype, termed *fetal alcohol effects* (FAEs) or *alcohol-related neurodevelopmental disorders*. FAS is seen in offspring born to ~5% of heavy-drinking females. The incidence of FAS is believed to be in the range of 0.5-1 per 1000 live births in the general U.S. population, with rates as high as 2-3 per 1000 in African American and Native American populations.
Craniofacial abnormalities commonly observed in the diagnosis of FAS consist of a pattern of microcephaly, a long and smooth philtrum, shortened palpebral fissures, a flat midface, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum. Maternal drinking in the first trimester has been associated with craniofacial abnormalities. CNS dysfunction following in utero exposure to alcohol manifests in the form of hyperactivity, attention deficits, mental retardation, and learning disabilities. FAS is the most common cause of preventable mental retardation in the Western world, with afflicted children consistently scoring lower than their peers on a variety of IQ tests. Although the evidence is not conclusive, there is a suggestion that even moderate alcohol consumption (2 drinks per day) in the second trimester of pregnancy is correlated with impaired academic performance of offspring at age 6. Maternal age also may be a factor. Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol. Apart from the risk of FAS or FAEs to the child, the intake of high amounts of alcohol by a pregnant woman, particularly during the first trimester, greatly increases the chances of spontaneous abortion.

PHARMACOTHERAPY OF ALCOHOLISM

Currently, 3 drugs are approved in the U.S. for treatment of alcoholism: disulfiram (Antabuse), naltrexone (Revia), and acamprosate (Table 23–2). Disulfiram has a long history of use but has fallen into disfavor because of its side effects and problems with patient adherence to therapy. Naltrexone and acamprosate were introduced more recently. The goal of these medications is to assist the patient in maintaining abstinence.

Table 23–2

Oral Medications for Treating Alcohol Abuse
NALTREXONE

Naltrexone, a N-opioid receptor antagonist, is chemically related to the highly selective opioid-receptor antagonist naloxone (NARCAN) but has higher oral bioavailability and a longer duration of action. These drugs were used initially in the treatment of opioid overdose and dependence because of their ability to antagonize all the actions of opioids (see Chapters 18 and 24). There is evidence that naltrexone blocks activation by alcohol of dopaminergic pathways in the brain that are thought to be critical to reward.

Naltrexone helps to maintain abstinence by reducing the urge to drink and increasing control when a “slip” occurs. It is not a “cure” for alcoholism and does not prevent relapse in all patients. Naltrexone works best when used in conjunction with some form of psychosocial therapy, such as cognitive behavioral therapy. It typically is administered after detoxification and given at a dose of 50 mg/day for several months. Adherence to the regimen is important to ensure the therapeutic value of naltrexone and has proven to be a problem for some patients. The most common side effect of naltrexone is nausea, which is more common in women than in men and subsides if the patients abstain from alcohol. When given in excessive doses, naltrexone can cause liver damage. It is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease. Nalmefene (REVEX) is another opioid antagonist that has a number of advantages over naltrexone, including greater oral bioavailability, longer duration of action, and lack of dose-dependent liver toxicity.

ACAMPROSATE

(N-acetylhomotaurine; CAMPRAL) is an analogue of GABA.
A number of double-blind, placebo-controlled studies have demonstrated that acamprosate (1.3-2 g/day) decreases drinking frequency and reduces relapse drinking in abstinent alcoholics and appears to have efficacy similar to that of naltrexone. Acamprosate generally is well tolerated by patients, with diarrhea being the main side effect. The drug undergoes minimal metabolism in the liver, is excreted primarily by the kidneys, and has an elimination $t_{1/2}$ of 18 h after oral administration. Concomitant use of disulfiram appears to increase the effectiveness of acamprosate, without any adverse drug interactions being noted.

**DISULFIRAM**

*Disulfiram* (tetraethylthiuram disulfide; ANTABUSE), given alone, is a relatively nontoxic substance, but it inhibits ALDH activity and causes the blood acetaldehyde concentration to rise to 5-10 times above the level achieved when ethanol is given to an individual not pretreated with disulfiram.

Following the administration of disulfiram, both cytosolic and mitochondrial forms of ALDH are irreversibly inactivated to varying degrees, and the concentration of acetaldehyde rises. It is unlikely that disulfiram itself is responsible for the enzyme inactivation in vivo; several active metabolites of the drug, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH in vitro. These metabolites reach significant concentrations in plasma following the administration of disulfiram.

The ingestion of alcohol by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. Within 5-10 min,
the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is replaced by pallor; the blood pressure may fall to shock levels. Alarming reactions may result from the ingestion of even small amounts of alcohol in persons being treated with disulfiram. The use of disulfiram as a therapeutic agent thus is not without danger, and it should be attempted only under careful medical and nursing supervision. Patients must learn to avoid disguised forms of alcohol, as in sauces, fermented vinegar, cough syrups, and even aftershave lotions and back rub lotions.

Disulfiram never should be administered until the patient has abstained from alcohol for at least 12 h. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1-2 weeks. Maintenance dosage then ranges from 125-500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH.

Disulfiram and/or its metabolites can inhibit many enzymes with crucial sulfhydryl groups, and it thus has a wide spectrum of biological effects. It inhibits hepatic CYPs and thereby interferes with the metabolism of phenytoin, chlordiazepoxide, barbiturates, warfarin, and other drugs. Disulfiram by itself usually is innocuous, but it may cause acne-form eruptions, urticaria, lassitude, tremor, restlessness, headache, dizziness, a garlic-like or metallic taste, and mild GI disturbances. Peripheral neuropathies, psychosis, and ketosis also have been reported.

**OTHER AGENTS**

**Ondansetron**, a 5HT₃-receptor antagonist and antiemetic drug (see Chapters 13 and 46), reduces alcohol consumption in laboratory animals and currently is being tested in humans. Preliminary findings suggest that ondansetron is effective in the treatment of early onset alcoholics, who respond poorly to
psychosocial treatment alone, although the drug does not appear to work well in other types of alcoholics. Ondansetron administration lowers the amount of alcohol consumed, particularly by drinkers who consume $\geq 10$ drinks per day. It also decreases the subjective effects of ethanol on 6 of 10 scales measured, including the desire to drink, while at the same time not having any effect on the pharmacokinetics of ethanol.

**Topiramate**, a drug used for treating seizure disorders *(see Chapter 21)*, appears useful for treating alcohol dependence. Compared with the placebo group, patients taking topiramate achieved more abstinent days and a lower craving for alcohol. The mechanism of action of topiramate is not well understood but is distinct from that of other drugs used for the treatment of dependence (e.g., opioid antagonists), suggesting that it may provide a new and unique approach to pharmacotherapy of alcoholism.
The terminology used in discussing drug dependence, abuse, and addiction has long been confusing. Confusion stems from the fact that repeated use of certain prescribed medications can produce neuroplastic changes resulting in 2 distinctly abnormal states. The first is dependence, or “physical” dependence, produced when there is progressive pharmacological adaptation to the drug resulting in tolerance. In the tolerant state, repeating the same dose of drug produces a smaller effect. If the drug is abruptly stopped, a withdrawal syndrome ensues in which the adaptive responses are now unopposed by the drug. The appearance of withdrawal symptoms is the cardinal sign of “physical” dependence. Addiction, the second abnormal state produced by repeated drug use, occurs in only a minority of those who initiate drug use; addiction leads progressively to compulsive, out-of-control drug use.

Addiction can be defined fundamentally as a form of maladaptive memory. It begins with the administration of substances (e.g., cocaine) or behaviors (e.g., the thrill of gambling) that directly and intensely activate brain reward circuits. Activation of these circuits motivates normal behavior and most humans simply enjoy the experience without being compelled to repeat it. For some (~16% of those who try cocaine) the experience produces strong conditioned associations to environmental cues that signal the availability of the drug or the behavior. The individual becomes drawn into compulsive repetition of the experience focusing on the immediate pleasure despite negative long-term consequences and neglect of important social responsibilities. The distinction between dependence and addiction is important because patients with pain sometimes are deprived of adequate opioid medication simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped or reduced abruptly.

ORIGINS OF SUBSTANCE DEPENDENCE
Most of those who initiate drug use do not progress to become addicts. Many variables operate simultaneously to influence the likelihood that a beginning drug user will lose control and develop an addiction. These variables can be organized into 3 categories: agent (drug), host (user), and environment (Table 24–1).

**AGENT (DRUG) VARIABLES.** Reinforcement refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused. Reinforcing properties of drugs are associated with their capacity to increase
neuronal activity in critical brain areas (see Chapter 14). Cocaine, amphetamine, ethanol, opiates, cannabinoids, and nicotine all reliably increase extracellular fluid dopamine (DA) levels in the ventral striatum, specifically the nucleus accumbens region. In contrast, drugs that block DA receptors generally produce bad feelings, i.e., dysphoric effects. Despite strong correlative findings, a causal relationship between DA and euphoria/dysphoria has not been established, and other findings emphasize additional roles of serotonin (5HT), glutamate, norepinephrine (NE), endogenous opioids, and γ-aminobutyric acid (GABA) in mediating the reinforcing effects of drugs.

The abuse liability of a drug is enhanced by rapidity of onset. When coca leaves are chewed, cocaine is absorbed slowly and this produces low cocaine levels in the blood and few, if any, behavior problems. Crack, sold illegally and at a low price ($1-3 per dose), is alkaloidal cocaine (free base) that can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable to those resulting from intravenous cocaine owing to the large surface area for absorption into the pulmonary circulation following inhalation. Thus, inhalation of crack cocaine is much more addictive than chewing, drinking, or sniffing cocaine. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 24–2). This does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, there are other variables listed in the categories of host factors and environmental conditions that influence the development of addiction.

| Table 24–2 |

Dependence among Users 1990–1992
HOST (USER) VARIABLES. Effects of drugs vary among individuals. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion and in receptor-mediated responses may contribute to the different degrees of reinforcement or euphoria observed among individuals (see Chapters 6 and 7). Innate tolerance to alcohol may represent a biological trait that contributes to the development of alcoholism (see Chapter 23). While innate tolerance increases vulnerability to alcoholism, impaired metabolism may protect against it (see Chapter 23). Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent.

Psychiatric disorders constitute another category of host variables. People with anxiety, depression, insomnia, or even shyness may find that certain drugs give them relief. However, the apparent beneficial effects are transient, and repeated use of the drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, most of these symptoms begin after the person starts abusing drugs. Thus, drugs of abuse appear to produce more psychiatric symptoms than they relieve.

ENVIRONMENTAL VARIABLES. Initiating and continuing illegal drug use is influenced significantly by societal norms and peer pressure.
PHARMACOLOGICAL PHENOMENA

TOLERANCE. Tolerance, the most common response to repetitive use of the same drug, can be defined as the reduction in response to the drug after repeated administrations. Figure 24–1 shows an idealized dose-response curve for an administered drug. As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). There are many forms of tolerance likely arising through multiple mechanisms.

Figure 24–1 Shifts in a dose-response curve with tolerance and sensitization. With tolerance, there is a shift of the curve to the right such that doses higher than initial doses are required to achieve the same effects. With sensitization, there is a leftward shift of the curve such that for a given dose, there is a greater effect than seen after the initial dose.

Tolerance to some drug effects develops much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and addicts tend to increase their dose in order to reexperience that elusive “high.” In contrast, tolerance to the GI effects of opioids develops more slowly. The discrepancy between tolerance to euphoric effects (rapid) and tolerance to effects on vital functions (slow), such as respiration and blood pressure, can lead to potentially fatal overdoses.
**Innate tolerance** refers to genetically determined lack of sensitivity to a drug that is observed the first time that the drug is administered. **Acquired tolerance** can be divided into 3 major types: pharmacokinetic, pharmacodynamic, and learned tolerance, and includes acute, reverse, and cross-tolerance.

**Pharmacokinetic or dispositional tolerance** refers to changes in the distribution or metabolism of a drug after repeated administrations such that a given dose produces a lower blood concentration than the same dose did on initial exposure. The most common mechanism is an increase in the rate of metabolism of the drug. For example, barbiturates stimulate the production of higher levels of hepatic CYPs, causing more rapid removal and breakdown of barbiturates from the circulation.

**Pharmacodynamic tolerance** refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is reduced. Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal-transduction pathways (see Chapter 3). **Learned tolerance** refers to a reduction in the effects of a drug due to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called behavioral tolerance. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. At higher levels of intoxication, behavioral tolerance is overcome, and the deficits are obvious.

**Conditioned tolerance** (situation-specific tolerance) develops when environmental cues or situations consistently are paired with the administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, and so on, there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug always is taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur, which will prevent the full manifestation of the drug’s effects (i.e., cause tolerance). This mechanism follows classical (pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is “expected.”

**Acute tolerance** refers to rapid tolerance developing with repeated use on a single occasion, such as in a “binge.” For example, repeated doses of cocaine over several hours produce a decrease in response to subsequent doses of
cocaine during the binge. This is the opposite of sensitization, observed with an intermittent dosing schedule. Sensitization or reverse tolerance refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose-response curve (see Figure 24–1). Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually ~1 day. Sensitization can occur with stimulants such as cocaine or amphetamine. Cross-tolerance occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same structural and mechanistic category. Understanding cross-tolerance is important in the medical management of persons dependent on any drug.

Detoxification is a form of treatment for drug dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence. Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin also are tolerant to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that activates opioid receptors.

**PHYSICAL DEPENDENCE.** Physical dependence is a state that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. A person in this adapted or physically dependent state requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems must readjust to a new equilibrium without the drug.

**WITHDRAWAL SYNDROME.** The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence. Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. Withdrawal symptoms have at least 2 origins:
• Removal of the drug of dependence
• CNS hyperarousal owing to readaptation to the absence of the drug of dependence

Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Withdrawal symptoms are characteristic for a given category of drugs and tend to be opposite to the original effects produced by the drug before tolerance developed. Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain medications repeatedly. These symptoms in themselves do not imply that the individual is involved in misuse or addiction. *Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal* symptoms if the drug is stopped abruptly rather than gradually.

**CLINICAL ISSUES**

Abuse of combinations of drugs is common. Alcohol is so widely available that it is combined with practically all other categories. Some combinations reportedly are taken because of their interactive effects. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician must be aware of these possible combinations because each drug may require specific treatment.

**CNS DEPRESSANTS**

**ETHANOL.** More than 90% of American adults report experience with ethanol (commonly called “alcohol”). Ethanol is classified as a depressant because it produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems (see Chapter 23). Heavy use of ethanol causes development of tolerance and physical dependence sufficient to define an alcohol withdrawal syndrome (Table 24–3).
Tolerance, Physical Dependence, and Withdrawal. The symptoms of mild intoxication by alcohol vary among individuals. Some experience motor incoordination and sleepiness. Others initially become stimulated. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at high alcohol levels. The innate tolerance to alcohol varies greatly among individuals and is related to family history of alcoholism. Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300-400 mg/dL) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose, and thus the margin of safety (therapeutic index) is decreased.

Heavy consumers of alcohol acquire tolerance and also develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. The alcohol-withdrawal syndrome generally depends on the size of the average daily dose and usually is “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life-threatening until they occur in conjunction with other problems, such as infection, trauma,
malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of delirium tremens becomes likely.

Alcohol addiction produces cross-tolerance to other sedatives such as benzodiazepines. This tolerance is operative in abstinent alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives. This is particularly true for benzodiazepines, which are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol. The chronic use of alcohol and other sedatives is associated with the development of depression and the risk of suicide. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve with abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (e.g., thiamine deficiency). Medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and GI effects, and malnutrition, in addition to the CNS dysfunctions outlined earlier. Ethanol readily crosses the placental barrier, producing the fetal alcohol syndrome, a major cause of mental retardation (see Chapter 23).

Pharmacological Interventions

Detoxification. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 24–3, a short-acting benzodiazepine such as oxazepam can be used at a dose of 15-30 mg every 6-8 h according to the stage and severity of withdrawal; some authorities recommend a long-acting benzodiazepine unless there is demonstrated liver impairment. Anticonvulsants such as carbamazepine have been shown to be effective in alcohol withdrawal, but not as well as benzodiazepines.

Pharmacotherapy. Detoxification is the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is accomplished mainly by behavioral approaches. Disulfiram (Antabuse; see Chapter 23) has been useful in some programs that focus behavioral efforts on ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, resulting in the
accumulation of acetaldehyde, which produces an unpleasant flushing reaction when alcohol is ingested. Knowledge of this unpleasant reaction helps the patient to resist taking a drink. However, disulfiram has not been found to be effective in controlled clinical trials because so many patients failed to take it.

Naltrexone (REViA; see Chapter 23) is an opioid receptor antagonist that blocks the reinforcing properties of alcohol. Chronic administration of naltrexone was found to decrease the rate of relapse to alcohol drinking. It works best in combination with behavioral treatment programs that encourage adherence to medication and abstinence from alcohol. A depot preparation with a duration of 30 days (VIVITROL) is now available; it greatly improves medication adherence. Acamprosate (CAMPRAL) is a competitive inhibitor of the N-methyl-D-aspartate (NMDA)–type glutamate receptor (see Table 23–2). The drug appears to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse (see Chapter 23).

**BENZODIAZEPINES.** Benzodiazepines are used mainly for the treatment of anxiety disorders and insomnia (see Chapters 15 and 17). Considering their widespread use, intentional abuse of prescription benzodiazepines is relatively uncommon. The proportion of patients who become tolerant increases after several months of use and reducing the dose or stopping the medication produces withdrawal symptoms (Table 24–4).

<table>
<thead>
<tr>
<th>Table 24–4</th>
</tr>
</thead>
<tbody>
<tr>
<td>Benzodiazepine Withdrawal Symptoms</td>
</tr>
</tbody>
</table>
It can be difficult to distinguish withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was prescribed initially. Some patients may increase their dose over time because tolerance definitely develops to the sedative effects. Antianxiety benefits, however, seem to continue to occur long after tolerance to the sedating effects. Moreover, these patients continue to take the medication for years according to medical directions without increasing their dose and are able to function very effectively as long as they take the benzodiazepine. Patients with a history of alcohol- or other drug-abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

**Pharmacological Interventions.** If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms may occur during this outpatient detoxification, but in most cases the symptoms are mild. If anxiety symptoms return, a non-benzodiazepine such as buspirone may be prescribed. Some authorities recommend transferring the patient to a long $t_{1/2}$ benzodiazepine during detoxification; others recommend the anticonvulsants carbamazepine and phenobarbital. Patients who have been on low doses of benzodiazepines for years usually have no adverse effects. The specific benzodiazepine receptor antagonist flumazenil is useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia.

Abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a
complex clinical pharmacological problem requiring knowledge of the pharmacokinetics of each drug. One approach to complex detoxification is to focus on the CNS-depressant drug and temporarily hold the opioid component constant with a low dose of methadone. A long-acting benzodiazepine such as diazepam or clorazepate (TRANXENE, others) or a long-acting barbiturate such as phenobarbital can be used to block the sedative withdrawal symptoms. After detoxification, the prevention of relapse requires a long-term outpatient rehabilitation program similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers but specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

**BARBITURATES.** Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways.

Treatment of abuse and addiction to barbiturates should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn and of possible causes for insomnia that are treatable by other means. Insomnia often is a symptom of an underlying chronic problem, such as depression or respiratory dysfunction. Prescription of sedative medications can change the physiology of sleep with subsequent tolerance to these medication effects. When the sedative is stopped, there is a rebound effect with worsened insomnia. This medication-induced insomnia requires detoxification by gradual dose reduction.

**NICOTINE**

Nicotine and agents for smoking cessation are discussed in Chapter 11. Because nicotine provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. Although >80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit.
Cigarette (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (≤5 cigarettes per day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 seconds. Thus, each puff produces some discrete reinforcement. With 10 puffs per cigarette, the 1-pack-per-day smoker reinforces the habit 200 times daily.

*Negative reinforcement* refers to the benefits obtained from the termination of an unpleasant state. In dependent smokers, the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain nicotine level and thus avoid nicotine withdrawal symptoms (Table 24–5). Depressed mood (dysthymic disorder, affective disorder) is associated with nicotine dependence, but it is not known whether depression can predispose one to begin smoking or depression develops during the course of nicotine dependence.

**PHARMACOLOGICAL INTERVENTIONS.** The nicotine withdrawal syndrome can be alleviated by nicotine-replacement therapy, available with a prescription (e.g., NICOTROL inhaler and nasal spray) or without (e.g., NICORETTE gum and others; COMMIT lozenges and others; and NICODERM CQ transdermal patch and others). Different methods of nicotine delivery provide different blood nicotine levels over varying time courses (Figure 24–2). These methods suppress the symptoms of nicotine withdrawal. Although this results in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. A sustained-release preparation of the antidepressant bupropion (ZYBAN; see
Chapter 15) improves abstinence rates among smokers and remains a useful option. The cannabinoid CB$_1$ receptor inverse agonist rimonabant improves abstinence rates and reduces the weight gain seen frequently in ex-smokers but is linked to depressive and neurologic symptoms. Varenicline, a partial agonist at the t$_{4;2}$ subtype of the nicotinic acetylcholine receptor, improves abstinence rates but has also been linked to risk of developing suicidal ideation. See Chapter 11 for the pharmacology of varenicline.

**OPIOIDS**

Opioid drugs are used primarily for the treatment of pain *(see Chapter 18)*. Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus, opioid drugs also are taken outside medical channels for the purpose of obtaining the effects on mood.

Heroin is the most frequently abused opiate. There is no legal supply of heroin for clinical use in the U.S.; however, heroin is widely available on the illicit market. The purity of street heroin in the U.S. has increased from ~4 mg heroin per 100 mg bag (range: 0-8 mg; the rest was filler such as quinine) to reach 45-75% purity in many large cities, with some samples testing as high as 90%. This increase in purity has led to increased levels of physical dependence among heroin addicts. Users who interrupt regular dosing develop more severe withdrawal symptoms. The more potent supplies can be smoked or administered nasally (snorted), making the initiation of heroin use accessible to people who would not insert a needle into their veins.

**TOLERANCE, DEPENDENCE, AND WITHDRAWAL.** Injection of a heroin solution produces a variety of sensations described as warmth, taste, or high and intense pleasure (“rush”) often compared with sexual orgasm. There are some differences among the opioids in their acute effects, with morphine producing more of a histamine-releasing effect and meperidine producing more excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and hydromorphone in double-blind tests. The popularity of heroin may be due to its availability on the illicit market and its rapid onset. After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility, crosses the blood-brain barrier quickly, and is deacetylated
to the active metabolites 6-monoacetyl morphine and morphine. After the intense euphoria, which lasts from 45 seconds to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3-5 h, depending on the dose. Experienced users may inject 2 to 4 times per day. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (Figure 24–3). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids.

![Figure 24–3](image)

**Figure 24–3** Comparative responses to heroin and methadone. A person who injects heroin (↑) several times per day oscillates (red line) between being sick and being high. In contrast, the a methadone patient (purple line) remains in the “normal” range (blue band) with little fluctuation after dosing once per day. Ordinate values represent the subject’s mental and physical state, not plasma levels of the drug.

Based on patient reports, tolerance develops early to the euphoria-producing effects of opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as fentanyl (SUBLIMAZE, others).
Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. Apart from the behavioral changes and the risk of overdose, chronic use of opioids is relatively nontoxic in and of itself. Nonetheless, the mortality rate for street heroin users is very high. Heroin users commonly acquire bacterial infections producing skin abscesses; endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and acquired immune deficiency syndrome (AIDS).

Opioids frequently are used in combinations with other drugs. A common combination is heroin and cocaine (“speedball”). Users report an improved euphoria because of the combination, and there is evidence of an interaction, because cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic cocaine users.

The first stage of treatment addresses physical dependence and consists of detoxification. The opioid-withdrawal syndrome (Table 24–6) is very unpleasant but not life-threatening. It begins within 6-12 h after the last dose of a short-acting opioid and as long as 72-84 h after a very long-acting opioid medication. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5-10 days) and intense. Methadone withdrawal is slower in onset and lasts longer.

**Characteristics of Opioid Withdrawal**
PHARMACOLOGICAL INTERVENTIONS. Opioid withdrawal signs and symptoms can be treated by 3 different approaches. The first and most commonly used approach consists of transfer to a prescription opioid medication and then gradual dose reduction. It is convenient to change the patient from a short-acting opioid such as heroin to a long-acting one such as methadone. The initial dose of methadone is typically 20-30 mg. The first day’s total dose then can be calculated depending on the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral clonidine (Catapres, others), an $\alpha_2$ adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. Many of the autonomic symptoms of opioid withdrawal result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine can alleviate many of the symptoms of opioid withdrawal but not the generalized aches and opioid craving. When using clonidine to treat withdrawal, the dose must be titrated according to the stage and severity of withdrawal; postural hypotension is commonly a side effect. A third method of treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation using transcutaneous electrical stimulation. While attractive theoretically, this has not yet been found to be practical.

LONG-TERM MANAGEMENT. If patients are simply discharged from the
hospital after withdrawal from opioids, there is a high probability of a quick return to compulsive opioid use. Numerous factors influence relapse. The withdrawal syndrome does not end in 5-7 days; a protracted withdrawal syndrome (see Table 24–6) persists for up to 6 months. Physiological measures tend to oscillate as though a new set point were being established; during this phase, outpatient drug-free treatment has a low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

The most successful treatment for heroin addiction consists of stabilization on methadone in accordance with state and federal regulations. Patients who relapse repeatedly during drug-free treatment can be transferred directly to methadone without requiring detoxification. The dose of methadone must be sufficient to prevent withdrawal symptoms for at least 24 h. The introduction of buprenorphine, a partial agonist at x-opioid receptors (see Chapter 18), represents a major change in the treatment of opiate addiction. This drug produces minimal withdrawal symptoms when discontinued and has a low potential for overdose, a long duration of action, and the ability to block heroin effects. Treatment can take place in a qualified physician’s private office rather than in a special center, as required for methadone. When taken sublingually, buprenorphine (SUBUTEX) is active, but it also has the potential to be dissolved and injected (abused). A buprenorphine-naloxone combination (SUBOXONE) is also available. When taken orally (sublingually), the naloxone moiety is not effective, but if the patient abuses the medication by injecting, the naloxone will block or diminish the subjective high that could be produced by buprenorphine alone.

**ANTAGONIST TREATMENT.** Naltrexone (REVI A, others; see Chapter 18) is an antagonist with a high affinity for the μ-opioid receptor; it will competitively block the effects of heroin or other μ-receptor agonists. Naltrexone will not satisfy craving or relieve protracted withdrawal symptoms, but it can be used after detoxification for patients with high motivation to remain opioid-free.

**COCAINE AND OTHER PSYCHOSTIMULANTS**

**COCAINE.** The number of frequent users (at least weekly) of cocaine in the U.S. has remained steady since 1991 at ~600,000. Not all users
become addicts. A key factor is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, “crack”) suitable for smoking and in the hydrochloride powder form suitable for nasal or intravenous use. Drug abuse occurs about twice as frequently in men as in women.

The reinforcing effects of cocaine and cocaine analogs correlate best with their effectiveness in blocking the transporter that recovers DA from the synapse. This leads to increased DA concentrations at critical brain sites. However, cocaine also blocks both NE and 5HT reuptake, and chronic use of cocaine leads to changes in these neurotransmitter systems. The general pharmacology and medicinal use of cocaine as a local anesthetic are discussed in Chapter 20.

Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Repeated doses may lead to involuntary motor activity, stereotyped behavior, and paranoia. Irritability and increased risk of violence are found among heavy chronic users. The $t_{1/2}$ of cocaine in plasma is ~50 min, but inhalant (crack) users typically desire more cocaine after 10-30 min.

The major route for cocaine metabolism involves hydrolysis of each of its 2 ester groups. Benzoylecgonine, produced on loss of the methyl group, represents the major urinary metabolite and can be found in the urine for 2-5 days after a binge. As a result, the benzoylecgonine test is a valid method for detecting cocaine use; the metabolite remains detectable in the urine of heavy users for up to 10 days. Ethanol is frequently abused with cocaine, as it reduces the irritability induced by cocaine. Dual addiction to alcohol and cocaine is common. When cocaine and alcohol are taken concurrently, cocaine may be transesterified to cocaethylene, which is equipotent to cocaine in blocking DA reuptake.

Addiction is the most common complication of cocaine abuse. In general, stimulants tend to be abused much more irregularly than opioids, nicotine, and alcohol. Binge use is very common, and a binge may last hours to days, terminating only when supplies of the drug are exhausted.

Toxicity. Other risks of cocaine, beyond the potential for addiction, include
cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, and seizures. Death from trauma also is associated with cocaine use. Cocaine may induce premature labor and abruptio placentae. Cocaine has been reported to produce a prolonged and intense orgasm if taken prior to intercourse, and users often indulge in compulsive and promiscuous sexual activity. However, chronic cocaine use reduces sexual drive. Chronic use is also associated with psychiatric disorders, including anxiety, depression, and psychosis.

Tolerance, Dependence, and Withdrawal. In intermittent users of cocaine, the euphoric effect typically is not subject to sensitization. On the contrary, most experienced users become desensitized and, over time, require more cocaine to obtain euphoria, i.e., tolerance develops. Because cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or “crash.” The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 24–7. Careful studies of cocaine users during withdrawal show gradual diminution of these symptoms over 1-3 weeks. Residual depression, often seen after cocaine withdrawal, should be treated with antidepressant agents if it persists (see Chapter 15).

Pharmacological Interventions. Because cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required. The major problem in treatment is not detoxification but helping the patient to resist the urge to resume compulsive cocaine use. Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous, and behavioral treatments based on reinforcing cocaine-free urine tests, result in significant improvement in the majority of cocaine users. Nonetheless, there is great interest in finding a medication that can aid in the rehabilitation of cocaine addicts.

AMPHELINE AND RELATED AGENTS. Subjective effects
similar to those of cocaine are produced by amphetamine, 
dextroamphetamine, methamphetamine, phenmetrazine, 
methylphenidate, and diethylpropion.

Amphetamines increase synaptic DA, NE, and 5HT primarily by stimulating 
pre-synaptic release rather than by blockade of reuptake, as is the case with 
cocaine. Intravenous or smoked methamphetamine produces an 
abuse/dependence syndrome similar to that of cocaine, although clinical 
deterioration may progress more rapidly. Methamphetamine addiction has 
become a major public health problem in the U.S. Behavioral and medical 
treatments for methamphetamine addiction are similar to those used for cocaine.

**CAFFEINE.** Caffeine, a mild stimulant, is the most widely used 
psychoactive drug in the world. It is present in soft drinks, coffee, tea, 
cocoa, chocolate, and numerous prescription and over-the-counter 
drugs.

Caffeine mildly increases NE and DA release and enhances neural activity in 
numerous brain areas. Caffeine is absorbed from the digestive tract, is distributed 
rapidly throughout all tissues, and easily crosses the placental barrier. Many of 
caffeine’s effects are believed to occur by means of competitive antagonism at 
adenosine receptors. Adenosine is a neuromodulator (see Chapter 14) that 
resembles caffeine structurally. The mild sedating effects that occur when 
adenosine activates particular adenosine-receptor subtypes can be antagonized 
by caffeine. Tolerance occurs rapidly to the stimulating effects of caffeine. Thus, 
a mild withdrawal syndrome has been produced in controlled studies by abruptly 
discontinuing the intake of as little as 1 to 2 cups of coffee per day. Caffeine 
withdrawal consists of feelings of fatigue and sedation. With higher doses, 
headaches and nausea have been reported during withdrawal; vomiting is rare.

**CANNABINOIDs (MARIJUANA)**

The cannabis plant has been cultivated for centuries for its presumed 
medicinal and psychoactive properties. The smoke from burning 
cannabis contains many chemicals, including 61 different 
cannabinoids that have been identified. One of these, Δ-9-
tetrahydrocannabinol (Δ-9-THC), produces most of the characteristic pharmacological effects of smoked marijuana. Marijuana is the most commonly used illegal drug in the U.S. The human cannabinoid endogenous ligand/receptor/signaling systems are described in Chapter 14.

The pharmacological effects of Δ-9-THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effect most frequently sought is the “high” and “mellowing out.” This effect is described as different from the high produced by a stimulant or opiate. Effects vary with dose, but typically last ~2 h. During the high, cognitive functions, perception, reaction time, learning, and memory are impaired. Coordination and tracking behavior may be impaired for several hours beyond the perception of the high. Marijuana also produces complex behavioral changes such as giddiness and increased hunger. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana. Numerous clinical reports suggest that marijuana use may precipitate a recurrence of psychosis in people with a history of schizophrenia. One of the most controversial of the reputed effects of marijuana is the production of an “amotivational syndrome.” This syndrome is not an official diagnosis, but it has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. There is no evidence that marijuana damages brain cells or produces any permanent functional changes.

Marijuana has medicinal effects, including antiemetic properties that relieve side effects of anticancer chemotherapy. It also has muscle-relaxing effects, anticonvulsant properties, and the capacity to reduce the elevated intraocular pressure of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Thus, there is no clear advantage of marijuana over conventional treatments for any of these indications.

**TOLERANCE, DEPENDENCE, AND WITHDRAWAL.** Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also
disappears rapidly. Withdrawal symptoms are not seen in clinical populations.
Human subjects develop a withdrawal syndrome when they receive regular oral
doses of the agent (Table 24–8). This syndrome, however, is only seen clinically
in persons who use marijuana on a daily basis and then suddenly stop. Marijuana
abuse and addiction have no specific treatments. Heavy users may suffer from
accompanying depression and thus may respond to antidepressant medication.

**PSYCHEDELIC AGENTS**

There are 2 main categories of psychedelic compounds, indoleamines and
phenethylamines. The indoleamine hallucinogens include LSD, N, N-dimethyltryptamine (DMT), and psilocybin. The
phenethylamines include mescaline, dimethoxymethylamphetamine (DOM), methylenedioxyamphetamine (MDA), and MDMA. Both
groups have a relatively high affinity for 5HT\textsubscript{2} receptors (see Chapter 13), but they differ in their affinity for other subtypes of 5HT
receptors. There is a good correlation between the relative affinity of
these compounds for 5HT\textsubscript{2} receptors and their potency as
hallucinogens in humans. However, LSD interacts with many receptor
subtypes at nanomolar concentrations, and it is not possible to
attribute the psychedelic effects to any single 5HT receptor subtype.

**LSD**. LSD is the most potent hallucinogenic drug and produces
significant psychedelic effects with a total dose of as little as 25-50
dg. This drug is >3000 times more potent than mescaline. LSD is sold
on the illicit market in a variety of forms. A popular contemporary
system involves postage stamp-sized papers impregnated with varying doses of LSD (50-300 μg or more).

The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40-60 min, peaking at 2-4 h, and gradually returning to baseline over 6-8 h. At a dose of 100 μg, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items such as the pattern of hairs on the back of the hand. A “bad trip” usually consists of severe anxiety, although at times it is marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders. Claims about the potential of psychedelic drugs for enhancing psychotherapy and for treating addictions and other mental disorders are not supported by controlled studies; there is no current indication for these drugs as medications.

Tolerance, Physical Dependence, and Withdrawal. Frequent, repeated use of psychedelic drugs is unusual, and thus tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after 3 or 4 daily doses, but no withdrawal syndrome has been observed.

Pharmacological Intervention. Because of the unpredictability of psychedelic drug effects, any use carries some risk. Users may require medical attention because of “bad trips.” Severe agitation may respond to diazepam (20 mg orally). “Talking down” by reassurance also is effective and is the management of first choice. Antipsychotic medications (see Chapter 16) may intensify the experience and thus are not indicated. A particularly troubling aftereffect of the use of LSD and similar drugs is the occasional occurrence of episodic visual
disturbances. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. Flashbacks belong to an official diagnostic category called the *hallucinogen persisting perception disorder*. The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages. The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, antipsychotic agents, and anxiety states.

**MDMA (“ECSTASY”) AND MDA.** MDMA and MDA are phenylethylamines that have stimulant as well as psychedelic effects.

Acute effects are dose-dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is 1 or 2 100-mg tablets and lasts 3-6 h, although dosage and potency of street samples are variable (~100 mg per tablet).

**PHENCYCLIDINE (PCP).** PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose.

As little as 50 μg/kg produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and may exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged nonreactive pupils. PCP binds with high affinity to
sites located in the cortex and limbic structures, resulting in blocking of NMDA–type glutamate receptors (see Chapter 14). LSD and other psychedelics do not bind to NMDA receptors. There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogs that block NMDA receptors but with fewer psychoactive effects. Both PCP and ketamine (“Special K”), another “club drug,” produce similar effects by altering the distribution of the neurotransmitter glutamate.

*Pharmacological Intervention.* Overdose must be treated by life support because there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma may last 7-10 days. The agitated or psychotic state produced by PCP can be treated with diazepam. Prolonged psychotic behavior requires antipsychotic medication. Because of the anticholinergic activity of PCP, antipsychotic agents with significant anticholinergic effects such as chlorpromazine should be avoided.
Section III
Modulation of Cardiovascular Function
RENNAL ANATOMY AND PHYSIOLOGY

The basic urine-forming unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to a long tubular portion that reabsorbs and conditions the glomerular ultrafiltrate. Each human kidney is composed of ~1 million nephrons. Figure 25–1 illustrates subdivisions of the nephron.
GLOMERULAR FILTRATION. In the glomerular capillaries, a portion of plasma water is forced through a filter that has 3 basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into the urinary (Bowman’s) space, whereas formed elements and macromolecules are retained by the
OVERVIEW OF NEPHRON FUNCTION. The kidney filters large quantities of plasma, reabsorbs substances that the body must conserve, and leaves behind or secretes substances that must be eliminated. The changing architecture and cellular differentiation along the length of a nephron is crucial to these functions (see Figure 25–1). The 2 kidneys in humans produce together ~120 mL of ultrafiltrate per minute, yet only 1 mL/min of urine is produced. Therefore, >99% of the glomerular ultrafiltrate is reabsorbed at a staggering energy cost. The kidneys consume 7% of total-body oxygen intake despite the fact that the kidneys make up only 0.5% of body weight.

The proximal tubule is contiguous with Bowman’s capsule and takes a tortuous path until finally forming a straight portion that dives into the renal medulla. Normally, ~65% of filtered Na\(^+\) is reabsorbed in the proximal tubule, and since this part of the tubule is highly permeable to water, reabsorption is essentially isotonic. Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the descending thin limb (DTL), which penetrates the inner medulla, makes a hairpin turn, and then forms the ascending thin limb (ATL). At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the thick ascending limb (TAL, with 3 segments noted in Figure 25–1). Together the proximal straight tubule, DTL, ATL, and TAL segments are known as the loop of Henle.

The DTL is highly permeable to water, yet its permeability to NaCl and urea is low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The TAL actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na\(^+\) is reabsorbed in the loop of Henle, mostly in the TAL, which has a large reabsorptive capacity. The TAL passes between the afferent and efferent arterioles and makes contact with the afferent arteriole by means of a cluster of specialized columnar epithelial cells known as the macula densa. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent
arteriole of the same nephron, causing it to constrict, thereby reducing the glomerular filtration rate (GFR). This homeostatic mechanism, known as *tubuloglomerular feedback* (TGF), protects the organism from salt and volume wasting. The macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the distal convoluted tubule (DCT). Like the TAL, the DCT actively transports NaCl and is impermeable to water. Because these characteristics impart the ability to produce a dilute urine, the TAL and the DCT are collectively called the *diluting segment of the nephron*, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the TAL, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (described below).

The collecting duct system (segments 10–14 in Figure 25–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, a process modulated by the adrenal steroid aldosterone. In addition, vasopressin (also called antidiuretic hormone [ADH]) modulates water permeability of this part of the nephron. The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and a dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, so water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between tubular fluid and medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the ability of mammals and birds to concentrate urine, which is accomplished by a combination of the unique topography of the loop of Henle and the specialized permeability features of the loop’s subsegments. The “passive countercurrent multiplier hypothesis” proposes that active transport in the TAL concentrates NaCl in the interstitium of the outer medulla. Because this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting-duct system, water is extracted if, and only if, ADH is present. Since the cortical and outer medullary collecting ducts have a low permeability to urea, urea is concentrated
in the tubular fluid. The inner medullary collecting duct, however, is permeable to urea, so urea diffuses into the inner medulla, where it is trapped by countercurrent exchange in the vasa recta. Because the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

GENERAL MECHANISM OF RENAL EPITHELIAL TRANSPORT. There are multiple mechanisms by which solutes may cross cell membranes (see Figure 5–4). The kinds of transport achieved in a nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. Figure 25–2 presents a general model of renal tubular transport that be summarized as follows:
Figure 25–2 *Generic mechanism of renal epithelial cell transport (see text for details).* S, symporter; A, antiporter; CH, ion channel; WP, water pore; U, uniporter; ATPase, Na+, K+-ATPase (sodium pump); X and Y, transported solutes; P, membrane-permeable (reabsorbable) solutes; I, membrane-impermeable (nonreabsorbable) solutes; PD, potential difference across indicated membrane or cell.

1. Na+, K+-ATPase (sodium pump) in the basolateral membrane transports Na⁺ into the intercellular and interstitial spaces and K⁺ into the cell, establishing an electrochemical gradient for Na⁺ across the cell membrane directed inward.

2. Na⁺ can diffuse down this Na⁺ gradient across the luminal membrane via
Na⁺ channels and via membrane symporters that use the energy stored in the Na⁺ gradient to transport solutes out of the tubular lumen and into the cell (e.g., Na⁺-glucose, Na⁺-H₂PO₄⁻, and Na⁺-amino acid) and antiporters (e.g., Na⁺-H⁺) that move solutes into the lumen as Na⁺ moves out of the tubular lumen and into the cell.

3. Na⁺ exits the basolateral membrane into intercellular and interstitial spaces via the Na⁺ pump.

4. The action of Na⁺-linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These substrate/solute gradients then permit simple diffusion or mediated transport (e.g., symporters, antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.

5. Accumulation of Na⁺ and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell. In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes, as well as through tight junctions (paracellular pathway). Bulk water flow carries some solutes into the intercellular space by solvent drag.

6. Movement of water into the intercellular space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space by both the trans-cellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.

7. As water and solutes accumulate in the intercellular space, hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries.

**ORGANIC ACID AND ORGANIC BASE SECRETION**

The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular
filtration or may be actively secreted directly into tubules. The proximal tubule has a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 25–3. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated-diffusion step. There are at least 9 different organic acid and 5 different organic base transporters (see Chapter 5). A family of organic anion transporters (OATs) links countertransport of organic anions with dicarboxylates (Figure 25–3A).

Figure 25–3 Mechanisms of organic acid (A) and organic base (B) secretion in the proximal tubule. The numbers 1, 2, and 3 refer to primary, secondary, and tertiary active transport. A⁻, organic acid [anion]; C⁺, organic base [cation]; αKG²⁻, α-ketoglutarate but also other dicarboxylates. BL and LM indicate basolateral and luminal membranes, respectively.

RENAL HANDLING OF SPECIFIC ANIONS AND CATIONS

Reabsorption of Cl⁻ generally follows reabsorption of Na⁺. In segments of the tubule with low-resistance tight junctions (i.e., “leaky” epithelium), such as the proximal tubule and TAL, Cl⁻ movement can occur paracellularly. Cl⁻ crosses the luminal membrane by antiport with formate and oxalate (proximal tubule), symport with Na⁺/K⁺ (TAL), symport with Na⁺ (DCT), and antiport with HCO₃⁻ (collecting-duct system). Cl⁻ crosses the basolateral membrane by symport with K⁺ (proximal tubule and TAL), antiport with Na⁺/HCO₃⁻ (proximal tubule), and
Cl– channels (TAL, DCT, collecting-duct system).

Eighty to ninety percent of filtered K+ is reabsorbed in the proximal tubule (diffusion and solvent drag) and TAL (diffusion), largely through the paracellular pathway. The DCT and collecting-duct system secrete variable amounts of K+ by a channel-mediated pathway. Modulation of the rate of K+ secretion in the collecting-duct system, particularly by aldosterone, allows urinary K+ excretion to be matched with dietary intake. The transepithelial potential difference (V_T), lumen-positive in the TAL and lumen-negative in the collecting-duct system, drives K+ reabsorption and secretion, respectively.

Most of the filtered Ca²⁺ (~70%) is reabsorbed by the proximal tubule by passive diffusion through a paracellular route. Another 25% of filtered Ca²⁺ is reabsorbed by the TAL in part by a paracellular route driven by the lumen-positive V_T and in part by active transcellular Ca²⁺ reabsorption modulated by parathyroid hormone (PTH; see Chapter 44). Most of the remaining Ca²⁺ is reabsorbed in DCT by a transcellular pathway. The transcellular pathway in the TAL and DCT involves passive Ca²⁺ influx across the luminal membrane through Ca²⁺ channels (TRPV5), followed by Ca²⁺ extrusion across the basolateral membrane by a Ca²⁺-ATPase. Also, in DCT and CNT, Ca²⁺ crosses the basolateral membrane by Na⁺-Ca²⁺ exchanger (antiport). Inorganic phosphate (Pᵢ) is largely reabsorbed (80% of filtered load) by the proximal tubule. The Na⁺-Pᵢ symporter uses the free energy of the Na⁺ electrochemical gradient to transport Pᵢ into the cell. The Na⁺-Pᵢ symporter is inhibited by PTH.

The renal tubules reabsorb HCO₃⁻ and secrete protons (tubular acidification), thereby participating in acid–base balance. These processes are described in the section on carbonic anhydrase inhibitors.

**PRINCIPLES OF DIURETIC ACTION**

Diuretics are drugs that increase the rate of urine flow; clinically useful diuretics also increase the rate of Na⁺ excretion (natriuresis) and of an accompanying anion, usually Cl–. Most clinical applications of diuretics are directed toward reducing extracellular fluid volume by decreasing total-body NaCl content.
Although continued diuretic administration causes a sustained net deficit in total-body Na⁺, the time course of natriuresis is finite because renal compensatory mechanisms bring Na⁺ excretion in line with Na⁺ intake, a phenomenon known as *diuretic braking*. These compensatory mechanisms include activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), renal epithelial cell hypertrophy, increased renal epithelial transporter expression, and perhaps alterations in natriuretic hormones such as atrial natriuretic peptide. The net effects on extracellular volume and body weight are shown in Figure 25–4.

**Figure 25–4** *Changes in extracellular fluid volume and weight with diuretic therapy.* The period of diuretic administration is shown in the shaded box along with its effects on body weight in the upper part of the figure and Na⁺ excretion in the lower half of the figure. Initially, when Na⁺ excretion exceeds intake, body weight and extracellular fluid volume (ECFV) decrease. Subsequently, a new
steady state is achieved where Na\(^+\) intake and excretion are equal but at a lower ECFV and body weight. This results from activation of the renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system (SNS), “the braking phenomenon.” When the diuretic is discontinued, body weight and ECFV rise during a period where Na\(^+\) intake exceeds excretion. A new steady state is then reached as stimulation of the RAAS and SNS wane.

Diuretics may modify renal handling of other cations (e.g., K\(^+\), H\(^+\), Ca\(^{2+}\), and Mg\(^{2+}\)), anions (e.g., Cl\(^-\), HCO\(_3^-\), and H\(_2\)PO\(_4^-\)), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 25–1 gives a comparison of the general effects of the major diuretic classes.

### INHIBITORS OF CARBONIC ANHYDRASE

There are 3 orally administered carbonic anhydrase inhibitors—acetazolamide, dichlorphenamide (not marketed in the U.S.), and methazolamide (Table 25–2).

**MECHANISM AND SITE OF ACTION.** Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase), as well as in the cytoplasm (type II carbonic anhydrase) (Figure 25–5). Carbonic anhydrase plays a role in NaHCO₃ reabsorption and acid secretion.

**Figure 25–5** Sites and mechanisms of action of diuretics. Three important features are noteworthy:
In the proximal tubule, the free energy in the Na\(^+\) gradient established by the basolateral Na\(^+\) pump is used by a Na\(^+\)-H\(^+\) antiporter (a.k.a. Na\(^+\)-H\(^+\) exchanger [NHE]) in the luminal membrane to transport H\(^+\) into the tubular lumen in exchange for Na\(^+\). In the lumen, H\(^+\) reacts with filtered HCO\(_3\)\(^-\) to form H\(_2\)CO\(_3\), which decomposes rapidly to CO\(_2\) and water in the presence of carbonic anhydrase in the brush border. Carbonic anhydrase reversibly accelerates this reaction several thousand fold. CO\(_2\) is lipophilic and rapidly diffuses across the luminal membrane into the epithelial cell, where it reacts with water to form H\(_2\)CO\(_3\), a reaction catalyzed by cytoplasmic carbonic anhydrase. Continued operation of the Na\(^+\)-H\(^+\) antiporter maintains a low proton concentration in the cell, so H\(_2\)CO\(_3\) ionizes spontaneously to form H\(^+\) and HCO\(_3\)\(^-\), creating an electrochemical gradient for HCO\(_3\)\(^-\) across the basolateral membrane. The electrochemical gradient for HCO\(_3\)\(^-\) is used by a Na\(^+\)-HCO\(_3\) symporter (a.k.a. the Na\(^+\)-HCO\(_3\) co-transporter [NBC]) in the basolateral membrane to transport NaHCO\(_3\) into the interstitial space. The net effect of this process is transport of NaHCO\(_3\) from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl\(^-\) in the tubular lumen, and consequently, Cl\(^-\) diffuses down its concentration gradient into the interstitium by the paracellular pathway.

**Carbonic anhydrase inhibitors potently inhibit both the membrane-bound and cytoplasmic forms of carbonic anhydrase, resulting in nearly complete abolition of NaHCO\(_3\) reabsorption in the proximal tubule.** Because of the large excess of carbonic anhydrase in proximal tubules, a high percentage of enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system, which is a secondary site of action for this class of drugs.

**EFFECTS ON URINARY EXCRETION.** Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO\(_3\)\(^-\) excretion to ~35% of filtered load. This, along with inhibition of titratable acid and NH\(_4^+\) secretion in the collecting-duct system, results in an increase in urinary pH to ~8 and development of a metabolic acidosis. However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO\(_3\)\(^-\) is rescued from excretion. The loop of Henle has a large reabsorptive capacity and captures most of the Cl\(^-\) and a portion of the Na\(^+\). Thus, only a small increase in Cl\(^-\) excretion occurs, HCO\(_3\)\(^-\)
being the major anion excreted along with the cations Na\(^+\) and K\(^+\). The fractional excretion of Na\(^+\) may be as much as 5\%, and the fractional excretion of K\(^+\) can be as much as 70\%. The increased excretion of K\(^+\) is in part secondary to increased delivery of Na\(^+\) to the distal nephron, as described in the section on inhibitors of Na\(^+\) channels. The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of \(\text{HCO}_3^-\) to the point that the uncatalyzed reaction between CO\(_2\) and water is sufficient to achieve \(\text{HCO}_3^-\) reabsorption.

**EFFECTS ON RENAL HEMODYNAMICS.** By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces renal blood flow (RBF) and GFR.

**OTHER ACTIONS.** These agents have extrarenal sites of action. Carbonic anhydrase in the ciliary processes of the eye mediates formation of \(\text{HCO}_3^-\) in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure. Acetazolamide frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO\(_2\) levels in peripheral tissues and decrease CO\(_2\) levels in expired gas. Acetazolamide causes vasodilation by opening vascular Ca\(^{2+}\)-activated K\(^+\) channels; however, the clinical significance of this effect is unclear.

**ABSORPTION AND ELIMINATION.** See Table 25–2 for pharmacokinetic data.

**TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS.** Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions. With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalinization or metabolic acidosis,
including: (1) diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis); (2) calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in an alkaline urine; (3) worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease); (4) reduction of the urinary excretion rate of weak organic bases.

**THERAPEUTIC USES.** The efficacy of carbonic anhydrase inhibitors as single agents is low. The combination of acetazolamide with diuretics that block Na\(^+\) reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na\(^+\) (<0.2%) who are resistant to diuretic monotherapy. Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis. The major indication for carbonic anhydrase inhibitors is open-angle glaucoma. Two products developed specifically for this use are dorzolamide (TRUSOPT, others) and brinzolamide (AZOPT), which are available only as ophthalmic drops. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute angle-closure glaucoma to lower intraocular pressure before surgery (see Chapter 64). Acetazolamide also is used for the treatment of epilepsy (see Chapter 21). Acetazolamide can provide symptomatic relief in patients with high-altitude illness or mountain sickness. Acetazolamide also is useful in patients with familial periodic paralysis. The mechanism for the beneficial effects of acetazolamide in altitude sickness and familial periodic paralysis may be related to the induction of a metabolic acidosis. Finally, carbonic anhydrase inhibitors can be useful for correcting a metabolic alkalosis, especially one caused by diuretic-induced increases in H\(^+\) excretion.

**OSMOTIC DIURETICS**

Osmotic diuretics are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in doses large enough to increase significantly the osmolality of plasma and tubular fluid. Table 25–3 lists 4 osmotic diuretics—glycerin (OSMOGLYN),
isosorbide, mannitol (OSMITROL, others), and urea (currently not available in the U.S.).

**MECHANISM AND SITE OF ACTION.** Osmotic diuretics act both in proximal tubule and loop of Henle, with the latter being the primary site of action. By extracting water from intracellular compartments, osmotic diuretics expand extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary tonicity. A reduction in medullary tonicity causes a decrease in the extraction of water from the DTL, which in turn limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition osmotic diuretics inhibit Mg\(^{2+}\) reabsorption in the TAL.

**EFFECTS ON URINARY EXCRETION.** Osmotic diuretics increase urinary excretion of nearly all electrolytes, including Na\(^+\), K\(^+\), Ca\(^{2+}\), Mg\(^{2+}\), Cl\(^-\), HCO\(_3^-\), and phosphate.

**EFFECTS ON RENAL HEMODYNAMICS.** Osmotic diuretics increase RBF by a variety of mechanisms, but total GFR is little changed.

**ABSORPTION AND ELIMINATION.** Pharmacokinetic data on the osmotic diuretics are gathered in Table 25–3. Glycerin and isosorbide can be given orally, whereas mannitol and urea must be administered intravenously.
INTERACTIONS. Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. Conversely, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics are contraindicated in patients who are anuric owing to severe renal disease. Urea may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

THERAPEUTIC USES. One use for mannitol is in the treatment of dialysis disequilibrium syndrome. Overly removing solutes from the extracellular fluid by hemodialysis results in a reduction in the osmolality of extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment. By increasing the osmotic pressure of plasma, osmotic diuretics extract water from the eye and brain. All osmotic diuretics are used to control intraocular pressure during acute attacks of glaucoma and for short-term reductions in intraocular pressure both preoperatively and postoperatively in patients who require ocular surgery. Also, mannitol and urea are used to reduce cerebral edema and brain mass before and after neurosurgery.

INHIBITORS OF NA⁺-K⁺-2CL⁻ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

These diuretics inhibit activity of the Na⁺-K⁺-2Cl⁻ symporter in the TAL of the loop of Henle, hence the moniker *loop diuretics*. Although the proximal tubule reabsorbs ~65% of filtered Na⁺, diuretics acting only in the proximal tubule have limited efficacy because the TAL has the capacity to reabsorb most of the rejectate from the proximal
tubule. In contrast, inhibitors of Na⁺-K⁺-2Cl⁻ symport in the TAL, sometimes called *high-ceiling diuretics*, are highly efficacious because (1) ~25% of the filtered Na⁺ load normally is reabsorbed by the TAL, and (2) nephron segments past the TAL do not possess the resorptive capacity to rescue the flood of rejectate exiting the TAL.

Of the inhibitors of Na⁺-K⁺-2Cl⁻ symport (Table 25–4), only furosemide (LASIX), bumetanide (BUMEX), ethacrynic acid (EDECRIN), and torsemide (DEMADEX) are available currently in the U.S. Furosemide and bumetanide contain a sulfonamide moiety. Ethacrynic acid is a phenoxyacetic acid derivative; torsemide is a sulfonylurea. All loop diuretics except torsemide are available as oral and injectable formulations.

*R, renal excretion of intact drug; M, metabolism; ID, insufficient data.
*Not available in the United States.
*For furosemide, metabolism occurs predominantly in the kidney.

**MECHANISM AND SITE OF ACTION.** These agents act primarily in the TAL, where the flux of Na⁺, K⁺, and Cl⁻ from the lumen into epithelial cells is mediated by a Na⁺-K⁺-2Cl⁻ symporter (Figure 25–5). Inhibitors of Na⁺-K⁺-2Cl⁻ symport block its function, bringing salt transport in this segment of the nephron to a virtual standstill. Evidence suggests that these drugs attach to the Cl⁻
binding site located in the symporter’s transmembrane domain. Inhibitors of Na⁺K⁺-2Cl⁻ symport also inhibit Ca²⁺ and Mg²⁺ reabsorption in the TAL by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations. Na⁺-K⁺-2Cl⁻ symporters are found in many secretory and absorbing epithelia. The Na⁺-K⁺-2Cl⁻ symporters are of 2 varieties. The “absorptive” symporter (called ENCC2, NKCC2, or BSCI) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the TAL, and is regulated by cyclic AMP/PKA. The “secretory” symporter (called ENCC3, NKCCI, or BSC2) is a “housekeeping” protein that is expressed widely and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., 4-fold difference for bumetanide).

EFFECTS ON URINARY EXCRETION. Loop diuretics increase urinary Na⁺ and Cl⁻ excretion profoundly (i.e., up to 25% of the filtered Na⁺ load) and markedly increase Ca²⁺ and Mg²⁺ excretion. Furosemide has weak carbonic anhydrase–inhibiting activity and thus increases urinary excretion of HCO; and phosphate. All inhibitors of Na⁺-K⁺-2Cl⁻ symport increase urinary K⁺ and titratable acid excretion. This effect is due in part to increased Na⁺ delivery to the distal tubule (the mechanism by which increased distal Na⁺ delivery enhances K⁺ and H⁺ excretion is discussed in the section on Na⁺ channel inhibitors). Other mechanisms contributing to enhanced K⁺ and H⁺ excretion include flow-dependent enhancement of ion secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin–angiotensin–aldosterone axis.

Acutely, loop diuretics increase uric acid excretion; their chronic administration results in reduced uric acid excretion. Chronic effects of loop diuretics on uric acid excretion may be due to enhanced proximal tubule transport or secondary to volume depletion or to competition between diuretic and uric acid for the organic acid secretory mechanism in proximal tubule. Asymptomatic hyperuricemia is a common consequence of loop diuretics, but painful episodes of gout are rarely reported. By blocking active NaCl reabsorption in the TAL, inhibitors of Na⁺-K⁺-2Cl⁻ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney’s ability to concentrate urine. Also, because the TAL is part of
the diluting segment, inhibitors of Na\(^{+}\)-K\(^{+}\)-2Cl\(^{-}\) symport markedly impair the kidney’s ability to excrete a dilute urine during water diuresis.

**EFFECTS ON RENAL HEMODYNAMICS.** If volume depletion is prevented by replacing fluid losses, inhibitors of Na\(^{+}\)-K\(^{+}\)-2Cl\(^{-}\) symport generally increase total RBF and redistribute RBF to the midcortex. The mechanism of the increase in RBF is not known, but may involve prostaglandins: nonsteroidal anti-inflammatory drugs (NSAIDs) attenuate the diuretic response to loop diuretics in part by preventing prostaglandin-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer can detect NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism.

**OTHER ACTIONS.** Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by prostaglandins and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. High doses of inhibitors of Na\(^{+}\)-K\(^{+}\)-2Cl\(^{-}\) symport can inhibit electrolyte transport in many tissues, but this effect is clinically important only in the inner ear.

**ABSORPTION AND ELIMINATION.** Table 25–4 presents some pharmacokinetic properties of the agents. Because these drugs are bound extensively to plasma proteins, delivery of these drugs to the tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule, and thereby gain access to the Na\(^{+}\)-K\(^{+}\)-2Cl\(^{-}\) symporter in the luminal membrane of the TAL. Approximately 65% of furosemide is excreted unchanged in urine, and the remainder is conjugated to glucuronic acid in the kidney. Thus, in patients with renal disease, the elimination \(t_{1/2}\) of furosemide is prolonged. Bumetanide and torsemide have significant hepatic metabolism, so liver disease can prolong the elimination \(t_{1/2}\) of these loop diuretics. Oral bioavailability of furosemide varies (10-100%). In contrast, oral availabilities of bumetanide and torsemide are reliably high. Heart
failure patients have fewer hospitalizations and better quality of life with torsemide than with furosemide, perhaps because of its more reliable absorption.

As a class, loop diuretics have short elimination half lives; prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer $t_{1/2}$ than other agents available in the U.S. As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na$^+$, which often nullifies the overall effect of the loop diuretic on total-body Na$^+$. This phenomenon of “postdiuretic Na$^+$ retention” can be overcome by restricting dietary Na$^+$ intake or by more frequent administration of the loop diuretic.

**TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS.** Most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na$^+$. This may manifest as hyponatremia and/or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and in patients with liver disease, hepatic encephalopathy. Increased Na$^+$ delivery to the distal tubule, particularly when combined with activation of the renin–angiotensin system, leads to increased urinary K$^+$ and H$^+$ excretion, causing a hypochloremic alkalosis. If dietary K$^+$ intake is not sufficient, hypokalemia may develop, and this may induce cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg$^{2+}$ and Ca$^{2+}$ excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca$^{2+}$ excretion may have deleterious effects on bone metabolism.

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be reserved for use only in patients who cannot tolerate other loop diuretics. Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia.
(infrequently precipitating diabetes mellitus) and can increase plasma levels of LDL cholesterol and triglycerides while decreasing plasma levels of HDL cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances. Contraindications to the use of loop diuretics include severe Na$^+$ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are coadministered with:

- Aminoglycosides, carboplatin, paclitaxel, and others (synergism of ototoxicity)
- Anticoagulants (increased anticoagulant activity)
- Digitalis glycosides (increased digitalis-induced arrhythmias)
- Lithium (increased plasma levels of lithium)
- Propranolol (increased plasma levels of propranolol)
- Sulfonylureas (hyperglycemia)
- Cisplatin (increased risk of diuretic-induced ototoxicity)
- NSAIDs (blunted diuretic response and salicylate toxicity with high doses of salicylates)
- Probenecid (blunted diuretic response)
- Thiazide diuretics (synergism of diuretic activity of both drugs leading to profound diuresis)
- Amphotericin B (increased potential for nephrotoxicity and intensification of electrolyte imbalance)

**THERAPEUTIC USES.** A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with a brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for treatment of chronic congestive heart failure when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (see Chapter 28). Diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity.
Diuretics are used widely for treatment of hypertension (see Chapter 28). Na\(^+\)-K\(^+\)-2Cl\(^-\) symport inhibitors appear to lower blood pressure as effectively as Na\(^+\)-Cl\(^-\) symport inhibitors while causing smaller perturbations in the lipid profile. However, the relative potency and short elimination half-lives of loop diuretics render them less useful for hypertension than thiazide-type diuretics.

The edema of nephrotic syndrome often is refractory to less potent diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce volume contraction. In patients with a drug overdose, loop diuretics can be used to induce a forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney’s capacity to produce a concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hyponatremia. Loop diuretics also are used to treat edema associated with chronic kidney disease, in which the dose-response curve may be right-shifted, requiring higher doses of the loop diuretic (see Figure 25–8 in the 12th edition of the parent text).
Figure 25–8 Interrelationships among renal function, Na⁺ intake, water homeostasis, distribution of extracellular fluid volume, and mean arterial blood pressure. Pathophysiological mechanisms of edema formation. 1. Rightward shift of renal pressure natriuresis curve. 2. Excessive dietary Na⁺ intake. 3. Increased distribution of extracellular fluid volume (ECFV) to peritoneal cavity (e.g., liver cirrhosis with increased hepatic sinusoidal hydrostatic pressure) leading to ascites formation. 4. Increased distribution of ECFV to lungs (e.g., left-sided heart failure with increased pulmonary capillary hydrostatic pressure) leading to pulmonary edema. 5. Increased distribution of ECFV to venous circulation (e.g., right-sided heart failure) leading to venous congestion. 6. Peripheral edema caused by altered Starling forces causing increased distribution of ECFV to interstitial space (e.g., diminished plasma proteins in nephrotic syndrome, severe burns, and liver disease).

INHIBITORS OF NA⁺-CL⁻ SYMPORT (THIAZIDE AND THIAZIDE-LIKE DIURETICS)

The term thiazide diuretics generally refers to all inhibitors of Na⁺-
Cl– symport (Table 25–5), so named because the original inhibitors of Na+-Cl– symport were benzothiadiazine derivatives. The class now includes drugs that are pharmacologically similar to thiazide diuretics but differ structurally (thiazide-like diuretics).

**MECHANISM AND SITE OF ACTION.** Thiazide diuretics inhibit NaCl transport in DCT; the proximal tubule may represent a secondary site of action.

*Figure 25–5* illustrates the current model of electrolyte transport in DCT. Transport is powered by a Na$^+$ pump in the basolateral membrane. Free energy in the electrochemical gradient for Na$^+$ is harnessed by a Na$^+$-Cl$^-$ symporter in the luminal membrane that moves Cl$^-$ into the epithelial cell against its electrochemical gradient. Cl$^-$ then exits the basolateral membrane passively by a Cl$^-$ channel. Thiazide diuretics inhibit the Na$^+$-Cl$^-$ symporter (called ENCCl or TSC) that is expressed predominantly in kidney and localized to the apical membrane of DCT epithelial cells. Expression of the symporter is regulated by aldosterone. Mutations in the Na$^+$-Cl$^-$ symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome.

**EFFECTS ON URINARY EXCRETION.** Inhibitors of Na$^+$-Cl$^-$ symport increase Na$^+$ and Cl$^-$ excretion. However, thiazides are only moderately efficacious (i.e., maximum excretion of filtered Na$^+$ load is only 5%) because ~90% of the filtered Na$^+$ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO$_3^-$ and phosphate excretion and probably accounts for their weak proximal tubular effects. Inhibitors of Na$^+$-Cl$^-$ symport increase K$^+$ and titratable acid excretion by the same mechanisms discussed for loop diuresis. Acute thiazide administration increases uric acid excretion. However, uric acid excretion is reduced following chronic administration by the same mechanisms discussed for loop diuretics. Acute effects of inhibitors of Na$^+$-Cl$^-$ symport on Ca$^{2+}$ excretion are variable; when administered chronically, thiazide diuretics decrease Ca$^{2+}$ excretion. The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca$^{2+}$ reabsorption in the DCT. Thiazide diuretics may cause a mild magnesuria; long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly. Because inhibitors of Na$^+$-Cl$^-$ symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the kidney’s ability to excrete dilute urine during water diuresis. However, since the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney’s ability to concentrate urine during hydropenia. In general, inhibitors of Na$^+$-Cl$^-$ symport do not affect RBF and
only variably reduce GFR owing to increases in intratubular pressure. Thiazides have little or no influence on TGF.

**ABSORPTION AND ELIMINATION.** Table 25–5 lists pharmacokinetic parameters of Na\(^{+}\)-Cl\(^{-}\) symporter inhibitors. Note the wide range of half-lives for these drugs. Sulfonamides, as organic acids, are secreted into the proximal tubule by the organic acid secretory pathway. Because thiazides must gain access to the tubular lumen to inhibit the Na\(^{+}\)-Cl\(^{-}\) symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

**TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS.** Thiazide diuretics rarely cause CNS (e.g., vertigo, headache), GI, hematological, and dermatological (e.g., photosensitivity and skin rashes) disorders. The incidence of erectile dysfunction is greater with Na\(^{+}\)-Cl\(^{-}\) symport inhibitors than with several other antihypertensive agents, but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia. Thiazide diuretics have caused fatal or near-fatal hyponatremia, and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance, and latent diabetes mellitus. The mechanism of impaired glucose tolerance appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia is reduced when K\(^{+}\) is given along with the diuretic. Thiazide-induced hypokalemia also impairs the antihypertensive effect and cardiovascular protection afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides. Thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonylureas, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or
selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

A potentially lethal drug interaction warranting special emphasis is that involving thiazide diuretics and quinidine. Prolongation of the QT interval by quinidine can lead to the development of polymorphic ventricular tachycardia (torsade de pointes; see Chapter 29). Torsade de pointes may deteriorate into fatal ventricular fibrillation. Hypokalemia increases the risk of quinidine-induced torsade de pointes, and thiazide diuretic–induced K\(^+\) depletion may account for many cases of quinidine-induced torsade de pointes.

**THERAPEUTIC USES.** Thiazide diuretics are used for the treatment of edema associated with diseases of the heart (congestive heart failure), liver (hepatic cirrhosis), and kidney (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis). With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is <130-40 mL/min. Thiazide diuretics decrease blood pressure in hypertensive patients and are used widely for the treatment of hypertension either alone or in combination with other antihypertensive drugs (see Chapter 27). Thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents.

Thiazide diuretics, which reduce urinary Ca\(^{2+}\) excretion, sometimes are employed to treat Ca\(^{2+}\) nephrolithiasis and may be useful for treatment of osteoporosis (see Chapter 44). Thiazide diuretics also are the mainstay for treatment of nephrogenic diabetes insipidus, reducing urine volume by up to 50%. Although it may seem counterintuitive to treat a disorder of increased urine volume with a diuretic, thiazides reduce the kidney’s ability to excrete free water: They increase proximal tubular water reabsorption (secondary to volume contraction) and block the ability of the DCT to form dilute urine. This latter effect results in an increase in urine osmolality. Because other halides are excreted by renal processes similar to those for Cl\(^-\), thiazide diuretics may be useful for the management of Br\(^-\) intoxication.
INHIBITORS OF RENAL EPITHELIAL NA\(^+\) CHANNELS (K\(^+\)-SPARING DIURETICS)

Triamterene (DYRENIUM) and amiloride (MIDAMOR) are the only 2 drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their anti-kaliuretic actions to offset the effects of other diuretics that increase K\(^+\) excretion. Consequently, triamterene and amiloride, along with spironolactone (described in the next section), often are classified as potassium (K\(^+\))-sparing diuretics.

Both drugs are organic bases and are transported by the organic base secretory mechanism in proximal tubule and have similar mechanisms of action (Figure 25–5). Principal cells in the late distal tubule and collecting duct have, in their luminal membranes, epithelial Na\(^+\) channels that provide a conductive pathway for Na\(^+\) entry into the cell down the electrochemical gradient created by the basolateral Na\(^+\) pump. The higher permeability of the luminal membrane for Na\(^+\) depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K\(^+\) into the lumen by K\(^+\) channels (ROMK) in the luminal membrane. Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase Na\(^+\) delivery to the late distal tubule and collecting duct, a situation that often is associated with increased K\(^+\) and H\(^+\) excretion.

Amiloride blocks epithelial Na\(^+\) channels in the luminal membrane of principal cells in late distal tubule and collecting duct. The amiloride-sensitive Na\(^+\) channel (called ENaC) consists of 3 subunits (\(\alpha\), \(\beta\), and \(\gamma\)). Although the \(\alpha\) subunit is sufficient for channel activity, maximal Na\(^+\) permeability is induced when all 3 subunits are coexpressed in the same cell, probably forming a tetrameric structure consisting of 2 \(\alpha\) subunits, 1 \(\beta\) subunit, and 1 \(\gamma\) subunit. Liddle syndrome is an autosomal dominant form of low-renin, volume-expanded hypertension that is due to mutations in the \(\beta\) or \(\gamma\) subunits, leading to increased basal ENaC activity.

EFFECTS ON URINARY EXCRETION. The late distal tubule and collecting duct have a limited capacity to reabsorb solutes, thus, Na\(^+\) channel blockade in
this part of the nephron increases \( \text{Na}^+ \) and \( \text{Cl}^- \) excretion rates only mildly (~2% of filtered load). Blockade of \( \text{Na}^+ \) channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Because the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases \( \text{K}^+ \), \( \text{H}^+ \), \( \text{Ca}^{2+} \), and \( \text{Mg}^{2+} \) excretion rates. Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence chronic administration of amiloride and triamterene may decrease uric acid excretion. Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

**ABSORPTION AND ELIMINATION.** Table 25–6 lists pharmacokinetic data for amiloride and triamterene. Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized in the liver to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in urine. Therefore, triamterene toxicity may be enhanced in both hepatic disease and renal failure.

**TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS.** The most dangerous adverse effect of renal \( \text{Na}^+ \)-channel inhibitors is hyperkalemia, which can be life threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K+-sparing diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K+ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving \( \text{Na}^+ \)-channel inhibitors. Routine monitoring of the serum K+ level is essential in patients receiving K+-sparing diuretics. Cirrhotic patients are prone to
megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

THERAPEUTIC USES. Because of the mild natriuresis induced by Na$^+$-channel inhibitors, these drugs seldom are used as sole agents in treatment of edema or hypertension; their major utility is in combination with other diuretics. Coadministration of a Na$^+$-channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na$^+$-channel inhibitors to reduce K$^+$ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics and to result in normal plasma K$^+$ values.

Liddle syndrome can be treated effectively with Na$^+$-channel inhibitors. Aerosolized amiloride has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na$^+$ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic diabetes insipidus because it blocks Li$^+$ transport into collecting tubule cells.

ANTAGONISTS OF MINERALOCORTICOID RECEPTORS (ALDOSTERONE ANTAGONISTS, K$^+$-SPARING DIURETICS)

Mineralocorticoids cause salt and water retention and increase K$^+$ and H$^+$ excretion by binding to specific mineralocorticoid receptors (MRs). Two MR antagonists are available in the U.S., spironolactone and eplerenone (Table 25–7).
Table 25–7

*M, metabolism; ID, insufficient data.
*Not available in United States.

MECHANISM AND SITE OF ACTION (FIGURE 25–6). Epithelial cells in late distal tubule and collecting duct contain cytosolic MRs with a high aldosterone affinity. When aldosterone binds to MRs, the MR-aldosterone complex translocates to the nucleus, where regulates the expression of multiple gene products called *aldosterone-induced proteins* (AIPs). Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for K+ and H+ secretion into the tubular lumen.
Figure 25–6 Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists. A. Cortisol also has affinity for the mineralocorticoid receptor (MR), but is inactivated in the cell by 11-v-hydroxysteroid dehydrogenase (HSD) type II. B. Serum and glucocorticoid-regulated kinase (SGK)-1 is upregulated by aldosterone. SGK-1 phosphorylates and inactivates Nedd4-2, a ubiquitin-protein ligase that acts on ENaC, leading to its degradation. Phosphorylated Nedd4-2 no longer interacts with the PY motif of ENaC; as a result, the protein is not ubiquitinated and remains in the membrane, leading to increased Na⁺ entry into the cell.

1. Activation of membrane-bound Na⁺ channels
2. Na⁺ channel (ENaC) removal from the membrane inhibited
3. De novo synthesis of Na⁺ channels
4. Activation of membrane-bound Na⁺,K⁺-ATPase
5. Redistribution of Na⁺,K⁺-ATPase from cytosol to membrane
6. De novo synthesis of Na⁺,K⁺-ATPase
7. Changes in permeability of tight junctions
8. Increased mitochondrial production of ATP

AIP, aldosterone-induced proteins; ALDO, aldosterone; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.
Drugs such as spironolactone and eplerenone competitively inhibit the binding of aldosterone to the MR. Unlike the MR-aldosterone complex, the MR-spironolactone complex is not able to induce the synthesis of AIPs. Since spironolactone and eplerenone block biological effects of aldosterone, these agents also are referred to as *aldosterone antagonists*. MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

**EFFECTS ON URINARY EXCRETION.** The effects of MR antagonists on urinary excretion are very similar to those induced by renal epithelial Na⁺-channel inhibitors. However, unlike Na⁺-channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous aldosterone levels. The higher the endogenous aldosterone level, the greater the effects of MR antagonists on urinary excretion. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

**OTHER ACTIONS.** Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to its 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. High spironolactone concentrations can interfere with steroid biosynthesis by inhibiting steroid hydroxylases; these effects have limited clinical relevance.

**ABSORPTION AND ELIMINATION.** Spironolactone is absorbed partially (~65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic recirculation, is highly protein bound, and has a short *t*₁/₂ (~1.6 h). The *t*₁/₂ is prolonged to 9 h in patients with cirrhosis. Eplerenone has good oral availability and is eliminated primarily by metabolism by CYP3A4 to inactive metabolites, with a *t*₁/₂ of ~5 h. Canrenone and K⁺ canrenoate also are in clinical use. Canrenoate is not active but is converted to canrenone.

**TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS.** Hyperkalemia is the principal risk of MR antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia. MR antagonists also can induce metabolic acidosis in cirrhotic patients. Salicylates may reduce the tubular secretion of canrenone and decrease diuretic efficacy of spironolactone.
Spironolactone may alter the clearance of cardiac glycosides. Owing to its affinity for other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, hirsutism, deepening of the voice, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause skin rashes and, rarely, blood dyscrasias. Strong inhibitors of CYP3A4 may increase plasma levels of eplerenone, and such drugs should not be administered to patients taking eplerenone, and vice versa. Other than hyperkalemia and GI disorders, the rate of adverse events for eplerenone is similar to that of placebo.

**THERAPEUTIC USES.** Spironolactone often is coadministered with thiazide or loop diuretics in the treatment of edema and hypertension. Such combinations result in increased mobilization of edema fluid while causing lesser perturbations of K⁺ homeostasis. Spironolactone is particularly useful in the treatment of resistant hypertension due to primary hyperaldosteronism (adrenal adenomas or bilateral adrenal hyperplasia) and of refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). Spironolactone is considered the diuretic of choice in patients with hepatic cirrhosis. Spironolactone, added to standard therapy, substantially reduces morbidity and mortality and ventricular arrhythmias in patients with heart failure (see Chapter 28). Clinical experience with eplerenone is limited. Eplerenone appears to be a safe and effective antihypertensive drug. In patients with acute myocardial infarction complicated by left ventricular systolic dysfunction, addition of eplerenone to optimal medical therapy significantly reduces morbidity and mortality.

**INHIBITORS OF THE NONSPECIFIC CATION CHANNEL: ATRIAL NATRIURETIC PEPTIDES**

Four natriuretic peptides are relevant with respect to human physiology: atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. The inner medullary collecting duct (IMCD) is a major site of action of natriuretic peptides.
Three natriuretic peptides (NPs)—ANP, BNP, and CNP—share a common homologous 17-member amino acid ring formed by a disulfide bridge between cysteine residues, although they are products of different genes. Urodilatin, also structurally similar, arises from altered processing of the same precursor molecule as ANP and has 4 additional amino acids at the N terminus. ANP and BNP are produced by the heart in response to wall stretch, CNP is of endothelial and renal cell origin; urodilatin is found in the kidney and urine. NP receptors (NPRs), classified as types A, B and C, are membrane monospans. NPRA (binds ANP and BNP) and NPRB (binds CNP) have intracellular domains with guanylate cyclase activity and a protein kinase element. NPRC (binds all NPs) has a truncated intracellular domain and may help with NP clearance. The various NPs have somewhat overlapping effects, causing natriuresis, inhibition of production of renin and aldosterone, and vasodilation (the result of cyclic GMP elevation in vascular smooth muscle).

**MECHANISM AND SITE OF ACTION.** The IMCD is the final site along the nephron where Na\(^+\) is reabsorbed. Up to 5% of the filtered Na\(^+\) load can be reabsorbed here. The effects of NPs are mediated via effects of cyclic GMP on Na\(^+\) transporters (Figure 25–7). Two types of Na\(^+\) channels are expressed in IMCD. The first is an amiloride-sensitive, 28pS, nonselective, cyclic nucleotide gated cation (CNG) channel. This channel is inhibited by cGMP and by ANPs via their capacity to stimulate membrane-bound guanylyl cyclase activity and elevate cellular cGMP. The second type of Na\(^+\) channel expressed in the IMCD is the low-conductance 4 pS highly selective Na\(^+\) channel ENaC. The majority of Na\(^+\) reabsorption in the IMCD is mediated via the CNG channel.
Figure 25–7 Inner medullary collecting duct (IMCD) Na\(^+\) transport and its regulation. Na\(^+\) enters the IMCD cell in one of two ways: via epithelial Na\(^+\) channel (ENaC), and through a cyclic nucleotide gated nonspecific cation channel (CNGC) that transports Na\(^+\), K\(^+\), and NH\(_4\)\(^+\) and is gated by cyclic GMP. Na\(^+\) then exits the cell via the Na\(^+\), K\(^+\)-ATPase. The CNGC is the primary pathway for Na\(^+\) entry, and is inhibited by natriuretic peptides. Atrial natriuretic peptides (ANP) bind to surface receptors (natriuretic peptide receptors A, B, and C). The A and B receptors are isoforms of particulate guanylyl cyclase that synthesize cyclic GMP. Cyclic GMP inhibits the CNGC directly, and indirectly through PKG. PKG activation also inhibits Na\(^+\) exit via the Na\(^+\), K\(^+\)-ATPase.

**EFFECTS ON URINARY EXCRETION AND RENAL HEMODYNAMICS.**
Nesiritide (human recombinant BNP) inhibits Na\(^+\) transport in both the proximal and distal nephron but its primary effect is in the IMCD. Urinary Na\(^+\) excretion increases with nesiritide but the effect may be attenuated by upregulation of Na\(^+\) reabsorption in upstream segments of the nephron. GFR increases in response to nesiritide in normal subjects, but in treated patients with congestive heart failure GFR may increase, decrease, or remain unchanged.
OTHER ACTIONS. Administration of nesiritide decreases systemic and pulmonary resistances and left ventricular filling pressure, and induces a secondary increase in cardiac output.

ELIMINATION. Natriuretic peptides are administered intravenously. Nesiritide has a distribution $t_{1/2}$ of 2 min and a mean terminal $t_{1/2}$ of 18 min. There is no need to adjust the dose for renal insufficiency.

TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS. There are concerns about adverse renal effects and reports of increased short-term mortality in patients treated with nesiritide. Increases in serum creatinine concentration may be related to decreases in extracellular fluid volume, higher doses of diuretics used, decreases in blood pressure, and activation of the renin–angiotensin–aldosterone system. The Vasodilation in the Management of Acute CHF (VAMC) trial showed no increased risk with low or moderate doses of diuretics but an increased risk with high-dose diuretics (>160 mg furosemide), rising with increasing doses. Oral ACE inhibitors may increase the risk of hypotension with nesiritide. There are no data to suggest that nesiritide reduces mortality in the short term or long term in patients with acute decompensated CHF.

THERAPEUTIC USES. Human recombinant ANP (carperitide, available only in Japan) and BNP (nesiritide [NATRECOR]) are the available therapeutic agents of this class. Urodilatin (ularitide) is in development. Use of nesiritide should be limited to patients with acutely decompensated CHF with shortness of breath at rest; the drug should not be used in place of diuretics. Nesiritide reduces symptoms and improves hemodynamic parameters in those with dyspnea at rest who are not hypotensive.

CLINICAL USE OF DIURETICS

SITE AND MECHANISM OF DIURETIC ACTION. An understanding of the sites and mechanisms of action of diuretics enhances comprehension of the clinical aspects of diuretic pharmacology. Figure 25–5 provides a summary view of the sites and mechanisms of actions of diuretics.
THE ROLE OF DIURETICS IN CLINICAL MEDICINE. Figure 25–8 illustrates the 3 fundamental strategies for mobilizing edema fluid and provides a road map for treatment:

- Correction of the underlying disease
- Restriction of Na$^+$ intake
- Administration of diuretics

Figure 25–9 presents a useful synthesis, Brater’s algorithm, a logically compelling algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders.

Figure 25–9 “Brater’s algorithm” for diuretic therapy of chronic renal failure, nephrotic syndrome, congestive heart failure, and cirrhosis. Follow algorithm until adequate response is achieved. If adequate response is not obtained, advance to the next step. For illustrative purposes, the thiazide diuretic used is
hydrochlorothiazide (HCTZ). An alternative thiazide-type diuretic may be substituted with dosage adjusted to be pharmacologically equivalent to the recommended dose of HCTZ. Do not combine 2 K⁺-sparing diuretics due to the risk of hyperkalemia. CrCl indicates creatinine clearance in mL/min, and ceiling dose refers to the smallest dose of diuretic that produces a near-maximal effect. Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state-specific. Doses are for adults only.

The clinical situation dictates whether a patient should receive diuretics and what therapeutic regimen should be used (type of diuretic, dose, route of administration, and speed of mobilization of edema fluid). Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy including intravenous administration of a loop diuretic. In this setting, use of oral diuretics is inappropriate. Conversely, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. Loop and thiazide diuretics decrease morbidity and mortality in heart failure patients: MR antagonists also demonstrate reduced morbidity and mortality in heart failure patients receiving optimal therapy with other drugs.

Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during the paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of more powerful loop diuretics usually are required. In nephrotic syndrome, diuretic response often is disappointing. In chronic renal failure and cirrhosis, edema will not pose an immediate health risk, but can greatly reduce quality of life. In such cases, only partial removal of edema fluid should be attempted, and fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology.

Diuretic resistance refers to edema that is or has become refractory to a given diuretic. If diuretic resistance develops against a less efficacious diuretic, a more efficacious diuretic should be substituted, such as a loop diuretic for a thiazide. However, resistance to loop diuretics can be due to several causes. NSAID coadministration is a common preventable cause of diuretic resistance.
Prostaglandin production, especially PGE₂, is an important counterregulatory mechanism in states of reduced renal perfusion such as volume contraction, congestive heart failure, and cirrhosis characterized by activation of the renin–angiotensin–aldosterone (RAA) and sympathetic nervous systems. NSAID administration can block these prostaglandin-mediated effects that counterbalance the RAA and sympathetic nervous system, resulting in salt and water retention. Diuretic resistance also occurs with COX-2-selective inhibitors.

In chronic renal failure, a reduction in RBF decreases delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, diuretic concentration at the active site in the tubular lumen is diminished. In nephrotic syndrome, binding of diuretics to luminal albumin was postulated to limit response; however, the validity of this concept has been challenged. In hepatic cirrhosis, nephrotic syndrome, and heart failure, nephrons may have diminished diuretic responsiveness because of increased proximal tubular Na⁺ reabsorption, leading to diminished Na⁺ delivery to distal nephron.

Faced with resistance to loop diuretics, the clinician has several options:

- Bed rest may restore drug responsiveness by improving the renal circulation.
- An increase in dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (the ceiling dose) of the diuretic.
- Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic will increase the length of time that an effective diuretic concentration is at the active site.
- Use of combination therapy to sequentially block more than 1 site in the nephron may result in a synergistic interaction between 2 diuretics. For example, a combination of a loop diuretic with a K⁺-sparing or a thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of 2 drugs of the same type. Thiazide diuretics with significant proximal tubular effects (e.g., metolazone) are particularly well suited for sequential blockade when coadministered with a loop diuretic.
• Reducing salt intake will diminish postdiuretic Na\(^+\) retention that can nullify previous increases in Na\(^+\) excretion.
• Scheduling of diuretic administration shortly before food intake will provide effective diuretic concentration in the tubular lumen when salt load is highest.

WATER HOMEOSTASIS

VASOPRESSIN

Arginine vasopressin (antidiuretic hormone or ADH in humans) is the main hormone that regulates body fluid osmolality. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia and/or hypotension. Vasopressin acts primarily in the renal collecting duct increasing the water permeability of the cell membrane, thus permitting water to move passively down an osmotic gradient across the collecting duct into the extracellular compartment.

Vasopressin is a potent vasopressor/vasoconstrictor. It is also a neurotransmitter; among its actions in the CNS are apparent roles in the secretion of adrenocorticotropic hormone (ACTH) and in regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also promotes release of coagulation factors by vascular endothelium and increases platelet aggregability.

PHYSIOLOGY

ANATOMY. The antidiuretic mechanism in mammals involves 2 anatomical components: a CNS component for synthesis, transport, storage, and release of vasopressin and a renal collecting-duct system composed of epithelial cells that respond to vasopressin by increasing their water permeability. The CNS component of the antidiuretic mechanism is called the hypothalamo-neurohypophyseal system and consists of neurosecretory neurons with perikarya
located predominantly in 2 specific hypothalamic nuclei, the supraoptic nucleus (SON) and paraventricular nucleus (PVN). Long axons of magnocellular neurons in SON and PVN terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin (see Figure 38–1).

**SYNTHESIS.** Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN. Parvicellular neurons in the PVN also synthesize vasopressin. Vasopressin synthesis appears to be regulated solely at the transcriptional level. In humans, a 168-amino acid preprohormone (Figure 25–10) is synthesized and then packaged into membrane-associated granules. The prohormone contains 3 domains: vasopressin (residues 1-9), vasopressin (VP)-neurophysin (residues 13-105), and VP-glycopeptide (residues 107-145). The vasopressin domain is linked to the VP-neurophysin domain through a GLY-LYS-ARG-processing signal, and the VP-neurophysin is linked to the VP-glycopeptide domain by an ARG-processing signal. In secretory granules, an endopeptidase, exopeptidase, monooxygenase, and lyase act sequentially on the prohormone to produce vasopressin, VP-neurophysin (sometimes referred to as neurophysin II), and VP-glycopeptide. The synthesis and transport of vasopressin depend on the preprohormone conformation. In particular, VP-neurophysin binds vasopressin and is critical to correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or VP-neurophysin give rise to central diabetes insipidus.
More than 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central diabetes insipidus. *Boxes indicate mutations leading to central diabetes insipidus.

**VASOPRESSIN SYNTHESIS OUTSIDE THE CNS.** Vasopressin also is synthesized by heart and adrenal gland. In the heart, elevated wall stress increases vasopressin synthesis several fold.

**REGULATION OF VASOPRESSIN SECRETION.** An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary. Severe hypovolemia/hypotension also is a powerful stimulus for vasopressin release. In addition, pain, nausea, and hypoxia can stimulate vasopressin secretion, and several endogenous hormones and pharmacological agents can modify vasopressin release.

**HYPEROSMOLALITY.** The osmolality threshold for secretion is ~280 mOsm/kg. Below the threshold, vasopressin is barely detectable in plasma, and
above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. Indeed, a 2% elevation in plasma osmolality causes a 2- to 3-fold increase in plasma vasopressin levels, which in turn causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. Above a plasma osmolality of ~290 mOsm/kg, plasma vasopressin levels exceed 5 pM. Since urinary concentration is maximal (~1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss. See Figure 25–17 in the 12th edition of the parent text for more details.

**HEPATIC PORTAL OSMORECEPTORS.** An oral salt load activates hepatic portal osmoreceptors leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

**HYPOVOLEMIA AND HYPOTENSION.** Vasopressin secretion is regulated hemodynamically by changes in effective blood volume and/or arterial blood pressure. Regardless of the cause (e.g., hemorrhage, Na⁺ depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume and/or arterial blood pressure are associated with high circulating vasopressin concentrations. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; i.e., small decreases (5%) in blood volume and/or pressure have little effect on vasopressin secretion, whereas larger decreases (20-30%) can increase vasopressin levels to 20-30 times normal (exceeding the vasopressin concentration required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss and/or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality-plasma vasopressin relationship (**Figure 25–11**).
Neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals are ultimately relayed to the SON and PVN.

**HORMONES AND NEUROTRANSMITTERS.** Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron. Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei that project, either directly or indirectly, to the SON and PVN. Because of these complexities, modulation of vasopressin secretion by most hormones or neurotransmitters is unclear. Several agents stimulate vasopressin secretion, including acetylcholine (by nicotinic
receptors), histamine (by H₁ receptors), dopamine (by both D₁ and D₂ receptors), glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, prostaglandins, and angiotensin II (AngII). Inhibitors of vasopressin secretion include ANP, γ-aminobutyric acid, and opioids (particularly dynorphin via κ receptors). The affects of AngII have received the most attention. AngII synthesized in the brain and circulating AngII may stimulate vasopressin release. Inhibition of the conversion of AngII to AngIII blocks AngII-induced vasopressin release, suggesting that AngIII is the main effector peptide of the brain renin–angiotensin system controlling vasopressin release.

PHARMACOLOGICAL AGENTS. A number of drugs alter urine osmolality by stimulating or inhibiting vasopressin secretion. In most cases the mechanism is not known. Stimulators of vasopressin secretion include vincristine, cyclophosphamide, tricyclic antidepressants, nicotine, epinephrine, and high doses of morphine. Lithium, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin secretion include ethanol, phenytoin, low doses of morphine, glucocorticoids, fluphenazine, haloperidol, promethazine, ondansetron, and butorphanol. Carbamazepine has a renal action to produce antidiuresis in patients with central diabetes insipidus but actually inhibits vasopressin secretion by a central action.

BASIC PHARMACOLOGY

VASOPRESSIN RECEPTORS. Cellular vasopressin effects are mediated mainly by interactions of the hormone with the 3 types of receptors, V₁a, V₁b, and V₂. All are GPCRs.

The V₁a receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, adrenal gland, myometrium, bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the renal cortical collecting-duct, spleen, testis, and many CNS structures. V₁b receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, pancreas, and adrenal medulla. V₂ receptors are located predominantly in principal cells of the renal collecting-duct system but also are present on
epithelial cells in TAL and on vascular endothelial cells.

**V₁ RECEPTOR-EFFECTOR COUPLING.** Figure 25–12 summarizes the current model of V₁ receptor-effector coupling. Vasopressin binding to V₁ receptors activates the Gq-PLC-IP₃ pathway, thereby mobilizing intracellular Ca²⁺ and activating PKC, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth responses in smooth muscle cells.
**Figure 25–12** Mechanism of V₁ receptor-effector coupling. Binding of AVP to V₁ vasopressin receptors (V₁) stimulates membrane-bound phospholipases. Stimulation of the G_q activates the PLCv-IP₃/DAG-Ca²⁺-PKC pathway. Activation of V₁ receptors also causes influx of extracellular Ca²⁺ by an unknown mechanism. PKC and Ca²⁺/calmodulin-activated protein kinases phosphorylate cell-type-specific proteins leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA₂; the resulting mobilization of arachidonic acid (AA) provides substrate for eicosanoid synthesis by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways, leading to local production of prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT), which may activate myriad signaling pathways, including those linked to Gₛ and G_q.

**V₂ RECEPTOR-EFFECTOR COUPLING.** Principal cells in renal collecting duct have V₂ receptors on their basolateral membranes that couple to Gₛ to stimulate adenylyl cyclase activity ([Figure 25–13](#)). When vasopressin binds to V₂ receptors, the resulting activation of the cyclic AMP/PKA pathway triggers an increased rate of insertion of water channel-containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane. Because WCVs contain preformed functional water channels (aquaporin 2), their net shift into apical membranes in response to V₂ receptor stimulation greatly increases water permeability of the apical membrane ([see Figures 25–13 and 25–14](#)).
Figure 25–13 Mechanism of V₂ receptor-effector coupling. Binding of vasopressin (AVP) to the V₂ receptor activates the Gₛ-adenylyl cyclase-cAMP-PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of Ser256 of aquaporin 2 is involved in V₂ receptor signaling, other proteins located both in the water channel-containing vesicles and the apical membrane of the cytoplasm also may be involved.
Aquaporins have 6 transmembrane domains, and the NH$_2$ and COOH termini are intracellular. Loops B and E each contain an asparagine-proline-alanine (NPA) sequence. Aquaporins fold with transmembrane domains 1, 2, and 6 in close proximity and transmembrane domains 3, 4 and 5 in juxtaposition. The long B and E loops dip into the membrane, and the NPA sequences align to create a pore through which water can diffuse. Most likely aquaporins form a tetrameric oligomer. At least 7 aquaporins are expressed at distinct sites in the kidney. Aquaporin 1, abundant in the proximal tubule and descending thin limb, is essential for concentration of urine. Aquaporin 2, exclusively expressed in the principal cells of the connecting tubule and collecting duct, is the major vasopressin-regulated water channel. Aquaporin 3 and aquaporin 4 are expressed in the basolateral membranes of collecting-duct principal cells and provide exit pathways for water reabsorbed apically by aquaporin 2. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6-8 are also expressed in kidney; their functions remain to be clarified. Vasopressin regulates water permeability of the collecting
duct by influencing the trafficking of aquaporin 2 from intracellular vesicles to the apical plasma membrane (Figure 25–13). AVP-induced activation of the cAMP-PKA pathway also enhances expression of aquaporin 2 mRNA and protein; chronic dehydration thus causes upregulation of aquaporin 2 and water transport in the collecting duct.

V_{2}-receptor activation also increases urea permeability by 400% in the terminal portions of the IMCD. V_{2} receptors increase urea permeability by activating a vasopressin-regulated urea transporter (termed VRUT, UT1, or UTA1), most likely by PKA-induced phosphorylation. Kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regulation of VRUT does not entail vesicular trafficking to the plasma membrane.

V_{2}-receptor activation also increases Na^{+} transport in TAL and collecting duct. Increased Na^{+} transport in TAL is mediated by 3 mechanisms that affect the Na^{+}-K^{+}-2C1− symporter: rapid phosphorylation of the symporter, translocation of the symporter into the luminal membrane, and increased expression of symporter protein. Enhanced Na^{+} transport in collecting duct is mediated by increased expression of subunits of the epithelial Na^{+} channel. The multiple mechanisms by which vasopressin increases water reabsorption are summarized in Figure 25–15.
Figure 25–15 Mechanisms by which vasopressin increases the renal conservation of water. Red and black arrows denote major and minor pathways, respectively. IMCD, inner medullary collecting duct; TAL, thick ascending limb; VRUT, vasopressin-regulated urea transporter.

RENAL ACTIONS OF VASOPRESSIN. Several sites of vasopressin action in kidney involve both $V_1$ and $V_2$ receptors (see Figure 25–15).

$V_1$ receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in vasa recta and efferent arteriole. $V_1$-receptor-mediated reduction of inner medullary
blood flow contributes to the maximum concentrating capacity of the kidney. V₁ receptors also stimulate prostaglandin synthesis by medullary interstitial cells. Since PGE₂ inhibits adenylyl cyclase in collecting duct, stimulation of prostaglandin synthesis by V₁ receptors may counterbalance V₂-receptor-mediated antidiuresis. V₁ receptors on principal cells in cortical collecting duct may inhibit V₂-receptor-mediated water flux by activation of PKC. V₂ receptors mediate the most prominent response to vasopressin, which is increased water permeability of the collecting duct at concentrations as low as 50 fM. Thus, V₂-receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage V₁-receptor-mediated actions. Other renal actions mediated by V₂ receptors include increased urea transport in IMCD and increased Na⁺ transport in TAL; both effects contribute to the urine-concentrating ability of the kidney. V₂ receptors also increase Na⁺ transport in cortical collecting duct, and this may synergize with aldosterone to enhance Na⁺ reabsorption during hypovolemia.

PHARMACOLOGICAL MODIFICATION OF THE ANTIDIURETIC RESPONSE TO VASOPRESSIN. NSAIDs, particularly indomethacin, enhance the antidiuretic response to vasopressin. Because prostaglandins attenuate antidiuretic responses to vasopressin and NSAIDs inhibit prostaglandin synthesis, reduced prostaglandin production probably accounts for potentiation of vasopressin’s antidiuretic response. Carbamazepine and chlorpropamide also enhance antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, chlorpropamide can induce water intoxication. A number of drugs inhibit the antidiuretic actions of vasopressin. Lithium is of particular importance because of its use in the treatment of manic-depressive disorders. Acutely, Li⁺ appears to reduce V₂-receptor-mediated stimulation of adenylyl cyclase. Also, Li⁺ increases plasma levels of PTH, a partial antagonist to vasopressin. In most patients, the antibiotic demeclocycline attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP.
NONRENEAL ACTIONS OF VASOPRESSIN

Cardiovascular System. The cardiovascular effects of vasopressin are complex. Vasopressin is a potent vasoconstrictor (V₁ receptor-mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appears most sensitive, with significant vasoconstriction also occurring in GI tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses in vivo are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V₁ receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V₂ receptors cause vasodilation in some blood vessels.

Vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. The effects of vasopressin on heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control diabetes insipidus, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

CNS. Vasopressin likely plays a role as a neurotransmitter and/or neuromodulator. Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the physiological significance of these actions is unclear. While vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic-pituitary-adrenal axis during chronic stress. CNS effects of vasopressin appear to be mediated predominantly by V₁ receptors.

Blood Coagulation. Activation of V₂ receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V₂ receptors. Presumably, vasopressin stimulates secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. However, since release of von Willebrand
factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

**Other Nonrenal Effects of Vasopressin.** At high concentrations, vasopressin stimulates smooth muscle contraction in uterus (by oxytocin receptors) and GI tract (by V₁ receptors). Vasopressin is stored in platelets, and activation of V₁ receptors stimulates platelet aggregation. Also, activation of V₁ receptors on hepatocytes stimulates glycogenolysis.

**VASOPRESSIN RECEPTOR AGONISTS AND ANTAGONISTS**

A number of vasopressin-like peptides occur naturally across the animal kingdom (Table 25–8); all are nonapeptides. In all mammals except swine, the neurohypophyseal peptide is 8-arginine vasopressin, and the terms vasopressin, arginine vasopressin (AVP), and ADH are used interchangeably. There are also a number of synthetic peptides with receptor-subtype specificity, and 1 non-peptide agonist.

Many vasopressin analogs were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (V₁ versus V₂ receptors, which mediate pressor responses and antidiuretic responses, respectively). Thus, the antidiuretic-to-vasopressor ratio for the V₂–selective agonist, 1-deamino-8-D-arginine vasopressin, also called desmopressin (DDAVP, MINIRIN, STIMATE), is ~3000 times greater than that for vasopressin, and is the preferred drug for the treatment of central diabetes insipidus. Substitution of valine for glutamine in position 4 further increases the antidiuretic selectivity, and the antidiuretic to vasopressor ratio for deamino [Val⁴, D-Arg⁸]AVP is ~11,000 times greater than that for vasopressin.
Increasing $V_1$ selectivity has proved more difficult than increasing $V_2$ selectivity. Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical $V_1$ nor $V_2$ receptors. Because vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical $V_1$ receptors, and since many vasopressin analogs with vasoconstrictor activity release ACTH, $V_1$ receptors have been subclassified into $V_{1a}$ (vascular/hepatic) and $V_{1b}$ (pituitary) receptors (also called $V_3$ receptors). There are selective agonists for $V_{1a}$ and $V_{1b}$ receptors.

The chemical structure of oxytocin is closely related to that of vasopressin: oxytocin is [Ile$^3$, Leu$^8$]AVP. With such structural similarities, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other’s receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

**DISEASES AFFECTING THEVASOPRESSIN SYSTEM**

**DIABETES INSIPIDUS (DI).** DI is a disease of impaired renal water conservation owing either to inadequate vasopressin secretion from the neurohypophysis (central DI) or to insufficient renal vasopressin response (nephrogenic DI). Very rarely, DI can be caused by an abnormally high degradation rate of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central and/or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing renal sensitivity to vasopressin. Patients with DI excrete large volumes (>30 mL/kg per day) of dilute (>200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are poly-dipsic. Central DI can be distinguished from nephrogenic DI by administration of desmopressin, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients
with DI.

**CENTRAL DI.** Head injury, either surgical or traumatic, in the region of the pituitary and/or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections. Central DI may also be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20), and vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI is linked to mutations in the vasopressin preprohormone gene that cause the prohormone to misfold and oligomerize improperly. Accumulation of mutant vasopressin precursor causes neuronal death, hence the dominant mode of inheritance. Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin mutant.

Antidiuretic peptides are the primary treatment for central DI, with desmopressin being the peptide of choice. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available. Chlorpropamide, an oral sulfonylurea, potentiates the action of small or residual amounts of circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. Doses of 125-500 mg daily appear effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic to the regimen usually results in an adequate reduction in urine volume. Carbamazepine (800-1000 mg daily in divided doses) also reduces urine volume in patients with central DI. Long-term use may induce serious adverse effects; therefore, carbamazepine is used rarely to treat central DI. These agents are not effective in nephrogenic DI, which indicates that functional V2 receptors are required for the antidiuretic effect. Because carbamazepine inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V2-receptor-mediated antidiuresis.

**NEPHROGENIC DI.** Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, Li+, foscarinet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many
as 1 in 3 patients treated with Li⁺ may develop nephrogenic DI. X-linked nephrogenic DI is caused by mutations in the gene encoding the V₂ receptor, which maps to Xq28. Mutations in the V₂-receptor gene may cause impaired routing of the V₂ receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased receptor affinity for vasopressin. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in humans.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate water intake, drugs also can be used to reduce polyuria. Amiloride blocks Li⁺ uptake by the Na⁺ channel in the collecting-duct system and may be effective in patients with mild to moderate concentrating defects. Thiazide diuretics reduce the polyuria of patients with DI and often are used to treat nephrogenic DI. In infants with nephrogenic DI, use of thiazides may be crucial because uncontrolled polyuria may exceed the child’s capacity to imbibe and absorb fluids. It is possible that the natriuretic action of thiazides and resulting extracellular fluid volume depletion play an important role in thiazide-induced antidiuresis. The antidiuretic effects appear to parallel the thiazide’s ability to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of Na⁺ intake can enhance the antidiuretic effectiveness of thiazides.

A number of case reports describe the effectiveness of indomethacin in the treatment of nephrogenic DI; however, other prostaglandin synthase inhibitors (e.g., ibuprofen) appear to be less effective. The mechanism of the effect may involve a decrease in GFR, an increase in medullary solute concentration, and/or enhanced proximal fluid reabsorption. Also, because prostaglandins attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V₂-receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the prostaglandin effect and enhancement of vasopressin effects on the principal cells of collecting duct.

**SYNDROME OF INAPPROPRIATE SECRETION OF ANTIDIURETIC HORMONE (SIADH).** SIADH is a disease of impaired water excretion with accompanying hyponatremia and hypoosmolality caused by the *inappropriate*
secretion of vasopressin. Clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH, including malignancies, pulmonary diseases, CNS injuries/diseases (e.g., head trauma, infections, and tumors), and general surgery.

Three drug classes are commonly implicated in drug-induced SIADH: psychotropic medications (e.g., selective serotonin reuptake inhibitors, haloperidol, and tricyclic antidepressants), sulfonylureas (e.g., chlorpropamide), and vinca alkaloids (e.g., vincristine and vinblastine). Other drugs strongly associated with SIADH include clonidine, cyclophosphamide, enalapril, felbamate, ifosfamide, and methyldopa, pentamidine, and vinorelbine. In a normal individual, an elevation in plasma vasopressin per se does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin. Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with kidney’s concentrating ability), and drugs that inhibit the effect of vasopressin to increase water permeability in collecting ducts. To inhibit vasopressin’s action in collecting ducts, demeclocycline, a tetracycline, has been the preferred drug, but tolvaptan and conivaptan, V2 receptor antagonists, are now available (see next section and Table 25–9).

Table 25–9

Vasopressin Receptor Antagonists
Although Li⁺ can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index. Therefore, Li⁺ should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated (e.g., patients with liver disease). It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na⁺ stabilizes in the range of 125-132 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na⁺ levels drop below 120 mM, should therapy with demeclocycline be initiated. Since hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal.

**OTHER WATER-RETAINING STATES.** In patients with congestive heart
failure, cirrhosis, or nephrotic syndrome, effective blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Because hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V\textsubscript{2} receptor antagonists and specific inhibitors of water channels in the collecting duct has provided a new therapeutic strategy not only in patients with SIADH but also in the more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome.

**CLINICAL USE OF VASOPRESSIN PEPTIDES**

**AGONISTS**

Two antidiuretic peptides are available for clinical use in the U.S.:

- **Vasopressin** (synthetic 8-L-arginine vasopressin; **PITRESSIN**, others) is available as a sterile aqueous solution; it may be administered subcutaneously, intramuscularly, or intranasally.
- **Desmopressin acetate** (synthetic 1-deamino-8-D-arginine vasopressin; DDAVP, others) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration.

**THERAPEUTIC USES.** The therapeutic uses of vasopressin and its congeners can be divided into 2 main categories according to the vasopressin receptor involved.

**V\textsubscript{1} receptor-mediated** therapeutic applications are based on the rationale that V\textsubscript{1} receptors cause GI and vascular smooth muscle contraction. Vasopressin is the main agent used.

V\textsubscript{1} receptor-mediated GI smooth muscle contraction has been used to treat postoperative ileus and abdominal distension and to dispel intestinal gas before abdominal roentgenography to avoid interfering gas shadows. V\textsubscript{1} receptor-mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow
to the portal system and, thereby, attenuates pressure and bleeding in esophageal varices. Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V₁ receptor agonists have been used in an emergency setting until endoscopy can be performed. Simultaneous administration of nitroglycerin with V₁ receptor agonists may attenuate the cardiotoxic effects of V₁ agonists while enhancing their beneficial splanchnic effects. Also, V₁ receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. Finally, V₁ receptor-mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection.

The applications of V₁ receptor agonists can be accomplished with vasopressin; however, the use of vasopressin for all these indications is no longer recommended because of significant adverse reactions. Terlipressin (LUCASSIN) is preferred for bleeding esophageal varices because of increased safety compared with vasopressin and is designated as an orphan drug for this use. Moreover, terlipressin is effective in patients with hepatorenal syndrome, particularly when combined with albumin. Terlipressin has been granted priority review, orphan drug status, and fast-track designation by the FDA for type I hepatorenal syndrome. Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of vasopressin. The combination of vasopressin and norepinephrine is superior to norepinephrine alone in the management of catecholamine-resistant vasodilatory shock. However, recent clinical trials show that, in comparison to catecholamines alone, addition of vasopressin does not improve outcomes in either cardiac arrest or septic shock.

**V₂ receptor-mediated** therapeutic applications are based on the rationale that V₂ receptors cause water conservation and release of blood coagulation factors. Desmopressin is the standard drug of choice.

Central but not nephrogenic DI can be treated with V₂ receptor agonists, and polyuria and polydipsia usually are well controlled by these agents. Some
patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients. The duration of effect from a single intranasal dose is from 6-20 h; twice-daily administration is effective in most patients. The usual intranasal dosage in adults is 10-40 μg daily either as a single dose or divided into 2 or 3 doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable peptide absorption following nasal administration. Oral administration of desmopressin in doses 10-20 times the intranasal dose provides adequate desmopressin blood levels to control polyuria. Subcutaneous administration of 1-2 μg daily of desmopressin also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V₁ receptor-mediated side effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

Desmopressin is used in bleeding disorders. In most patients with type I von Willebrand disease (vWD) and in some with type IIIn vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types IIa, IIb, and III vWD. Desmopressin may cause a marked transient thrombocytopenia in individuals with type IIb vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild to moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. In patients with renal insufficiency, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII-related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with liver cirrhosis- or drug-induced (e.g., heparin, hirudin, and antiplatelet agents) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 μg/kg, increases factor VIII
Desmopressin can be given at intervals of 12-24 h depending on the clinical response and severity of bleeding. Tachyphylaxis to desmopressin usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another $V_2$ receptor-mediated therapeutic application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin intranasal spray or tablets provides a high response rate that is sustained with long-term use, that is safe, and that accelerates the cure rate. Desmopressin also relieves post-lumbar puncture headache, probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

**PHARMACOKINETICS.** When vasopressin and desmopressin are given orally, they are inactivated quickly by trypsin. Inactivation by peptidases in various tissues (particularly liver and kidney) results in a plasma $t_{1/2}$ of vasopressin of 17-35 min. Following intramuscular or subcutaneous injection, antidiuretic effects of vasopressin last 2-8 h.

**TOXICITY, ADVERSE EFFECTS, CONTRAINDICATIONS, DRUG INTERACTIONS.** Most adverse effects are mediated through $V_1$ receptor activation on vascular and GI smooth muscle; such adverse effects are much less common and less severe with desmopressin than with vasopressin. After injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Vasopressin should be administered with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene were encountered in patients receiving large doses of vasopressin.

The major $V_2$ receptor-mediated adverse effect is water intoxication. Many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs such as Li$^+$, demeclocycline, and ethanol can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin should
be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue. Mild facial flushing and headache are the most common adverse effects. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

**VASOPRESSIN RECEPTOR ANTAGONISTS**

Table 25–9 summarizes selectivity of vasopressin receptor antagonists.

**THERAPEUTIC USES.** When the kidney perceives the arterial blood volume to be low (as in the disease states of CHF, cirrhosis, and nephrosis), AVP perpetuates a state of total body salt and water excess. V₂ receptor (V₂R) antagonists or “aquaretics” may have a therapeutic role in these conditions, especially in patients with concomitant hyponatremia. They are also effective in hyponatremia associated with SIADH. Aquaretics increase renal free water excretion with little or no change in electrolyte excretion. Since they do not affect Na⁺ reabsorption they do not stimulate the TGF mechanism with its associated consequence of reducing GFR.

**AVAILABLE AGENTS**

*Mozavaptan.* Mozavaptan causes a dose-dependent increase in free water excretion with only slight increases in urinary Na⁺ and K⁺ excretion. Mozavaptan is available in 30-mg tablets. Its peak effects occur 60-90 min after an oral dose. Mozavaptan’s major side effects are dry mouth and abnormal liver function tests.

*Tolvaptan.* Tolvaptan (SAMSca) is a selective oral V₂R antagonist. Tolvaptan is approved for clinically significant hypervolemic and euvolemic hyponatremia. The drug is labeled with a black box warning against too rapid correction of
hyponatremia (can have serious and fatal consequences) and the recommendation to initiate therapy in a hospital setting capable of close monitoring of serum Na\(^+\). Tolvaptan is contraindicated in patients receiving drugs that inhibit CYP3A4.

Tolvaptan is available in 15 and 30 mg tablets. Tolvaptan is 29 times more selective for the \(V_2\)R than the \(V_{1a}\)R. Tolvaptan has a \(t_{1/2}\) of 6-8 h and <1% is excreted in the urine. Tolvaptan is a substrate and inhibitor of P-glycoprotein and is eliminated entirely by CYP3A metabolism. Plasma concentrations of the drug are increased by ketoconazole. Adverse effects include GI effects, hyperglycemia, and pyrexia. Less common are cerebrovascular accident, deep vein thrombosis, disseminated intravascular coagulation, intracardiac thrombus, ventricular fibrillation, urethral hemorrhage, vaginal hemorrhage, pulmonary embolism, respiratory failure, diabetic ketoacidosis, ischemic colitis, increase in prothrombin time, and rhabdomyolysis.

**Conivaptan.** Conivaptan (VAPRISOL) is a nonselective \(V_{1a}\)R/\(V_2\)R antagonist that is FDA-approved for the treatment of hospitalized patients with euvolemic hyponatremia and hypervolemic hyponatremia. The drug is available only for intravenous infusion. In CHF patients, conivaptan increases renal free water excretion without a change in systemic vascular resistance.

Conivaptan is highly protein bound, has a terminal elimination \(t_{1/2}\) of 5-12 h, is metabolized via CYP3A4, and is partially excreted by the kidney. Caution should be exercised in those with hepatic and renal disease. At higher doses clearance may be reduced in the elderly. Conivaptan should not be administered in patients receiving ketoconazole, itraconazole, ritonavir, indinavir, clarithromycin, or other strong CYP3A4 inhibitors. Conivaptan increases levels of simvastatin, digoxin, amlodipine, and midazolam. The most common adverse effect of conivaptan is an infusion site reaction. Other adverse effects include headache, hypertension, hypotension, hypokalemia, and pyrexia.
The renin–angiotensin system (RAS) participates significantly in the pathophysiology of hypertension, congestive heart failure, myocardial infarction, and diabetic nephropathy.

**COMPONENTS OF THE RENIN-ANGIOTENSIN SYSTEM**

Angiotensin II (AngII), the most vasoactive angiotensin peptide, participates in blood pressure regulation, aldosterone release, Na⁺ reabsorption from renal tubules, and electrolyte and fluid homeostasis. AngII is derived from angiotensinogen in two proteolytic steps (Figure 26–1). First, renin, an enzyme released from the juxtaglomerular cells of the kidneys, cleaves the decapeptide angiotensin I (AngI) from the amino terminus of angiotensinogen (renin substrate). Then, angiotensin-converting enzyme (ACE) removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. AngII is an agonist ligand for 2 GPCRs, AT₁ and AT₂. The RAS includes local (tissue) RAS, alternative pathways for AngII synthesis (ACE-independent), formation of other biologically active angiotensin peptides (AngIII, AngIV, Ang[1–7]), and additional angiotensin-binding receptors (AT₁, AT₂, AT₄, Mas) that participate in cell growth differentiation, hypertrophy, inflammation, fibrosis, and apoptosis.
Figure 26–1 Components of the RAS. The heavy arrows show the classical pathway, and the light arrows indicate alternative pathways. ACE, angiotensin-converting enzyme; Ang, angiotensin; AP, aminopeptidase; E, endopeptidases; IRAP, insulin-regulated aminopeptidases; PCP, prolylcarboxylpeptidase; PRR, (pro)renin receptor. Receptors involved: AT$_1$, AT$_2$, Mas, AT$_4$, and PRR.

*Exposure of the active site of renin can also occur nonproteolytically; see text and Figure 26–4.

RENIN AND THE PRORENIN/RENIN RECEPTOR. Renin is the major determinant of the rate of AngII production. It is synthesized, stored, and secreted by exocytosis into the renal arterial circulation by the granular juxtaglomerular cells (Figure 26–2) located in the walls of the afferent arterioles that enter the glomeruli. Renin is an aspartyl protease that cleaves the bond between residues 10 and 11 at the amino terminus of angiotensinogen to generate AngI. The active form of renin is a large glycoprotein that is synthesized as a preproenzyme and processed to prorenin. Prorenin may be activated in 2 ways: proteolytically, by proconvertase 1 or cathepsin B that remove 43 amino acids (propeptide) from prorenin’s amino terminus to uncover the active site of renin (Figure 26–3); and nonproteolytically, when prorenin binds to the prorenin/renin receptor (PRR), resulting in conformational changes that unfold the propeptide and expose the active catalytic site of the enzyme. Both renin and prorenin are stored in the juxtaglomerular cells. The concentration of plasma prorenin is ~10x that of the active enzyme. The $t_{1/2}$ of circulating renin is ~15 min.
Figure 26–2 Physiological pathways, feedback loops, and pharmacological regulation of the renin-angiotensin system. Schematic portrayal of the three major physiological pathways regulating renin release. See text for details. MD, macula densa; PGI₂/PGE₂ prostaglandins I₂ and E₂; NSAIDs, nonsteroidal anti-inflammatory drugs; Ang II, angiotensin II; ACE, angiotensin-converting enzyme. AT₁ R, angiotensin subtype 1 receptor; NE/Epi, norepinephrine/epinephrine; JGCs, juxtaglomerular cells.
Figure 26–3 Regulation of J-G cell renin release by the macula densa.
Mechanisms by which the macula densa regulates renin release. Changes in tubular delivery of NaCl to the macula densa cause appropriate signals to be conveyed to the juxtaglomerular cells. Sodium depletion upregulates nNOS and COX-2 in the macula densa to enhance production of prostaglandins (PGs). PGs and catecholamines stimulate cyclic AMP production and thence renin release from the juxtaglomerular cells. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels. Adenosine diffuses to the juxtaglomerular cells and inhibits cyclic AMP production and renin release via G\textsubscript{i}-coupled A\textsubscript{1} receptors. Increased NaCl transport in the macula densa augments the efflux of ATP, which may inhibit renin release directly by binding to P2Y receptors and activating the G\textsubscript{q}-PLC-IP\textsubscript{3}-Ca\textsuperscript{2+} pathway in juxtaglomerular cells. Circulating AngII also inhibits renin release on juxtaglomerular cells via G\textsubscript{q}-coupled AT\textsubscript{1} receptors.

CONTROL OF RENIN SECRETION. The secretion of renin from juxtaglomerular cells is controlled predominantly by 3 pathways (see Figure 26–2):

1. The macula densa pathway. The macula densa lies adjacent to the juxtaglomerular cells and is composed of specialized columnar epithelial cells in the wall of the cortical thick ascending limb that passes between the afferent and efferent arterioles of the glomerulus. A change in NaCl reabsorption by the macula densa results in the transmission to nearby juxtaglomerular cells of chemical signals that modify renin release. Increases in NaCl flux across the macula densa inhibit renin release, whereas decreases in NaCl flux stimulate renin release.

ATP, adenosine, and prostaglandins modulate the macula densa pathway (Figure 26–3). ATP and adenosine are released when NaCl transport increases: ATP acts on P2Y receptors and adenosine acts via the A\textsubscript{1} adenosine receptor to inhibit renin release. Prostaglandins (PGE\textsubscript{2}, PGI\textsubscript{2}) are released when NaCl transport decreases, and stimulate renin release through enhancing cyclic AMP formation. Prostaglandin production is stimulated by inducible COX-2 and neuronal NO synthase.

Regulation of the macula densa pathway is more dependent on the luminal
concentration of Cl– than Na+. NaCl transport into the macula densa is mediated by the Na+-K+-2Cl– symporter (see Figure 26–3), and the half-maximal concentrations of Na+ and Cl– required for transport via this symporter are 2-3 and 40 mEq/L, respectively. Because the luminal concentration of Na+ at the macula densa usually is much greater than the level required for half-maximal transport, physiological variations in luminal Na+ concentrations at the macula densa have little effect on renin release (i.e., the symporter remains saturated with respect to Na+). Conversely, physiological changes in Cl– concentrations (20-60 mEq/L) at the macula densa profoundly affect macula densa–mediated renin release.

2. The intrarenal baroreceptor pathway. Increases and decreases in blood pressure or renal perfusion pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. The release of renal prostaglandins may mediate in part the intrarenal baroreceptor pathway.

3. The β adrenergic receptor pathway is initiated by the release of NE from postganglionic sympathetic nerves. Activation of β1 receptors on juxtaglomerular cells (↑ cyclic AMP) enhances renin secretion. Increased renin secretion enhances the formation of AngII, which stimulates AT1 receptors on juxtaglomerular cells to inhibit renin release, an effect termed short-loop negative feedback. The inhibition of renin release owing to AngII-induced increases in blood pressure has been termed long-loop negative feedback. AngII increases arterial blood via AT1 receptors; this effect inhibits renin release by: (1) activating high-pressure baroreceptors, thereby reducing renal sympathetic tone; (2) increasing pressure in the preglomerular vessels; and (3) reducing NaCl reabsorption in the proximal tubule (pressure natriuresis), which increases tubular delivery of NaCl to the macula densa.

Renin release is regulated by arterial blood pressure, dietary salt intake, and a number of pharmacological agents (see Figure 26–2). Loop diuretics stimulate renin release by decreasing arterial blood pressure and by blocking the reabsorption of NaCl at the macula densa. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin synthesis and thereby decrease renin release. ACE inhibitors, angiotensin receptor blockers (ARBs), and renin inhibitors
interrupt both the short- and long-loop negative feedback mechanisms and therefore increase renin release. Centrally acting sympatholytic drugs, as well as β adrenergic receptor antagonists, decrease renin secretion by reducing activation of β₁ adrenergic receptors on juxtaglomerular cells.

**ANGIOTENSINOGEN.** AngI is cleaved by renin from the amino terminus of angiotensinogen, an abundant globular protein synthesized mainly by the liver. Angiotensinogen transcripts also are abundant in fat, certain regions of the CNS, and the kidneys. Angiotensinogen synthesis is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII. During pregnancy, plasma levels of angiotensinogen increase several-fold owing to increased estrogen. Circulating levels of angiotensinogen are approximately equal to the $K_m$ of renin for its substrate (~1 μM). Consequently, the rate of AngII synthesis, and therefore blood pressure, can be influenced by changes in angiotensinogen levels. Oral contraceptives containing estrogen increase circulating levels of angiotensinogen and can induce hypertension.

**ANGIOTENSIN-CONVERTING ENZYME (ACE, KININASE II, DIPEPTIDYL CARBOXYPEPTIDASE).** ACE is an ectoenzyme and glycoprotein that contains 2 homologous domains, each with a catalytic site and a Zn$^{2+}$-binding region. ACE is rather nonspecific and cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have only 1 free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, the enzyme does not degrade AngII. ACE is identical to kininase II, the enzyme that inactivates bradykinin and other potent vasodilator peptides. Although slow conversion of AngI to AngII occurs in plasma, the very rapid metabolism that occurs in vivo is due largely to the activity of membrane-bound ACE present on the luminal surface of endothelial cells throughout the vascular system.

The *ACE* gene contains an insertion/deletion polymorphism in intron 16 that explains 47% of the phenotypic variance in serum ACE levels. The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin, may confer an increased risk of hypertension, cardiac hypertrophy, atherosclerosis, and diabetic nephropathy.

**ANGIOTENSIN-CONVERTING ENZYME 2 (ACE2).** Human ACE2 contains a single catalytic domain that is 42% identical to the 2 catalytic domains of
ACE. ACE2 cleaves 1 amino acid from the carboxyl terminal to convert AngI to Ang(1-9) and AngII to Ang(1-7). AngII is the preferred substrate for ACE2 with 400-fold higher affinity than AngI. ACE2 may serve as a counterregulatory mechanism to oppose the effects of ACE. ACE2 regulates the levels of AngII and limits its effects by converting it to Ang(1-7), which binds to Mas receptors and elicits vasodilator and anti-proliferative responses. ACE2 is not inhibited by ACE inhibitors and has no effect on bradykinin. In animals, reduced expression of ACE2 is associated with hypertension, defects in cardiac contractility, and elevated levels of AngII.

**ANGIOTENSIN PEPTIDES.** AngI is rapidly converted to AngII. Angiotensin III (AngIII), also called Ang(2–8), can be formed either by the action of aminopeptidase on AngII or by the action of ACE on Ang(2-10). AngII and AngIII cause qualitatively similar effects. AngII and AngIII stimulate aldosterone secretion with equal potency; however, AngIII is only 25% and 10% as potent as AngII in elevating blood pressure and stimulating the adrenal medulla, respectively.

Ang(1-7) is formed by multiple pathways (see Figure 26–1). Ang(1-7) opposes many of the effects of AngII: It induces vasodilation, promotes NO production, potentiates the vasodilatory effects of bradykinin, and inhibits AngII-induced activation of ERK1/2; it has antiangiogenic, antiproliferative, and antithrombotic effects; and is cardioprotective in cardiac ischemia and heart failure. The effects of Ang(1-7) are mediated by a specific Mas receptor. ACE inhibitors increase tissue and plasma levels of Ang(1-7), both because AngI levels are increased and diverted away from AngII formation and because ACE contributes to the plasma clearance of Ang(1-7). AT1 receptor blockade boosts the levels of AngII that is converted to Ang(1-7) by ACE2.

Angiotensin IV (AngIV), also called Ang(3-8), is formed from AngIII through the action of aminopeptidase M and has potent effects on memory and cognition. Central and peripheral actions of AngIV are mediated through specific AT4 receptors identified as insulin-regulated aminopeptidases (IRAPs). AngIV binding to AT4 receptors inhibits the catalytic activity of IRAPs and enables accumulation of various neuropeptides linked to memory potentiation. Other actions include renal vasodilation, natriuresis, neuronal differentiation, hypertrophy, inflammation, and extracellular matrix remodeling. Analogs of
angiotensin IV are being developed for their therapeutic potential in cognition in Alzheimer disease or head injury.

**LOCAL (TISSUE) RENIN-ANGIOTENSIN SYSTEMS.** Many tissues—including the brain, pituitary, blood vessels, heart, kidney, and adrenal gland—express mRNAs for renin, angiotensinogen, and/or ACE, and various cells cultured from these tissues produce renin, angiotensinogen, ACE, and angiotensins I, II, and III. Thus, it appears that local RASs exist independently of the renal/hepatic-based system and may influence vascular, cardiac, and renal function and structure. Activation of (tissue) RAS and local AngII production require the binding of renin or prorenin to the specific (pro)renin receptor (PRR), located on cell surfaces.

**The (Pro)Renin Receptor.** The PRR is the functional cell surface receptor that binds prorenin and renin with high affinity ($K_D \sim 6$ and 20 nM, respectively) and specificity. Binding of (pro)renin to PRR enhances the catalytic activity of renin by 4- to 5-fold and induces non-proteolytic activation of prorenin (Figure 26–4). Bound, activated (pro)renin catalyzes the conversion of angiotensinogen to AngI, which can be converted to AngII by ACE located on the cell surface. AngII binds to $\text{AT}_1$ receptors and activates intracellular signaling events that regulate cell growth, collagen deposition, fibrosis, inflammation, and apoptosis.

![Figure 26–4](image)

**Figure 26–4** Biological activation of prorenin and pharmacological inhibition of renin. Prorenin is inactive; accessibility of angiotensinogen (AGT) to the catalytic site is blocked by the propeptide (black segment). The blocked catalytic site can be activated non-proteolytically by the binding of prorenin to the (pro)renin receptor (PRR) or by proteolytic removal of the propeptide. The competitive renin inhibitor, aliskiren, has a higher affinity ($\sim 0.1 \mu$m) for the
active site of renin than does AGT (~1 μm).

The binding of (pro)renin to PRR also induces AngII-independent signaling events that include activation of ERK1/2, p38, tyrosine kinases, TGF-β gene expression, and plasminogen activator inhibitor type 1 (PAI-1). These signaling pathways are not blocked by ACE inhibitors or AT₁ receptor antagonists and are reported to contribute to fibrosis, nephrosis, and organ damage. PRR is abundant in the heart, brain, eye, adrenals, placenta, adipose tissue, liver, and kidneys.

Prorenin is no longer considered the inactive precursor of renin, as it is capable of activating local RAS and AngII-independent events that may contribute to organ damage. Circulating plasma concentrations of prorenin are 10-fold higher than renin in healthy subjects but are elevated to 100-fold in diabetic patients and are associated with increased risk of nephropathy, renal fibrosis, and retinopathy. The interaction of prorenin with PRR has become a target for therapeutic interventions.

Prorenin and renin also bind to the mannose-6-phosphate receptor (M6P), an insulin-like growth factor II receptor that functions as a clearance receptor. Knockout of the PRR gene is lethal. In humans, mutations in the PRR gene are associated with mental retardation and epilepsy, suggesting an important role in cognition, brain development, and survival.

ALTERNATIVE PATHWAYS FOR ANGIOTENSIN BIOSYNTHESIS. Angiotensinogen may be converted to AngI or directly to AngII by cathepsin G and tonin. Other enzymes that convert AngI to AngII include cathepsin G, chymostatin-sensitive AngII-generating enzyme, and heart chymase.

ANGIOTENSIN RECEPTORS. AngII and AngIII bind to specific GPCRs designated AT₁ and AT₂. Most of the known biological effects of AngII are mediated by the AT₁ receptor. The AT₁ receptor gene contains a polymorphism (A-to-C transversion in position 1166) associated with hypertension, hypertrophic cardiomyopathy, and coronary artery vasoconstriction. Preeclampsia is associated with the development of agonistic auto-antibodies against the AT₁ receptor.
The functional role of the AT\textsubscript{2} receptor is less defined, but may counterbalance many of the effects of the AT\textsubscript{1} receptor by having antiproliferative, proapoptotic, vasodilatory, natriuretic, and antihypertensive effects. The AT\textsubscript{2} receptor is distributed widely in fetal tissues, but its distribution is more restricted in adults. Expression of AT\textsubscript{2} receptor is upregulated in cardiovascular diseases, including heart failure, cardiac fibrosis, and ischemic heart disease; however, the significance of increased AT\textsubscript{2} receptor expression is unclear.

The Mas receptor mediates the effects of Ang(1-7), which include vasodilation and antiproliferation. Deletion of the Mas gene in transgenic mice reveals cardiac dysfunction.

The AT\textsubscript{4} receptor mediates the effects of AngIV. This receptor is a single transmembrane protein (1025 amino acids) that co-localizes with the glucose transporter GLUT4. AT\textsubscript{4} receptors are detectable in a number of tissues, such as heart, vasculature, adrenal cortex, and brain regions processing sensory and motor functions.

**ANGIOTENSIN RECEPTOR-EFFECTOR COUPLING.** AT\textsubscript{1} receptors activate a large array of signal-transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses. AT\textsubscript{1} receptors couple to several heterotrimeric G proteins, including G\textsubscript{q}, G\textsubscript{12/13}, and G\textsubscript{i}. In most cell types, AT\textsubscript{1} receptors couple to G\textsubscript{q} to activate the PLCβ–IP\textsubscript{3}–Ca\textsuperscript{2+} pathway. Secondary to G\textsubscript{q} activation, activation of PKC, PLA\textsubscript{2}, and PLD and eicosanoid production, as well as activation of Ca\textsuperscript{2+}-dependent and MAP kinases and the Ca\textsuperscript{2+}–calmodulin–dependent activation of NOS may occur. Activation of G\textsubscript{i} may occur and will reduce the activity of adenyl cyclase, lowering cellular cyclic AMP content. The βγ subunits of G\textsubscript{i} and activation of G\textsubscript{12/13} lead to activation of tyrosine kinases and small G proteins such as Rho. Ultimately, the JAK/STAT pathway may be activated and a variety of transcriptional regulatory factors induced. AT\textsubscript{1} receptors also stimulate the activity of a membrane-bound NADH/NADPH oxidase that generates reactive oxygen species (ROS). ROS may contribute to biochemical effects (activation of MAP kinase, tyrosine
kinase, and phosphatases; inactivation of NO; and expression of monocyte chemoattractant protein-1) and physiological effects (acute effects on renal function, chronic effects on blood pressure, and vascular hypertrophy and inflammation). The presence of other receptors may alter the response to AT\textsubscript{1} receptor activation. For example, AT\textsubscript{1} receptors heterodimerize with bradykinin B\textsubscript{2} receptors, a process that enhances AngII sensitivity in preeclampsia.

Signaling from AT\textsubscript{2} receptors is mediated by G protein-dependent and independent pathways. Stimulation of AT\textsubscript{2} receptor activates phosphoprotein phosphatases, K\textsuperscript{+} channels, synthesis of NO and cyclic GMP, bradykinin production, and inhibition of Ca\textsuperscript{2+} channel functions. AT\textsubscript{2} receptors may possess constitutive activity: overexpression of AT\textsubscript{2} receptors can induce NO production in vascular smooth muscle cells and hypertrophy in cardiac myocytes through an intrinsic activity of the AT\textsubscript{2} receptor independent of AngII binding.

**FUNCTIONS AND EFFECTS OF THE RENIN-ANGIOTENSIN SYSTEM**

AngII increases total peripheral resistance (TPR) and alters renal function and cardiovascular structure through direct and indirect mechanisms (Figure 26–5).
Figure 26–5 *Major effects of AngII*. NE, norepinephrine.

**EFFECTS ON TPR**

**Direct Vasoconstriction.** AngII constricts precapillary arterioles and, to a lesser extent, postcapillary venules by activating AT$_1$ receptors located on vascular smooth muscle cells and stimulating the G$_q$–PLC–IP$_3$–Ca$^{2+}$ pathway. AngII has differential effects on vascular beds. Direct vasoconstriction is strongest in the kidneys (see Figure 26–5) and the splanchnic vascular bed. AngII-induced vasoconstriction is much less in vessels of the brain, lungs, and skeletal muscle. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow.

**Enhancement of Peripheral Noradrenergic Neurotransmission.** AngII augments NE release from sympathetic nerve terminals by inhibiting the reuptake of NE...
into nerve terminals and by enhancing the vascular response to NE.

**Effects on the CNS.** AngII increases sympathetic tone. Small amounts of AngII infused into the vertebral arteries cause an increase in arterial blood pressure. This response reflects effects of the hormone on circumventricular nuclei that are not protected by a blood-brain barrier. Circulating AngII also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial pressure. The CNS is affected both by blood-borne AngII and by AngII formed within the brain. The brain contains all components of the RAS. AngII also causes a centrally mediated dipsogenic (thirst) effect and enhances the release of vasopressin from the neurohypophysis.

**Release of Catecholamines from the Adrenal Medulla.** AngII stimulates the release of catecholamines from the adrenal medulla by depolarizing chromaffin cells.

**EFFECTS ON RENAL FUNCTION**

**Alteration of Renal Function.** AngII has pronounced effects on renal function, reducing the urinary excretion of Na⁺ and water while increasing the excretion of K⁺. The overall effect of AngII on the kidneys is to shift the renal pressure–natriuresis curve to the right (Figure 26–6).
Figure 26–6 Pressure-natriuresis curve: effects of Na\(^+\) intake on renin release (AngII formation) and arterial blood pressure. Inhibition of the renin-angiotensin system will cause a large drop in blood pressure in Na\(^+\)-depleted individuals. (Modified with permission from Jackson EK, Branch RA, et al: Physiological functions of the renal prostaglandin, renin, and kallikrein systems, in Seldin DW, Giebisch GH, eds: The Kidney: Physiology and Pathophysiology, Vol 1. Philadelphia: Lippincott Williams & Wilkins, 1985, p 624.)

Direct Effects of Angiotensin II on Na\(^+\) Reabsorption in the Renal Tubules. Very low concentrations of AngII stimulate Na\(^+\)/H\(^+\) exchange in the proximal tubule—an effect that increases Na\(^+\), Cl\(^-\), and bicarbonate reabsorption. Approximately 20-30% of the bicarbonate handled by the nephron may be affected by this mechanism. AngII also increases the expression of the Na\(^+\)–glucose symporter in the proximal tubule. Paradoxically, at high concentrations, AngII may inhibit Na\(^+\) transport in the proximal tubule. AngII also directly stimulates the Na\(^+\)–K\(^+\)–2Cl\(^-\) symporter in the thick ascending limb.

Release of Aldosterone from the Adrenal Cortex. AngII stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone, and augments responses to other stimuli (e.g., adrenocorticotropic hormone, K\(^+\)). Increased output of aldosterone is elicited by concentrations of AngII that have little or no acute effect on blood pressure. Aldosterone acts on the distal and collecting tubules to cause retention of Na\(^+\) and excretion of K\(^+\) and H\(^+\). The stimulant effect of AngII on aldosterone synthesis and release is enhanced under conditions of hyponatremia or hyperkalemia and is reduced when concentrations of Na\(^+\) and K\(^+\) in plasma are altered in the opposite directions.

Altered Renal Hemodynamics. AngII reduces renal blood flow and renal excretory function by directly constricting the renal vascular smooth muscle, by enhancing renal sympathetic tone (a CNS effect), and by facilitating renal adrenergic transmission (an intrarenal effect). AngII-induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine owing to signal-transduction systems activated by AT\(_1\) and the adenosine A\(_1\) receptor. AngII influences glomerular filtration rate (GFR) by means of several mechanisms:

• Constriction of the afferent arterioles, which reduces intraglomerular
pressure and tends to reduce GFR
• Contraction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and also tends to decrease GFR
• Constriction of efferent arterioles, which increases intraglomerular pressure and tends to increase GFR

Normally, GFR is slightly reduced by AngII; however, during renal artery hypotension, the effects of AngII on the efferent arteriole predominate so that AngII increases GFR. Thus, blockade of the RAS may cause acute renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

EFFECTS ON CARDIOVASCULAR STRUCTURE. Pathological alterations involving cardiac hypertrophy and remodeling increase morbidity and mortality. The cells involved include vascular smooth muscle cells, cardiac myocytes, and fibroblasts. AngII stimulates the migration, proliferation, and hypertrophy of vascular smooth muscle cells; causes hypertrophy of cardiac myocytes; and increases extracellular matrix production by cardiac fibroblasts. AngII alters extracellular matrix formation and degradation indirectly by increasing aldosterone. In addition to the direct cellular effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na\(^+\) retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

ROLE OF THE RAS IN LONG-TERM MAINTENANCE OF ARTERIAL BLOOD PRESSURE DESPITE EXTREMES IN DIETARY Na\(^+\) INTAKE. Arterial blood pressure is a major determinant of Na\(^+\) excretion. This is illustrated graphically by plotting urinary Na\(^+\) excretion versus mean arterial blood pressure (see Figure 26–6), a plot known as the renal pressure–natriuresis curve. Over the long term, Na\(^+\) excretion must equal Na\(^+\) intake. The RAS plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na\(^+\) intake. When dietary Na\(^+\) intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure–natriuresis curve to the right. Conversely, when dietary Na\(^+\) is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure–natriuresis curve to the left. When modulation of RAS is blocked by
drugs, changes in salt intake markedly affect long-term levels of arterial blood pressure.

**INHIBITORS OF THE RENIN-ANGIOTENSIN SYSTEM**

Clinical interest focuses on developing inhibitors of the RAS. Three types of inhibitors are used therapeutically (Figure 26–7):

![Inhibitors of the RAS](image)

**Figure 26–7 Inhibitors of the RAS.** ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; DRI, direct renin inhibitor.

- ACE inhibitors (ACEIs)
- Angiotensin receptor blockers (ARBs)
- Direct renin inhibitors (DRIs)

While all of these classes of agents will reduce the actions of AngII and lower blood pressure, they have different effects on the individual components of the RAS (Table 26–1).

**ANGIOTENSIN-CONVERTING ENZYME INHIBITORS**

**PHARMACOLOGICAL EFFECTS.** The effect of ACE inhibitors on the RAS is to inhibit the conversion of AngI to the active AngII. Inhibition of AngII production will lower blood pressure and enhance natriuresis. ACE is an enzyme with many substrates; thus, there are other consequences of its inhibition, including inhibition of bradykinin degradation. ACE inhibitors increase by 5-fold the circulating levels of the natural stem cell regulator N-acetyl-seryl-aspartyl-lysyl-proline, which may contribute to the cardioprotective effects of ACE inhibitors. In addition, ACE inhibitors will increase renin release and the rate of formation of AngI by interfering with both short- and long-loop negative feedbacks on renin release (see Figure 26–2). Accumulating AngI is directed down alternative metabolic routes that increase production of vasodilator peptides such as Ang(1-7).

**Clinical Pharmacology.** ACE inhibitors can be classified into 3 broad groups based on chemical structure: (1) sulfhydryl-containing ACE inhibitors structurally related to captopril; (2) dicarboxyl-containing ACE inhibitors structurally related to enalapril (e.g., lisinopril, benazepril, quinapril, moexipril,
ramipril, trandolapril, perindopril); and (3) phosphorus-containing ACE inhibitors structurally related to fosinopril. Many ACE inhibitors are ester-containing prodrugs that are 100-1000 times less potent but have a better oral bioavailability than the active molecules. With the exceptions of fosinopril and spirapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and dosages of these drugs should be reduced in patients with renal impairment.

All ACE inhibitors block the conversion of AngI to AngII and have similar therapeutic indications, adverse-effect profiles, and contraindications. Because hypertension usually requires lifelong treatment, quality-of-life issues are an important consideration in comparing antihypertensive drugs. ACE inhibitors differ markedly in tissue distribution, and it is possible that this difference could be exploited to inhibit some local (tissue) RAS while leaving others relatively intact.

*Captopril* (Capoten, others). Captopril is a potent ACE inhibitor with a $K_i$ of 1.7 nM. Given orally, captopril is absorbed rapidly and has a bioavailability $\approx 75\%$. Bioavailability is reduced by 25-30% with food. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly with a $t_{1/2}$ $\approx 2$ h. Most of the drug is eliminated in urine, 40-50% as captopril and the rest as captopril disulfide dimers and captopril–cysteine disulfide. The oral dose of captopril ranges from 6.25-150 mg 2-3 times daily, with 6.25 mg 3 times daily or 25 mg twice daily being appropriate for the initiation of therapy for heart failure or hypertension, respectively.

*Enalapril* (Vasotec, others). Enalapril maleate is a prodrug that is hydrolyzed by esterases in the liver to enalaprilat. Enalaprilat is a potent inhibitor of ACE with a $K_i$ of 0.2 nM. Enalapril is absorbed rapidly and has an oral bioavailability of $\approx 60\%$ (not reduced by food). Although peak concentrations of enalapril in plasma occur within an hour, enalaprilat concentrations peak only after 3-4 h. Enalapril has a $t_{1/2}$ $\approx 1.3$ h, but enalaprilat, because of tight binding to ACE, has a plasma $t_{1/2}$ of $\approx 11$ h. Elimination is by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5-40 mg daily, with 2.5 and 5 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively.
**Enalaprilat** *(VASOTEC INJECTION, others).* Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate. For hypertensive patients, the dosage is 0.625 to 1.25 mg given intravenously over 5 min. This dosage may be repeated every 6 h.

**Lisinopril** *(PRINIVIL, ZESTRIL, others).* Lisinopril is the lysine analog of enalaprilat; unlike enalapril, lisinopril itself is active. Lisinopril is absorbed slowly, and incompletely (~30%) after oral administration (not reduced by food); peak concentrations in plasma are achieved in ~7 h. It is cleared as the intact compound by the kidney, and its $t_{1/2}$ in plasma is ~12 h. Lisinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5–40 mg daily (single or divided dose), with 5 and 10 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg and close medical supervision is recommended for patients with heart failure who are hyponatremic or have renal impairment.

**Benazepril** *(LOTENSIN, others).* Hepatic esterases transforms benazepril, a prodrug, into benazeprilat. Benazepril is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is metabolized to benazeprilat and to the glucuronide conjugates of benazepril and benazeprilat, which are excreted into both the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in 0.5-1 h and 1-2 h, respectively. Benazeprilat has a plasma $t_{1/2}$ of 10-11 h. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5-80 mg daily (single or divided dose).

**Fosinopril** *(MONOPRIL, others).* Cleavage of the ester moiety by hepatic esterases transforms fosinopril into fosinoprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugate of fosinoprilat. These are excreted in both the urine and bile; peak concentrations of fosinoprilat in plasma are achieved in ~3 h. Fosinoprilat has an effective plasma $t_{1/2}$ of ~11.5 h; its clearance is not significantly altered by renal impairment. The oral dosage of fosinopril ranges from 10-80 mg daily (single or divided dose). The initial dose is reduced to 5 mg daily in patients with Na⁺ or water depletion or renal failure.
Trandolapril (Mavik, others). An oral dose of trandolapril is absorbed without reduction by food and produces plasma levels of trandolapril (10% bioavailability) and trandolaprilat (70% bioavailability). Trandolaprilat is ~8 times more potent than trandolapril as an ACE inhibitor. Trandolapril is metabolized to trandolaprilat and to inactive metabolites that are recovered in the urine (33%, mostly trandolaprilat) and feces (66%). Trandolaprilat displays biphasic elimination kinetics with an initial \( t_{1/2} \) of ~10 h (the major component of elimination), followed by a more prolonged \( t_{1/2} \) (owing to slow dissociation of trandolaprilat from tissue ACE). Plasma clearance of trandolaprilat is reduced by both renal and hepatic insufficiency. The oral dosage ranges from 1 to 8 mg daily (single or divided dose). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment, and 2 mg for African Americans.

Quinapril (Accupril, others). Cleavage of the ester moiety by hepatic esterases transforms quinapril, a prodrug, into quinaprilat. Quinapril is absorbed rapidly (peak concentrations are achieved in 1 h), and the rate, but not extent, of oral absorption (60%) may be reduced by food (delayed peak). Quinaprilat and other minor metabolites of quinapril are excreted in the urine (61%) and feces (37%). Conversion of quinapril to quinaprilat is reduced in patients with diminished liver function. The initial \( t_{1/2} \) of quinaprilat is ~2 h; a prolonged terminal \( t_{1/2} \approx 25 \) h may be due to high-affinity binding of the drug to tissue ACE. The oral dosage range of quinapril is 5-80 mg daily.

Ramipril (Altace, others). Cleavage of the ester moiety by hepatic esterases transforms ramipril into ramiprilat, an ACE inhibitor that in vitro is about as potent as benazeprilat and quinaprilat. Ramipril is absorbed rapidly (peak concentrations are achieved in 1 h), and the rate but not extent of its oral absorption (50-60%) is reduced by food. Ramipril is metabolized to ramiprilat and to inactive metabolites that are excreted predominantly by the kidneys. Ramiprilat displays triphasic elimination kinetics with half-lives of 2-4 h, 9-18 h, and >50 h. This triphasic elimination is due to extensive distribution to all tissues (initial \( t_{1/2} \)), clearance of free ramiprilat from plasma (intermediate \( t_{1/2} \)), and dissociation of ramiprilat from tissue ACE (long terminal \( t_{1/2} \)). The oral dosage range of ramipril is 1.25-20 mg daily (single or divided dose).

Moexipril (Univasc, others). Moexipril’s antihypertensive activity is due to its de-esterified metabolite, moexiprilat. Moexipril is absorbed incompletely, with
bioavailability as moexiprilat of ~13%. Bioavailability is markedly decreased by food. The elimination $t_{1/2}$ varies between 2 and 12 h. The recommended dosage range is 7.5-30 mg daily (single or divided doses). The dosage range is halved in patients who are taking diuretics or who have renal impairment.

**Perindopril (ACEON).** Perindopril erbumine is a prodrug, and 30-50% of systemically available perindopril is transformed to perindoprilat by hepatic esterases. Although the oral bioavailability of perindopril (75%) is not affected by food, the bioavailability of perindoprilat is reduced by ~35%. Perindopril is metabolized to perindoprilat and to inactive metabolites that are excreted predominantly by the kidneys. Perindoprilat displays biphasic elimination kinetics with half-lives of 3-10 h (the major component of elimination) and 30-120 h (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage range is 2-16 mg daily (single or divided dose).

**THERAPEUTIC USES OF ACE INHIBITORS.** Drugs that interfere with RAS play a prominent role in the treatment of cardiovascular disease, the major cause of mortality in modern Western societies.

**ACE Inhibitors in Hypertension.** Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states except when high blood pressure is due to primary aldosteronism (see Chapter 27). The initial change in blood pressure tends to be positively correlated with plasma renin activity (PRA) and AngII plasma levels prior to treatment. The long-term decrease in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure–natriuresis curve (see Figure 26–6) and a reduction in total peripheral resistance in which there is variable participation by different vascular beds. The kidney is a notable exception: because the renal vessels are extremely sensitive to the vasoconstrictor actions of AngII, ACE inhibitors increase renal blood flow via vasodilation of the afferent and efferent arterioles. Increased renal blood flow occurs without an increase in GFR; thus, the filtration fraction is reduced.

ACE inhibitors cause systemic arteriolar dilation and increase the compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed,
although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Even when a substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K+. Excessive retention of K+ is encountered in patients taking supplemental K+, in patients with renal impairment, or in patients taking other medications that reduce K+ excretion.

ACE inhibitors alone normalize blood pressure in ~50% of patients with mild to moderate hypertension. Ninety percent of patients with mild to moderate hypertension will be controlled by the combination of an ACE inhibitor and either a Ca²⁺ channel blocker, a β adrenergic receptor blocker, or a diuretic. Several ACE inhibitors are marketed in fixed-dose combinations with a thiazide diuretic or Ca²⁺ channel blocker for the management of hypertension.

**ACE Inhibitors in Left Ventricular Systolic Dysfunction.** Unless contraindicated, ACE inhibitors should be given to patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure (see Chapter 28). Inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and cardiac index increase. In systolic dysfunction, AngII decreases arterial compliance, and this is reversed by ACE inhibition. Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by AngII, and the diminished direct effects of AngII on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an
increased capacity of the venous bed.

The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced. In heart failure, ACE inhibitors reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling via changes in preload/afterload, by preventing the growth effects of AngII on myocytes, and by attenuating cardiac fibrosis induced by AngII and aldosterone.

ACE Inhibitors in Acute Myocardial Infarction. The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive and diabetic patients (see Chapter 27). Unless contraindicated (e.g., cardiogenic shock or severe hypotension), ACE inhibitors should be started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists. In high-risk patients (e.g., large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term.

ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events. Patients at high risk of cardiovascular events benefit considerably from treatment with ACE inhibitors. ACE inhibition significantly decreases the rates of myocardial infarction, stroke, and death. In patients with coronary artery disease but without heart failure, ACE inhibition reduces cardiovascular disease death and myocardial infarction.

ACE Inhibitors in Diabetes Mellitus and Renal Failure. Diabetes mellitus is the leading cause of renal disease. In patients with type 1 diabetes mellitus and diabetic nephropathy, captopril prevents or delays the progression of renal disease. Renoprotection in type 1 diabetes, as defined by changes in albumin excretion, also is observed with lisinopril. The renoprotective effects of ACE inhibitors in type 1 diabetes are in part independent of blood pressure reduction. In addition, ACE inhibitors may decrease retinopathy progression in type 1 diabetics and attenuate the progression of renal insufficiency in patients with a variety of non-diabetic nephropathies.
Several mechanisms participate in the renal protection afforded by ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter both by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to peptide and protein factors that may stimulate mesangial cell proliferation and matrix production, 2 processes that contribute to expansion of the mesangium in diabetic nephropathy. Because AngII is a growth factor, reductions in the intrarenal levels of AngII may further attenuate mesangial cell growth and matrix production.

**ADVERSE EFFECTS OF ACE INHIBITORS**

In general, ACE inhibitors are well tolerated. The drugs do not alter plasma concentrations of uric acid or Ca\(^{2+}\) and may improve insulin sensitivity in patients with insulin resistance and decrease cholesterol and lipoprotein (a) levels in proteinuric renal disease.

*Hypotension.* A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. Care should be exercised in patients who are salt depleted, are on multiple antihypertensive drugs, or who have congestive heart failure.

*Cough.* In 5-20% of patients, ACE inhibitors induce a bothersome, dry cough mediated by the accumulation in the lungs of bradykinin, substance P, and/or prostaglandins. Thromboxane antagonism, aspirin, and iron supplementation reduce cough induced by ACE inhibitors. ACE dose reduction or switching to an ARB is sometimes effective. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days.

*Hyperkalemia.* ACE inhibitors may cause hyperkalemia in patients with renal insufficiency or diabetes or in patients taking K\(^+\)-sparing diuretics, K\(^+\) supplements, β receptor blockers, or NSAIDs.

*Acute Renal Failure.* Inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or
diuretics.

**Fetopathic Potential.** The fetopathic effects may be due in part to fetal hypotension. Once pregnancy is diagnosed, use of ACE inhibitors must be discontinued immediately.

**Skin Rash.** ACE inhibitors occasionally cause a maculopapular rash that may itch, but that may resolve spontaneously or with antihistamines.

**Angioedema.** In 0.1-0.5% of patients, ACE inhibitors induce a rapid swelling in the nose, throat, mouth, glottis, larynx, lips, and/or tongue. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient’s airway should be protected, and if necessary, epinephrine, an antihistamine, and/or a glucocorticoid should be administered. Although rare, angioedema of the intestine (visceral angioedema) characterized by emesis, watery diarrhea, and abdominal pain also has been reported.

**Other Side Effects.** Extremely rare but reversible side effects include *dysgeusia* (an alteration in or loss of taste), *neutropenia* (symptoms include sore throat and fever), *glycosuria* (spillage of glucose into the urine in the absence of hyperglycemia), and *hepatotoxicity*.

**Drug Interactions.** Antacids may reduce the bioavailability of ACE inhibitors; capsaicin may worsen ACE inhibitor–induced cough; NSAIDs, including aspirin, may reduce the antihypertensive response to ACE inhibitors; and K+-sparing diuretics and K+ supplements may exacerbate ACE inhibitor–induced hyperkalemia. ACE inhibitors may increase plasma levels of digoxin and lithium and may increase hypersensitivity reactions to allopurinol.

**NON-PEPTIDE ANGIOTENSIN II RECEPTOR ANTAGONISTS**

**PHARMACOLOGICAL EFFECTS.** The AngII receptor blockers bind to the AT₁ receptor with high affinity and show >10,000-fold selectivity for the AT₁ receptor over the AT₂ receptor. Although binding of ARBs to the AT₁ receptor is competitive, the inhibition by ARBs of biological responses to AngII often is insurmountable (the maximal response to AngII cannot be restored in the presence of the
ARB regardless of the concentration of AngII added to the experimental preparation).

ARBs inhibit most of the biological effects of AngII which include AngII–induced: (1) contraction of vascular smooth muscle, (2) rapid pressor responses, (3) slow pressor responses, (4) thirst, (5) vasopressin release, (6) aldosterone secretion, (7) release of adrenal catecholamines, (8) enhancement of noradrenergic neurotransmission, (9) increases in sympathetic tone, (10) changes in renal function, and (11) cellular hypertrophy and hyperplasia.

Do ARBs have therapeutic efficacy equivalent to that of ACE inhibitors? Although both classes of drugs block the RAS, they differ in several important aspects:

- **ARBs reduce activation of AT$_1$ receptors more effectively than do ACE inhibitors.** ACE inhibitors do not inhibit alternative non-ACE AngII-generating pathways. ARBs block the actions of AngII via the AT$_1$ receptor regardless of the biochemical pathway leading to AngII formation.

- **ARBs permit activation of AT$_2$ receptors.** Both ACE inhibitors and ARBs stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of AngII. Because ARBs block AT$_1$ receptors, this increased level of AngII is available to activate AT$_2$ receptors.

- **ACE inhibitors may increase Ang(1-7) levels more than do ARBs.** ACE is involved in the clearance of Ang(1-7), so inhibition of ACE may increase Ang(1-7) levels more so than do ARBs.

- **ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin and Ac-SDKP.**

Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

**CLINICAL PHARMACOLOGY**
Oral bioavailability of ARBs generally is modest (<50%, except for irbesartan, 70%), and protein binding is high (>90%).

**Candesartan Cilexetil** *(ATACAND)*. Candesartan cilexetil is an inactive ester prodrug that is completely hydrolyzed to the active form, candesartan, during absorption from the GI tract. Plasma $t_{1/2}$ is ~9 h. Plasma clearance of candesartan is due to renal elimination (33%) and biliary excretion (67%). The plasma clearance of candesartan is affected by renal insufficiency but not by mild-to-moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dose of 4-32 mg.

**Eprosartan** *(TEVETEN)*. Peak plasma levels are obtained 1-2 h after oral administration, and the plasma $t_{1/2}$ is 5-9 h. Eprosartan is metabolized in part to the glucuronide conjugate. Clearance is by renal elimination and biliary excretion. The plasma clearance of eprosartan is affected by both renal insufficiency and hepatic insufficiency. The recommended dosage of eprosartan is 400-800 mg/day in 1 or 2 doses.

**Irbesartan** *(AVAPRO)*. The plasma $t_{1/2}$ is 11-15 h. Irbesartan is metabolized in part to the glucuronide conjugate; the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild-to-moderate hepatic insufficiency. The oral dosage of irbesartan is 150-300 mg once daily.

**Losartan** *(COZAAR)*. Approximately 14% of an oral dose of losartan is converted by CYP2C9 and CYP3A4 to the 5-carboxylic acid metabolite EXP 3174, which is more potent than losartan as an AT$_1$ receptor antagonist. Plasma half-lives of losartan and EXP 3174 are 2.5 and 6-9 h, respectively. The plasma clearances of losartan and EXP 3174 are due to renal clearance and hepatic clearance (metabolism and biliary excretion) and are affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25-00 mg. Losartan is a competitive antagonist of the thromboxane A$_2$ receptor and attenuates platelet aggregation. Also, EXP 3179, a metabolite of losartan without angiotensin receptor effects, reduces COX-2 mRNA upregulation and COX-dependent prostaglandin generation.

**Olmesartan Medoxomil** *(BENICAR)*. Olmesartan medoxomil is an inactive ester
prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the gastrointestinal tract. The plasma $t_{1/2}$ is 10-15 h. Plasma clearance of olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20-40 mg once daily.

**Telmisartan (MICARDIS).** The plasma $t_{1/2}$ is ~24 h. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of telmisartan is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40-80 mg once daily.

**Valsartan (DIOVAN).** The plasma $t_{1/2}$ is ~9 h. Food markedly decreases absorption. Valsartan is cleared from the circulation by the liver (~70% of total clearance). The plasma clearance of valsartan is affected by hepatic but not renal insufficiency. The oral dosage of valsartan is 80-320 mg once daily.

**Azilsartan Medoxomil (EDARBI)** is a prodrug that is hydrolyzed in the GI tract to the active drug azilsartan. The drug is available in 40 mg and 80 mg once-daily doses. The bioavailability of azilsartan is ~60% and is not affected by food. The elimination $t_{1/2}$ is ~11 h. Azilsartan is metabolized mostly by CYP2C9 into inactive metabolites. Elimination of the drug is 55% in feces and 42% in urine. No dose adjustments are necessary for elderly patients or patients with renal impairment or mild to moderate hepatic impairment. The recommended dose is 80 mg once a day. Fixed–doses of azilsartan medoxomil with the diuretic chlorthalidone (EDARBYCLOR) are available as 40/12.5 mg and 40/25 mg once-daily single tablets.

**Therapeutic Uses of AngII Receptor Antagonists.** All ARBs are approved for the treatment of hypertension. In addition, irbesartan and losartan are approved for diabetic nephropathy, losartan is approved for stroke prophylaxis, and valsartan is approved for heart failure and to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or left ventricular dysfunction following myocardial infarction. The efficacy of ARBs in lowering blood pressure is comparable with that of ACE inhibitors and other established antihypertensive drugs, with a favorable adverse-effect profile. ARBs also are
available as fixed-dose combinations with hydrochlorothiazide or amlodipine (see Chapters 27 and 28).

Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for treatment of heart failure in patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors. There is conflicting evidence regarding the advisability of combining an ARB and an ACE inhibitor in heart failure patients.

ARBs are renoprotective in type 2 diabetes mellitus, in part via blood pressure–independent mechanisms. Many experts now consider them the drugs of choice for renoprotection in diabetic patients.

**Adverse Effects.** ARBs are well tolerated. The incidence of angioedema and cough with ARBs is less than that with ACE inhibitors. ARBs have teratogenic potential and should be discontinued in pregnancy. In patients whose arterial blood pressure or renal function is highly dependent on the RAS (e.g., renal artery stenosis), ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or in patients taking K⁺ supplements or K⁺-sparing diuretics. There are rare reports of anaphylaxis, abnormal hepatic function, hepatitis, neutropenia, leukopenia, agranulocytosis, pruritus, urticaria, hyponatremia, alopecia, and vasculitis, including Henoch-Schönlein purpura.

**DIRECT RENIN INHIBITORS**

DRIs are a new class of antihypertensive drugs that inhibit the RAS at the level of the rate limiting step, renin. Angiotensinogen is the only specific substrate for renin, and its conversion to AngI presents a rate-limiting step for the generation of angiotensin peptides. Aliskiren hemifumarate (TEKTURNA) is the only DRI approved for clinical use.

**Pharmacological Effects.** Aliskiren is a low-molecular-weight non-peptide that is a potent competitive inhibitor of renin. It binds the active site of renin to block conversion of angiotensinogen to AngI, thus reducing the consequent production of AngII (see Figure 26–4). Aliskiren has a 10,000-fold higher affinity to renin (IC$_{50}$ ~0.6 nM) than to any other aspartic peptidases. In healthy volunteers,
Aliskiren (40-640 mg/day) induces a dose-dependent decrease in blood pressure, reduces PRA and AngI and AngII levels, but increases plasma renin concentration by 16- to 34-fold due to the loss of the short-loop negative feedback by AngII. Aliskiren also decreases plasma and urinary aldosterone levels and enhances natriuresis.

**Clinical Pharmacology.** Aliskiren is recommended as a single oral dose of 150 or 300 mg/day. Bioavailability is low (~2.5%), but its high affinity and potency compensate for the low bioavailability. Peak plasma concentrations are reached within 3-6 h. The $t_{1/2}$ is 20-45 h; steady-state plasma level is achieved in 5-8 days. Aliskiren is a substrate for P-glycoprotein (Pgp), which accounts for low absorption. Fatty meals significantly decrease the absorption of aliskiren. Elimination is mostly as unchanged drug in feces. About 25% of the absorbed dose appears in the urine as parent drug. Aliskiren is well tolerated in the elderly population, in patients with hepatic disease and renal insufficiency, and in patients with type 2 diabetes.

**Therapeutic Uses of Aliskiren in Hypertension.** Aliskiren is an effective antihypertensive agent that induces significant dose-dependent (75-300 mg) reductions in blood pressure. Aliskiren is as effective as ACE inhibitors (ramipril), ARBs (losartan, irbesartan, valsartan), and hydrochlorothiazide (HCTZ) in lowering blood pressure in patients with mild-to-moderate hypertension. Aliskiren also is as effective as lisinopril in lowering blood pressure in patients with severe hypertension. The long $t_{1/2}$ of aliskiren allows its antihypertensive effects to be sustained for several days following termination of therapy.

Several studies indicate that the effect of aliskiren in combination with ACE inhibitors, ARBs, and HCTZ is additive in lowering systolic and diastolic blood pressure than any of the drugs alone. PRA is inhibited by aliskiren but significantly elevated with ramipril, irbesartan, and HCTZ (see Table 26–1). Coadministration of aliskiren with ramipril, irbesartan, or HCTZ neutralizes the increase in PRA to baseline levels. Because plasma renin levels correlate with the capacity to generate AngII, the ability of aliskiren to neutralize plasma renin in combination therapy may contribute to better control of blood pressure than monotherapy. Combination therapy of aliskiren with ACE inhibitors or ARBs is contraindicated in patients with diabetes or kidney impairment. Fixed-dose
combinations of aliskiren/HCTZ (TekturnaHCT), aliskiren and the Ca++ channel blocker amlodipine besylate (Tekamlo) and aliskiren/HCTZ/amlodipine besylate (Amturnide) are available for antihypertensive therapy.

Aliskiren is an effective antihypertensive agent that is well tolerated in monotherapy and combination therapy. It has cardioprotective and renoprotective effects in combination therapy. The ability of aliskiren to inhibit the increased PRA caused by ACE inhibitors and ARBs theoretically provides a more comprehensive blockade of the RAS and may limit activation of the local (tissue) RAS (see Table 26–1). Studies are ongoing to address whether aliskiren provides long-term advantages against end-organ damage in cardiovascular disease.

Aliskiren is currently recommended in patients who are intolerant to other antihypertensive therapies or for use in combination with other drugs for further blood pressure control.

**Adverse Events.** Aliskiren is well tolerated, and adverse events are mild or comparable to placebo with no gender difference. Adverse effects include mild gastrointestinal symptoms such as diarrhea observed at high doses (600 mg daily), abdominal pain, dyspepsia, and gastroesophageal reflux; headache; nasopharyngitis; dizziness; fatigue; upper respiratory tract infection; back pain; angioedema; and cough (much less common than with ACE inhibitors). Other adverse effects reported for aliskiren that were slightly increased compared with placebo include rash, hypotension, hyperkalemia in diabetics on combination therapy, elevated uric acid, renal stones, and gout. Like other RAS inhibitors, aliskiren is not recommended in pregnancy.

**Drug Interactions.** Aliskiren does not interact with drugs that interact with CYPs. Aliskiren reduces absorption of furosemide by 50%. Irbesartan reduces the Cmax of aliskiren by 50%. Aliskiren plasma levels are increased by drugs, such as ketoconazole, atorvastatin, and cyclosporine, that inhibit P-glycoprotein.

**PHARMACOLOGICAL LOWERING OF BLOOD PRESSURES ALTERS COMPONENTS OF THE RAS**

The RAS responds to alterations in blood pressure with compensatory changes (see Figure 26–2). Thus, pharmacological agents that lower
blood pressure will alter the feedback loops that regulate the RAS and cause changes in the levels and activities of the system’s components. These changes are summarized in Table 26–1.
Angina pectoris, the primary symptom of ischemic heart disease, is caused by transient episodes of myocardial ischemia that are due to an imbalance in the myocardial oxygen supply–demand relationship that may be caused by an increase in myocardial oxygen demand or by a decrease in myocardial oxygen supply or sometimes by both (Figure 27–1). Typical angina is experienced as a heavy, pressing substernal discomfort (rarely described as a “pain”), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrium. However, a significant minority of patients note discomfort in a different location or of a different character. Myocardial ischemia also may be silent, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms.

Figure 27–1 Pharmacological modification of the major determinants of myocardial O₂ supply. When myocardial O₂ requirements exceed O₂ supply, an ischemic episode results. This figure shows the primary hemodynamic sites of actions of pharmacological agents that can reduce O₂ demand (left side) or enhance O₂ supply (right side). Some classes of agents have multiple effects. Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O₂ supply. Both pharmacotherapy and mechanotherapy attempt to restore a dynamic balance between O₂ demand and O₂ supply.

This section describes the principal pharmacological agents used in the treatment
of angina: nitrovasodilators, β adrenergic receptor antagonists, and Ca^{2+} channel antagonists. These anti-anginal agents improve the balance of myocardial O_2 supply and O_2 demand, increasing supply by dilating the coronary vasculature and/or decreasing demand by reducing cardiac work (see Figure 27–1).

Drugs used in typical angina function principally by reducing myocardial O_2 demand by decreasing heart rate, myocardial contractility, and/or ventricular wall stress. By contrast, the principal therapeutic goal in unstable angina is to increase myocardial blood flow; strategies include the use of antiplatelet agents and heparin to reduce intracoronary thrombosis, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

**ORGANIC NITRATES**

These agents are prodrugs that are sources of nitric oxide (NO) (Table 27–1).

*B, buccal (transmucosal) tablet; C, sustained-release capsule or tablet; D, transdermal disc or patch; IV, intravenous injection; O, ointment; S, lingual spray; T, tablet for sublingual use; (C), chewable tablet; (O), oral tablet or capsule.*

Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid. Nitrate esters (—C—O—NO_2) and nitrite esters (—C—O—NO) are characterized by the sequence of carbon–oxygen–nitrogen. Organic
nitrates of low molecular mass (such as nitroglycerin) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (e.g., erythrityl tetranitrate, isosorbide dinitrate, and isosorbide mononitrate) are solids. The organic nitrates and nitrites, collectively termed nitrovasodilators, must be metabolized (reduced) to produce gaseous NO, the active principle of this class of compounds. NO gas also may be administered by inhalation.

**PHARMACOLOGICAL PROPERTIES**

*Mechanism of Action.* Nitrites, organic nitrates, nitroso compounds, and a variety of other nitrogen oxide–containing substances (including nitroprusside) are basically exogenous sources of NO. NO can activate guanylyl cyclase and thereby increase the cellular level of cyclic GMP, which activates PKG and can modulate the activities of cyclic nucleotide phosphodiesterases (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is phosphorylative activation of myosin light chain phosphatase, reduced phosphorylation of myosin light chain, reduced Ca\(^{2+}\) concentration in the cytosol, and relaxation. The pharmacological and biochemical effects of the nitrovasodilators appear to be identical to those of EDRF (endothelium-derived relaxing factor), now known to be NO. This NO-mediated pathway leads to relaxation of smooth muscle in the vasculature, bronchi, and GI tract, and inhibition of platelet aggregation. Chapter 3 presents details of NO biosynthesis and action.

*Cardiovascular Effects; Hemodynamic Effects.* Low concentrations of nitroglycerin preferentially dilate veins more than arterioles. This venodilation decreases venous return, leading to a fall in left and right ventricular chamber size and end-diastolic pressures, but usually results in little change in systemic vascular resistance. Systemic arterial pressure may fall slightly; heart rate is unchanged or may increase slightly in response to a decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of nitroglycerin that do not alter systemic arterial pressure may still produce arteriolar dilation in the face and neck, resulting in a facial flush, or dilation of meningeal arterial vessels, causing headache.

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and cardiac output and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. The reflex tachycardia and
peripheral arteriolar vasoconstriction tend to restore systemic vascular resistance; this is superimposed on sustained venous pooling. Coronary blood flow may increase transiently as a result of coronary vasodilation but may decrease subsequently if cardiac output and blood pressure decrease sufficiently. In patients with autonomic dysfunction and an inability to increase sympathetic outflow, the physiological means to compensate for this fall in blood pressure are absent. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina. The appropriate therapy in patients with orthostatic angina and normal coronary arteries is to correct the orthostatic hypotension by expanding volume (fludrocortisone and a high-sodium diet), to prevent venous pooling with fitted support garments, and to carefully titrate use of oral vasopressors. Because patients with autonomic dysfunction occasionally may have coexisting coronary artery disease, the coronary anatomy should be defined before therapy is undertaken.

Effects on Coronary Blood Flow. Myocardial ischemia is a powerful stimulus to coronary vasodilation, and regional blood flow is adjusted by autoregulatory mechanisms. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation; if the stenosis is severe, much of the capacity to dilate is used to maintain resting blood flow and further dilation may not be possible when demand increases. Significant coronary stenoses disproportionately reduce blood flow to the subendocardial regions of the heart, which are subjected to the greatest extravascular compression during systole; organic nitrates tend to restore blood flow in these regions toward normal. The hemodynamic mechanisms responsible for these effects are likely the capacity of organic nitrates to cause dilation and prevent vasoconstriction of large epicardial vessels without impairing autoregulation in the small vessels. An important indirect mechanism for a preferential increase in subendocardial blood flow is the nitroglycerin-induced reduction in intracavitary systolic and diastolic pressures that oppose blood flow to the subendocardium (see below).

Effects on Myocardial O2 Requirements. By their effects on the systemic circulation, the organic nitrates can reduce myocardial O2 demand. The major determinants of myocardial O2 consumption include left ventricular wall tension, heart rate, and myocardial contractility. Ventricular wall tension is affected by a number of factors that may be considered under the categories of preload and
afterload. **Preload** is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Decreasing end-diastolic volume reduces ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases O₂ consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. **Afterload** is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and O₂ consumption.

Organic nitrates decrease both preload and afterload as a result of respective dilation of venous capacitance and arteriolar resistance vessels. They do not directly alter the inotropic or chronotropic state of the heart. Since nitrates reduce the primary determinants of myocardial O₂ demand, their net effect usually is to decrease myocardial O₂ consumption. The effect of nitrovasodilators to inhibit platelet function may contribute to their anti-anginal efficacy, this effect appears to be modest.

**Mechanism of Relief of Symptoms of Angina Pectoris.** The capacity of nitrates to dilate epicardial coronary arteries, even in areas of atherosclerotic stenosis, is modest, and the preponderance of evidence continues to favor a reduction in myocardial work, and thus in myocardial O₂ demand, as their primary effect in chronic stable angina. Paradoxically, high doses of organic nitrates may reduce blood pressure to such an extent that coronary flow is compromised; reflex tachycardia and adrenergic enhancement of contractility also occur. These effects may override the beneficial action of the drugs on myocardial O₂ demand and can aggravate ischemia. Additionally, sublingual nitroglycerin administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

**OTHER EFFECTS.** The nitrovasodilators act on almost all smooth muscle tissues. Bronchial smooth muscle is relaxed irrespective of the preexisting tone. The muscles of the biliary tract, including those of the gallbladder, biliary ducts, and sphincter of Oddi, are effectively relaxed. Smooth muscle of the GI tract, including that of the esophagus, can be relaxed and its spontaneous motility
decreased by nitrates both in vivo and in vitro. The effect may be transient and incomplete in vivo, but abnormal “spasm” frequently is reduced. Indeed, many incidences of atypical chest pain and “angina” are due to biliary or esophageal spasm, and these too can be relieved by nitrates. Similarly, nitrates can relax ureteral and uterine smooth muscle, but these responses are of uncertain clinical significance.

**ADME AND PREPARATIONS**

**Nitroglycerin.** In humans, peak concentrations of nitroglycerin are found in plasma within 4 min of sublingual administration; the drug has a $t_{1/2}$ of 1-3 min. The onset of action of nitroglycerin may be even more rapid if it is delivered as a sublingual spray rather than as a sublingual tablet. Glyceryl dinitrate metabolites, which have about one-tenth the vasodilator potency, appear to have half-lives of ~40 min.

**Isosorbide Dinitrate.** The major route of metabolism of isosorbide dinitrate in humans appears to be by enzymatic denitration followed by glucuronide conjugation. Sublingual administration produces maximal plasma concentrations of the drug by 6 min, and the fall in concentration is rapid ($t_{1/2}$ of ~45 min). The primary initial metabolites, isosorbide-2-mononitrate and isosorbide-5-mononitrate, have longer half-lives (3-6 h) and presumably contribute to the therapeutic efficacy of the drug.

**Isosorbide-5-Mononitrate.** This agent is available in tablet form. It does not undergo significant first-pass metabolism and so has excellent bioavailability after oral administration. The mononitrate has a significantly longer $t_{1/2}$ than does isosorbide dinitrate and has been formulated as a plain tablet and as a sustained-release preparation; both preparations have longer durations of action than the corresponding dosage forms of isosorbide dinitrate.

**Inhaled NO.** Nitric oxide gas administered by inhalation appears to exert most of its therapeutic effects on the pulmonary vasculature; systemically, it rapidly interacts with heme groups in hemoglobin in the blood. Inhaled NO is used to treat pulmonary hypertension in hypoxemic neonates, where inhaled NO reduces morbidity and mortality.

**TOLERANCE**
Sublingual organic nitrates should be taken at the time of an anginal attack or in anticipation of exercise or stress. Such intermittent treatment provides reproducible cardiovascular effects. However, frequently repeated or continuous exposure to high doses of organic nitrates leads to a marked attenuation in the magnitude of most of their pharmacological effects. The magnitude of tolerance is a function of dosage and frequency of use. Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO, *true vascular tolerance*, or to the activation of mechanisms extraneous to the vessel wall, *pseudotolerance*. Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals. Inactivation of mitochondrial aldehyde dehydrogenase, an enzyme implicated in biotransformation of nitroglycerin, is seen in models of nitrate tolerance, potentially associated with oxidative stress. A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway; tolerance could involve endothelium-derived reactive oxygen species.

An effective approach to restoring responsiveness is to interrupt therapy for 8-12 h each day, which allows the return of efficacy. It is usually most convenient to omit dosing at night in patients with exertional angina either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous nitroglycerin. However, patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (i.e., occurring in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Tolerance also has been seen with isosorbide-5-mononitrate; an eccentric twice-daily dosing schedule appears to maintain efficacy. Some patients develop an increased frequency of nocturnal angina when a nitrate-free interval is employed using nitroglycerin patches; such patients may require another class of anti-anginal agent during this period. Tolerance is not universal, and some patients develop only partial tolerance. The problem of anginal rebound during nitrate-free intervals is especially problematic in the treatment of unstable angina with intravenous nitroglycerin. As tolerance develops, increasing doses are required to achieve the same therapeutic effects; eventually, despite dose escalation, the drug loses efficacy.

A special form of nitroglycerin tolerance is observed in individuals exposed to
nitroglycerin in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment. Tolerance then develops, but headache and other symptoms may reappear after a few days away from the job—the “Monday disease.” The most serious effect of chronic exposure is a form of organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of acute coronary syndromes during the 24-72-h periods away from the work environment. Because of the potential problem of nitrate dependence, it seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.

**TOXICITY AND UNTOWARD RESPONSES.** Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe. It usually decreases over a few days if treatment is continued and often can be controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by alcohol. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

**INTERACTION OF NITRATES WITH PDE5 INHIBITORS.** Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of coronary artery disease. Thus, many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) anti-anginal therapy. The combination of sildenafil and other phosphodiesterase 5 (PDE5) inhibitors with organic nitrate vasodilators can cause extreme
Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission. NO stimulates the formation of cyclic GMP, which leads to relaxation of smooth muscle of the corpus cavernosum and penile arteries, engorgement of the corpus cavernosum, and erection. The accumulation of cyclic GMP can be enhanced by inhibition of the cyclic GMP–specific PDE5 family. Sildenafil (VIAGRA, REVATIO) and congeners inhibit PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction. Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. Since the introduction of sildenafil, 3 additional PDE5 inhibitors have been developed for use in therapy of erectile dysfunction. Tadalafil (CIALIS, ADCIRCA), vardenafil (LEVITRA), and avanafil (STENDRA) share similar therapeutic efficacy and side-effect profiles with sildenafil; tadalafil has a longer time to onset of action and a longer therapeutic $t_{1/2}$ than the other PDE5 inhibitors. Sildenafil has been the most thoroughly characterized of these compounds, but all 3 PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators, and the PDE5 inhibitors should be used with caution in patients taking α or β adrenergic receptor antagonists (see Chapter 12).

The side effects of sildenafil and other PDE5 inhibitors are largely predictable on the basis of their effects on PDE5. Headache, flushing, and rhinitis may be observed, as well as dyspepsia owing to relaxation of the lower esophageal sphincter. Sildenafil and vardenafil also weakly inhibit PDE6, the enzyme involved in photoreceptor signal transduction (see Chapters 3 and 64), and can produce visual disturbances, most notably changes in the perception of color hue or brightness. In addition to visual disturbances, sudden one-sided hearing loss has also been reported. Tadalafil inhibits PDE11, a widely distributed PDE isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe coronary artery disease, these drugs have modest effects on blood pressure, producing >10% fall in systolic, diastolic, and mean systemic pressures and in pulmonary artery systolic and mean pressures. However, sildenafil, tadalafil, and vardenafil all have a significant and potentially dangerous interaction with organic nitrates, which act therapeutically via enhancing cyclic GMP production in smooth muscle. In the presence of a...
PDE5 inhibitor, nitrates cause profound increases in cyclic GMP and can produce dramatic reductions in blood pressure. This drug class toxicity is the basis for the warning that PDE5 inhibitors should not be prescribed to patients receiving any form of nitrate and dictates that patients should be warned about the prior use of PDE5 inhibitors within 24 h of administration of nitrates. A period of longer than 24 h may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with tadalafil because of its prolonged $t_{1/2}$. In the event that patients develop significant hypotension following combined administration of sildenafil and a nitrate, fluids and $\alpha$ adrenergic receptor agonists, if needed, should be used for support. These same hemodynamic responses to PDE5 inhibition also may underlie the efficacy of sildenafil in the treatment of patients with primary pulmonary hypertension, in whom chronic treatment with the drug appears to result in enhanced exercise capacity associated with a decrease in pulmonary vascular resistance. PDE5 inhibitors also are being studied in patients with congestive heart failure and cardiac hypertrophy (see Chapter 28).

Sildenafil, tadalafil, vardenafil, and avanafil are metabolized via CYP3A4, and their toxicity may be enhanced in patients who receive other substrates of this enzyme, including macrolide and imidazole antibiotics, some statins, and antiretroviral agents (see individual chapters and Chapter 6). PDE5 inhibitors also may prolong cardiac repolarization by blocking the $I_{Kr}$. In patients with coronary artery disease whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered. Such therapy needs to be individualized, and appropriate warnings must be given about the risk of toxicity if nitrates are taken subsequently for angina. Alternative non-nitrate anti-anginal therapy, such as $\beta$ adrenergic receptor antagonists, should be used during these time periods.

**THERAPEUTIC USES**

**ANGINA.** Diseases that predispose to angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute anxiety can precipitate anginal symptoms in many patients. Patients should be counseled to stop smoking, lose weight, and maintain a
low-fat, high-fiber diet; hypertension and hyperlipidemia should be corrected; and daily aspirin (or clopidogrel if aspirin is not tolerated) (see Chapter 30) should be prescribed. Exposure to sympathomimetic agents (e.g., those in nasal decongestants and other sources) probably should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved. Table 27–1 lists the preparations and dosages of the nitrites and organic nitrates.

Sublingual Administration. Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug of the organic nitrates given sublingually. The onset of action is within 1-2 min, but the effects are undetectable by 1 h after administration.

Oral Administration. Oral nitrates often are used to provide prophylaxis against anginal episodes. Higher doses of either isosorbide dinitrate (e.g., 20 mg or more orally every 4 h) or sustained-release preparations of nitroglycerin decrease the frequency of anginal attacks and improve exercise tolerance. Effects peak at 60-90 min and last for 3-6 h. Administration of isosorbide mononitrate (typically starting at 20 mg) once or twice daily (in the latter case, with the doses administered 7 h apart) is efficacious in the treatment of chronic angina, and once-daily dosing or an eccentric twice-daily dosing schedule can minimize the development of tolerance.

Cutaneous Administration. Nitroglycerin ointment (2%) is applied to the skin (2.5-5 cm); the dosage must be adjusted for each patient. Effects are apparent within 30-60 min (although absorption is variable) and last for 4-6 h. The ointment is particularly useful for controlling nocturnal angina, which commonly develops within 3 h after the patient goes to sleep. To avoid tolerance, therapy should be interrupted for at least 8 h each day.

Transmucosal or Buccal Nitroglycerin. This formulation is inserted under the upper lip above the incisors, where it adheres to the gingiva and dissolves gradually in a uniform manner. Hemodynamic effects are seen within 2-5 min, and it is therefore useful for short-term prophylaxis of angina.

CONGESTIVE HEART FAILURE. The utility of nitrovasodilators to relieve
pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 28.

UNSTABLE ANGINA PECTORIS AND NON-ST-SEGMENT–ELEVATION MYOCARDIAL INFARCTION. The term unstable angina pectoris has been used to describe a broad spectrum of clinical entities characterized by an acute or subacute worsening in a patient’s anginal symptoms. The variable prognosis of unstable angina reflects the broad range of clinical entities subsumed by the term. Efforts have been directed toward identifying patients with unstable angina on the basis of their risks for subsequent adverse outcomes such as MI or death. The term acute coronary syndrome has been useful in this context: Common to most clinical presentations of acute coronary syndrome is disruption of a coronary plaque, leading to local platelet aggregation and thrombosis at the arterial wall, with subsequent partial or total occlusion of the vessel. There is some variability in the pathogenesis of unstable angina, with gradually progressive atherosclerosis accounting for some cases of new-onset exertional angina. Less commonly, vasospasm in minimally atherosclerotic coronary vessels may account for some cases where rest angina has not been preceded by symptoms of exertional angina. For the most part, the pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial oxygen demand—have limited efficacy in the treatment of acute coronary syndromes characterized by an insufficiency of myocardial oxygen (blood) supply.

OTHER AGENTS; DRUG COMBINATIONS. Drugs that reduce myocardial O₂ consumption by reducing ventricular preload (nitrates) or by reducing heart rate and ventricular contractility (β adrenergic receptor antagonists) are efficacious, but additional therapies are directed at an atherosclerotic plaque and the consequences (or prevention) of its rupture. These therapies include combinations of:

- Antiplatelet agents, including aspirin and thienopyridines such as clopidogrel or prasugrel
- Antithrombin agents such as heparin and the thrombolytics anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein (GP)IIb/IIIa mechano-pharmacological approaches with percutaneously deployed intracoronary stents
• Coronary bypass surgery for selected patients

Along with nitrates and β adrenergic receptor antagonists, antiplatelet agents represent the cornerstone of therapy for acute coronary syndrome. Aspirin inhibits platelet aggregation and improves survival. Heparin (either unfractionated or low-molecular-weight) also appears to reduce angina and prevent infarction. These and related agents are discussed in detail in Chapters 30 and 34. Anti-integrin agents directed against the platelet integrin GPIIb/IIIa (including abciximab, tirofiban, and eptifibatide) are effective in combination with heparin, as discussed later. Nitrates are useful both in reducing vasospasm and in reducing myocardial O_2 consumption by decreasing ventricular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous nitroglycerin is likely to be effective, although the addition of a Ca^{2+} channel blocker may be required to achieve complete control.

**ACUTE MYOCARDIAL INFARCTION.** Therapeutic maneuvers in MI are directed at reducing the size of the infarct, preserving or retrieving viable tissue by reducing the O_2 demand of the myocardium, and preventing ventricular remodeling that could lead to heart failure.

Nitroglycerin is commonly administered to relieve ischemic pain in patients presenting with MI, but evidence that nitrates improve mortality in MI is sparse. Because they reduce ventricular preload through vasodilation, nitrates are effective in relief of pulmonary congestion. A decreased ventricular preload should be avoided in patients with right ventricular infarction because higher right-sided heart filling pressures are needed in this clinical context. Nitrates are relatively contraindicated in patients with systemic hypotension. According to the American Heart Association/American College of Cardiology (AHA/ACC) guidelines, “nitrates should not be used if hypotension limits the administration of β blockers, which have more powerful salutary effects.” Because the proximate cause of MI is intracoronary thrombosis, reperfusion therapies are critically important, employing, when possible, direct percutaneous coronary interventions (PCIs) for acute MI, usually using drug-eluting intracoronary
stents. Thrombolytic agents are administered at hospitals where emergency PCI is not performed, but outcomes are better with direct PCI than with thrombolytic therapy.

**VARIANT (PRINZMETAL) ANGINA.** The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca\(^{2+}\) channel blockers usually is required.

**CA\(^{2+}\) CHANNEL ANTAGONISTS**

Voltage-sensitive Ca\(^{2+}\) channels (L-type or slow channels) mediate the entry of extracellular Ca\(^{2+}\) (~1.25 mM) into smooth muscle and cardiac myocytes and sinoatrial (SA) and atrioventricular (AV) nodal cells (cytosolic concentration in resting cell, ~100 nM) in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca\(^{2+}\) is a trigger for contraction, albeit by different mechanisms. Ca\(^{2+}\) channel antagonists, also called Ca\(^{2+}\) entry blockers, inhibit Ca\(^{2+}\) channel function. In vascular smooth muscle, this leads to relaxation, especially in arterial beds. In the heart, these drugs can produce negative inotropic and chronotropic effects.

Clinically used Ca\(^{2+}\) channel antagonists include the phenylalkylamine compound verapamil, the benzothiazepine diltiazem, and numerous dihydropyridines, including nifedipine, amlodipine, felodipine, isradipine, nicardipine, nisoldipine, and nimodipine. The specificities of several of these drugs are shown in Table 27–2. Although these drugs are commonly grouped together as “Ca\(^{2+}\) channel blockers,” there are fundamental differences among verapamil, diltiazem, and the dihydropyridines, especially with respect to pharmacological characteristics, drug interactions, and toxicities.

**Table 27–2**

Comparative CV Effects\(^{a}\) of Ca\(^{2+}\) Channel Blockers
Mechanisms of Action. An increased concentration of cytosolic Ca\(^{2+}\) causes increased contraction in both cardiac and vascular smooth muscle cells. The entry of extracellular Ca\(^{2+}\) initiates contraction of cardiac myocytes (Ca\(^{2+}\)-induced Ca\(^{2+}\) release, where the bulk of contractile Ca\(^{2+}\) is from the sarcoplasmic reticulum) and provides a major source of contractile Ca\(^{2+}\) in smooth muscle (in which the release of Ca\(^{2+}\) from IP\(_3\)-sensitive intracellular storage vesicles and Ca\(^{2+}\) entry via receptor-operated channels can also contribute to contraction, particularly in some vascular beds). The Ca\(^{2+}\) channel antagonists produce their effects by binding to the α\(_1\) subunit of the L-type Ca\(^{2+}\) channels and reducing Ca\(^{2+}\) flux through the channel. The vascular and cardiac effects of some of the Ca\(^{2+}\) channel blockers are summarized in the next section and in Table 27–2.

PHARMACOLOGICAL PROPERTIES

CARDIOVASCULAR EFFECTS

Vascular Tissue. At least 3 distinct mechanisms may be responsible for contraction of vascular smooth muscle cells. First, voltage-sensitive Ca\(^{2+}\) channels open in response to depolarization of the membrane, and extracellular Ca\(^{2+}\) moves down its electrochemical gradient into the cell. Second, agonist-induced contractions that occur without depolarization of the membrane result from stimulation of the G\(_q\)-PLC–IP\(_3\) pathway, resulting in the release of intracellular Ca\(^{2+}\) from the sarcoplasmic reticulum (see Chapter 3). Third, receptor-operated Ca\(^{2+}\) channels allow the entry of extracellular Ca\(^{2+}\) in response to receptor occupancy.

Ca\(^{2+}\) channel antagonists inhibit the voltage-dependent Ca\(^{2+}\) channels in vascular smooth muscle at significantly lower concentrations than are required to
interfere with the release of intracellular Ca\textsuperscript{2+} or to block receptor-operated Ca\textsuperscript{2+} channels. All Ca\textsuperscript{2+} channel blockers relax arterial smooth muscle, but they have a less pronounced effect on most venous beds and hence do not affect cardiac preload significantly.

Cardiac Cells. In the SA and AV nodes, depolarization largely depends on the movement of Ca\textsuperscript{2+} through the slow channel. The effect of a Ca\textsuperscript{2+} channel blocker on AV conduction and on the rate of the sinus node pacemaker depends on whether or not the agent delays the recovery of the slow channel. Although nifedipine reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca\textsuperscript{2+} channel. The channel blockade caused by nifedipine and related dihydropyridines also shows little dependence on the frequency of stimulation. At doses used clinically, nifedipine does not affect conduction through the AV node. In contrast, verapamil not only reduces the magnitude of the Ca\textsuperscript{2+} current through the slow channel but also decreases the rate of recovery of the channel. In addition, channel blockade caused by verapamil (and to a lesser extent by diltiazem) is enhanced as the frequency of stimulation increases, a phenomenon known as frequency dependence or use dependence. Verapamil and diltiazem depress the rate of the sinus node pacemaker and slow AV conduction; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 29). Bepridil, like verapamil, inhibits both slow inward Ca\textsuperscript{2+} current and fast inward Na\textsuperscript{+} current. It has a direct negative inotropic effect. Its electrophysiological properties lead to slowing of the heart rate, prolongation of the AV nodal effective refractory period, and importantly, prolongation of the QTc interval. Particularly in the setting of hypokalemia, the last effect can be associated with torsade de pointes, a potentially lethal ventricular arrhythmia (see Chapter 29).

In cardiac myocytes, initiation of Ca\textsuperscript{2+}-induced Ca\textsuperscript{2+} release relies on entry Ca\textsuperscript{2+} of through the L-type channel in response to depolarization. By reducing this entry, Ca\textsuperscript{2+} channel blockers can produce a negative inotropic effect.

Hemodynamic Effects. All the Ca\textsuperscript{2+} channel blockers approved for clinical use decrease coronary vascular resistance and can lead to an increase in coronary blood flow. The dihydropyridines are more potent vasodilator than verapamil, which is more potent than diltiazem. The hemodynamic effects of these agents vary depending on the route of administration and the extent of left ventricular dysfunction. Drugs that significantly lower mean pressure will elicit a
baroreceptor reflex response.

Nifedipine, the prototypical dihydropyridine, selectively dilates arterial resistance vessels. The decrease in arterial blood pressure elicits sympathetic reflexes, with resulting tachycardia and positive inotropy. Nifedipine has direct negative inotropic effects in vitro but relaxes vascular smooth muscle at significantly lower concentrations than those required for prominent direct effects on the heart. Thus, arteriolar resistance and blood pressure are lowered, contractility and segmental ventricular function are improved, and heart rate and cardiac output are increased modestly. After oral administration of nifedipine, arterial dilation increases peripheral blood flow; venous tone does not change. The other dihydropyridines—amlodipine, felodipine, isradipine, nicardipine, nisoldipine, nimodipine, and clevidipine—share many of the cardiovascular effects of nifedipine.

Amlodipine has a slow absorption and a prolonged effect. Amlodipine produces both peripheral arterial vasodilation and coronary dilation. There is less reflex tachycardia with amlodipine than with nifedipine, possibly because the long $t_{1/2}$ (35-50 h) produces minimal peaks and troughs in plasma concentrations. Felodipine may have even greater vascular specificity than does nifedipine or amlodipine. At concentrations producing vasodilation, there is no negative inotropic effect. Nicardipine has anti-anginal properties similar to those of nifedipine and may have selectivity for coronary vessels. Isradipine also produces the typical peripheral vasodilation seen with other dihydropyridines, but because of its inhibitory effect on the SA node, little or no rise in heart rate is seen. Despite the negative chronotropic effect, isradipine appears to have little effect on the AV node, so it may be used in patients with AV block or combined with a β adrenergic receptor antagonist. In general, because of their lack of myocardial depression and, to a greater or lesser extent, lack of negative chronotropic effect, dihydropyridines are less effective as monotherapy in stable angina than are verapamil, diltiazem, or a β adrenergic receptor antagonist. Nisoldipine is more than 1000 times more potent in preventing contraction of human vascular smooth muscle than in preventing contraction of human cardiac muscle in vitro, suggesting a high degree of vascular selectivity. Although nisoldipine has a short elimination $t_{1/2}$, a sustained-release preparation that is efficacious as an anti-anginal agent has been developed. Nimodipine has high lipid solubility and is effective in inhibiting cerebral vasospasm and has been
used primarily to treat patients with neurological defects associated with cerebral vasospasm after subarachnoid hemorrhage.

Clevidipine is a novel dihydropyridine L-type Ca$^{2+}$ channel blocker—available for intravenous administration—that has a very rapid ($t_{1/2} \sim 2$ min) onset and offset of action. It is metabolized by esterases in blood, similar to the fate of esmolol. Clevidipine preferentially affects arterial smooth muscle compared to targeting veins or the heart. Infusions are typically started at a rate of 1-2 μg/kg/min and titrated to the desired effect on blood pressure.

Verapamil is a less potent vasodilator the dihydropyridines. Like dihydropyridines, verapamil causes little effect on venous resistance vessels at concentrations that produce arteriolar dilation. With doses of verapamil sufficient to produce peripheral arterial vasodilation, there are more direct negative chronotropic, dromotropic, and inotropic effects than with the dihydropyridines. Intravenous verapamil causes a decrease in arterial blood pressure owing to a decrease in vascular resistance, but the reflex tachycardia is blunted or abolished by the direct negative chronotropic effect of the drug. This intrinsic negative inotropic effect is partially offset by both a decrease in afterload and the reflex increase in adrenergic tone. Thus, in patients without congestive heart failure, ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with congestive heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. Oral administration of verapamil reduces peripheral vascular resistance and blood pressure, often with minimal changes in heart rate. The relief of pacing-induced angina seen with verapamil is due primarily to a reduction in myocardial oxygen demand.

Intravenous administration of diltiazem can result initially in a marked decrease in peripheral vascular resistance and arterial blood pressure, which elicits a reflex increase in heart rate and cardiac output. Heart rate then falls below initial levels because of the direct negative chronotropic effect of the agent. Oral administration of diltiazem decreases both heart rate and mean arterial blood pressure. While diltiazem and verapamil produce similar effects on the SA and AV nodes, the negative inotropic effect of diltiazem is more modest.

**ADME.** Although the absorption of these agents is nearly complete after oral administration, their bioavailability is reduced, in some cases markedly, by first-
pass hepatic metabolism. The effects of these drugs are evident within 30-60 min of an oral dose, with the exception of the more slowly absorbed and longer-acting agents amlodipine, isradipine, and felodipine. These agents all are bound extensively to plasma proteins (70-98%); their elimination half-lives vary widely, from 1.3 to 64 h. During repeated oral administration, bioavailability and $t_{1/2}$ may increase because of saturation of hepatic metabolism. The bioavailability of some of these drugs may be increased by grapefruit juice, likely through inhibition of enzyme CYP3A4. A major metabolite of diltiazem is desacetyldiltiazem, which has about one-half of diltiazem’s potency as a vasodilator. $N$-Demethylation of verapamil results in production of norverapamil, which is biologically active but much less potent than the parent compound. The $t_{1/2}$ of norverapamil is ~10 h. The metabolites of the dihydropyridines are inactive or weakly active. In patients with hepatic cirrhosis, the bioavailabilities and half-lives of the Ca$^{2+}$ channel blockers may be increased, and dosage should be adjusted. The half-lives of these agents also may be longer in older patients. Except for diltiazem and nifedipine, all the Ca$^{2+}$ channel blockers are administered as racemic mixtures.

**Toxicity and Untoward Responses.** The profile of adverse reactions to the Ca$^{2+}$ channel blockers varies among the drugs in this class. Patients receiving immediate-release capsules of nifedipine develop headache, flushing, dizziness, and peripheral edema. Dizziness and flushing are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long $t_{1/2}$ and relatively constant concentrations of drug in plasma. Peripheral edema may occur in some patients with Ca$^{2+}$ channel blockers; it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction. Some other adverse effects of these drugs are due to actions in nonvascular smooth muscle. Contraction of the lower esophageal sphincter is inhibited by the Ca$^{2+}$ channel blockers. Ca$^{2+}$ channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of verapamil, but it occurs less frequently with other Ca$^{2+}$ channel blockers. Uncommon adverse effects include urinary retention, rash, and elevations of liver enzymes.

Worsened myocardial ischemia has been observed with nifedipine from excessive hypotension and decreased coronary perfusion, selective coronary vasodilation in nonischemic regions of the myocardium in a setting where
vessels perfusing ischemic regions were already maximally dilated (i.e., coronary steal), or an increase in O₂ demand owing to increased sympathetic tone and excessive tachycardia. Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration of verapamil in patients with disease of the SA node or AV nodal conduction disturbances or in the presence of β blockade. The use of intravenous verapamil with an intravenous β adrenergic receptor antagonist is contraindicated because of the increased propensity for AV block and/or severe depression of ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures < 90 mm Hg should not be treated with verapamil or diltiazem, particularly intravenously. Some Ca²⁺ channel antagonists such as verapamil can cause an increase in the concentration of digoxin in plasma; resulting toxicity from the cardiac glycoside rarely develops, but the use of verapamil to treat digitalis toxicity thus is contraindicated; AV nodal conduction disturbances may be exacerbated.

Drug Interactions. Verapamil blocks the P-glycoprotein drug transporter. Both the renal and hepatic disposition of digoxin occurs via this transporter. Accordingly, verapamil inhibits the elimination of digoxin and other drugs that are cleared from the body by the P-glycoprotein (see Chapter 5). When used with quinidine, Ca²⁺ channel blockers may cause excessive hypotension, particularly in patients with idiopathic hypertrophic subaortic stenosis.

THERAPEUTIC USES

VARIANT ANGINA. Variant angina results from reduced blood flow rather than increased oxygen demand. Ca²⁺ channel blocking agents have proven efficacy for the treatment of variant angina. These drugs can attenuate ergonovine-induced vasospasm in patients with variant angina, which suggests that protection in variant angina is due to coronary dilation rather than to alterations in peripheral hemodynamics.

EXERTIONAL ANGINA. Ca²⁺ channel antagonists also are effective in the treatment of exertional, or exercise-induced, angina. Their utility may result from an increase in blood flow owing to coronary arterial dilation, from a decrease in myocardial oxygen demand (secondary to a decrease in arterial blood pressure, heart rate, or contractility), or both. These drugs decrease the
number of anginal attacks and attenuate exercise-induced ST-segment depression.

Ca$^{2+}$ channel antagonists, particularly the dihydropyridines, may aggravate anginal symptoms in some patients when used without a β adrenergic receptor antagonist. This adverse effect is not prominent with verapamil or diltiazem because of their limited ability to induce marked peripheral vasodilation and reflex tachycardia. Concurrent therapy with nifedipine and the β receptor antagonist propranolol or with amlodipine and any of several β receptor antagonists has proven more effective than either agent given alone in exertional angina, presumably because the β antagonist suppresses reflex tachycardia. This concurrent drug therapy is particularly attractive because the dihydropyridines, unlike verapamil and diltiazem, do not delay AV conduction and will not enhance the negative dromotropic effects associated with β receptor blockade. Although concurrent administration of verapamil or diltiazem with a β receptor antagonist also may reduce angina, the potential for AV block, severe bradycardia, and decreased left ventricular function requires that these combinations be used judiciously, especially if left ventricular function is compromised prior to therapy. Amlodipine produces less reflex tachycardia than does nifedipine probably because of a flatter plasma concentration profile. Isradipine, approximately equivalent to nifedipine in enhancing exercise tolerance, also produces less rise in heart rate, possibly because of its slower onset of action.

**Unstable Angina.** Medical therapy for unstable angina involves the administration of aspirin, which reduces mortality, nitrates, β adrenergic receptor blocking agents, and heparin. Because vasospasm occurs in some patients with unstable angina, Ca$^{2+}$ channel blockers may offer an additional approach to this condition.

**Myocardial Infarction.** There is no evidence that Ca$^{2+}$ channel antagonists are of benefit in the early treatment or secondary prevention of acute MI. Diltiazem and verapamil may reduce the incidence of reinfarction in patients with MI who are not candidates for a β adrenergic receptor antagonist, but β adrenergic receptor antagonists remain the drugs of first choice.

**Other Uses.** Ca$^{2+}$ channel antagonists are also used as anti-arrhythmic agents, for the treatment of hypertension, and for the treatment of heart failure. Verapamil
has been demonstrated to improve left ventricular outflow obstruction and symptoms in patients with hypertrophic cardiomyopathy. Verapamil also has been used in the prophylaxis of migraine headaches. While several studies suggest that dihydropyridines may suppress the progression of mild atherosclerosis, there is no evidence that this alters mortality or reduces the incidence of ischemic events. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm. Nifedipine, diltiazem, amlodipine, and felodipine appear to provide symptomatic relief in Raynaud disease. The Ca\(^{2+}\) channel antagonists cause relaxation of the myometrium \textit{in vitro} and may be effective in stopping preterm uterine contractions in preterm labor (see Chapter 66).

\textbf{β ADRENERGIC RECEPTOR ANTAGONISTS}

β Adrenergic receptor antagonists are effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. In contrast, these agents are not useful for vasospastic angina and, if used in isolation, may worsen the condition. \textit{Timolol}, metoprolol, \textit{atenolol}, and propranolol exert cardioprotective effects. The effectiveness of β adrenergic receptor antagonists in the treatment of exertional angina is attributable primarily to a fall in myocardial O\(_2\) consumption at rest and during exertion; there also is some tendency for increased flow toward ischemic regions. The decrease in myocardial O\(_2\) consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise.

Not all actions of β adrenergic receptor antagonists are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O\(_2\) consumption. However, the net effect of β receptor blockade usually is to decrease myocardial O\(_2\) consumption, particularly during exercise. In patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β receptor blockade can result in profound decreases in left
ventricular function. Despite this, several β adrenergic receptor antagonists have been shown to reduce mortality in patients with congestive heart failure (see Chapters 12 and 28). Numerous β receptor antagonists are approved for clinical use in the U.S. (see Chapter 12).

**THERAPEUTIC USES**

**UNSTABLE ANGINA.** β Adrenergic receptor antagonists are effective in reducing recurrent episodes of ischemia and the risk of progression to acute MI. Clinical trials have lacked sufficient statistical power to demonstrate beneficial effects of β receptor antagonists on mortality. If the underlying pathophysiology is coronary vasospasm, nitrates and Ca²⁺ channel blockers may be effective, and β receptor antagonists should be used with caution. In some patients, there is a combination of severe fixed disease and superimposed vasospasm; if adequate antiplatelet therapy and vasodilation have been provided by other agents and angina continues, the addition of a β receptor antagonist may be helpful.

**MYOCARDIAL INFARCTION.** β Adrenergic receptor antagonists that do not have intrinsic sympathomimetic activity improve mortality in MI. They should be given early and continued indefinitely in patients who can tolerate them.

**COMPARISON OF ANTI-ANGINAL THERAPEUTIC STRATEGIES**

In evaluating trials in which different forms of anti-anginal therapy are compared, one must pay careful attention to the patient population studied and to the pathophysiology and stage of the disease. An important placebo effect may be seen in these trials. The efficacy of anti-anginal treatment will depend on the severity of angina, the presence of coronary vasospasm, and myocardial O₂ demand. Optimally, the dose of each agent should be titrated to maximum benefit.

Task forces from the ACC and the AHA have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. Patients with coronary artery disease should be treated with aspirin and a β receptor blocking drug (particularly if there is a history of prior MI). The guidelines also note that solid data support the use of ACE
inhibitors in patients with coronary artery disease who also have left ventricular dysfunction and/or diabetes. Therapy of hypercholesterolemia also is indicated. Nitrates, for treatment of angina symptoms, and Ca\(^{2+}\) antagonists also may be used. Table 27–3 summarizes the issues that the ACC/AHA task force considered to be relevant in choosing between β receptor antagonists and Ca\(^{2+}\) channel blockers in patients with angina and other medical conditions. Comparison of β adrenergic receptor antagonists with Ca\(^{2+}\) channel blockers showed that β receptor antagonists are associated with fewer episodes of angina per week and a lower rate of withdrawal because of adverse events. However, there were no differences in time to ischemia during exercise or in the frequency of adverse events when Ca\(^{2+}\) channel blockers other than nifedipine were compared with β adrenergic receptor antagonists. There were no significant differences in outcome between the studies comparing long-acting nitrates and Ca\(^{2+}\) channel blockers and the studies comparing long-acting nitrates with β receptor antagonists.

**COMBINATION THERAPY AND NEW ANTI-ANGINAL DRUGS.**

Because the different categories of anti-anginal agents have different mechanisms of action, it has been suggested that combinations of these agents would allow the use of lower doses, increasing effectiveness and reducing the incidence of side effects. Despite the predicted advantages, combination therapy rarely achieves this potential and may be accompanied by serious side effects. The new anti-anginal agent ranolazine elicits its therapeutic effects by different and incompletely understood mechanisms that distinguish this new drug from the “classical” classes of anti-anginal drugs (organic nitrates, β adrenergic blockers and Ca\(^{2+}\) channel blockers). Ranolazine may have additional efficacy in combination with other anti-anginal agents, and the effects of ranolazine on cardiac arrhythmias and glucose metabolism may identify indications for this drug independent of its role as an anti-anginal agent. Table 27–3 shows some of the important indications and contraindications for use of anti-anginal agents in the context of other disease states.

**Nitrates and β Adrenergic Receptor Antagonists.** The concurrent use of organic nitrates and β adrenergic receptor antagonists can be very effective in the treatment of typical exertional angina. The additive efficacy primarily is a result of the blockade by one drug of a reflex effect elicited by the other. β Adrenergic receptor antagonists can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that are sometimes associated with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β receptor blockade. Concurrent administration of nitrates also can alleviate the increase in coronary
vascular resistance associated with blockade of β adrenergic receptors.

**Ca\(^{2+}\) Channel Blockers and β Receptor Antagonists.** Because there is a proven mortality benefit from the use of β adrenergic receptor antagonists in patients with heart disease, this class of drugs represents the first line of therapy. However, when angina is not controlled adequately by a β receptor antagonist plus nitrates, additional improvement sometimes can be achieved by the addition of a Ca\(^{2+}\) channel blocker, especially if there is a component of coronary vasospasm. The differences among the chemical classes of Ca\(^{2+}\) channel blockers can lead to important adverse or salutary drug interactions with β receptor antagonists. If the patient already is being treated with maximal doses of verapamil or diltiazem, it is difficult to demonstrate any additional benefit of β receptor blockade, and excessive bradycardia, heart block, or heart failure may ensue. However, in patients treated with a dihydropyridine such as nifedipine or with nitrates, substantial reflex tachycardia often limits the effectiveness of these agents. A β receptor antagonist may be a helpful addition in this situation, resulting in a lower heart rate and blood pressure with exercise.

Relative contraindications to the use of β receptor antagonists for treatment of angina—bronchospasm, Raynaud syndrome, or Prinzmetal angina—may lead to a choice to initiate therapy with a Ca\(^{2+}\) channel blocker. Fluctuations in coronary tone are important determinants of variant angina. It is likely that episodes of increased tone, such as those precipitated by cold and by emotion, superimposed on fixed disease have a role in the variable anginal threshold seen in some patients with otherwise chronic stable angina. Increased coronary tone also may be important in the anginal episodes occurring early after MI and after coronary angioplasty, and it probably accounts for those patients with unstable angina who respond to dihydropyridines. Atherosclerotic arteries have abnormal vasomotor responses to a number of stimuli, including exercise, other forms of sympathetic activation, and cholinergic agonists; in such vessels, stenotic segments actually may become more severely stenosed during exertion. This implies that the normal exercise-induced increase in coronary flow is lost in atherosclerosis. Similar exaggerated vascular contractile responses are seen in hyperlipidemia, even before anatomical evidence of atherosclerosis develops. Because of this, coronary vasodilators (nitrates and/or Ca\(^{2+}\) channel blockers) are an important part of the therapeutic program in the majority of patients with ischemic heart disease.
**Ca²⁺ Channel Blockers and Nitrates.** In severe exertional or vasospastic angina, the combination of a nitrate and a Ca²⁺ channel blocker may provide additional relief over that obtained with either type of agent alone. Because nitrates primarily reduce preload, whereas Ca²⁺ channel blockers reduce afterload, the net effect on reduction of O₂ demand should be additive. However, excessive vasodilation and hypotension can occur. The concurrent administration of a nitrate and nifedipine has been advocated in particular for patients with exertional angina with heart failure, the sick-sinus syndrome, or AV nodal conduction disturbances, but excessive tachycardia may be seen.

**Ca²⁺ Channel Blockers, β Receptor Antagonists, and Nitrates.** In patients with exertional angina that is not controlled by the administration of 2 types of anti-anginal agents, the use of all 3 may provide improvement, although the incidence of side effects increases significantly. The dihydropyridines and nitrates dilate epicardial coronary arteries, the dihydropyridines decrease afterload, the nitrates decrease preload, and the β receptor antagonists decrease heart rate and myocardial contractility. Combining verapamil or diltiazem with a β receptor antagonist greatly increases the risk of conduction system and left ventricular dysfunction–related side effects and should be undertaken only with extreme caution.

**ANTIPLATELET, ANTI-INTEGRIN, AND ANTITHROMBOTIC AGENTS**

Aspirin reduces the incidence of MI and death in patients with unstable angina. In addition, low doses of aspirin appear to reduce the incidence of MI in patients with chronic stable angina. Aspirin, given in doses of 160-325 mg at the onset of treatment of MI, reduces mortality in patients presenting with unstable angina. The addition of the clopidogrel to aspirin therapy reduces mortality in patients with acute coronary syndromes; a related thienopyridine, prasugrel, has been approved for treatment of acute coronary syndromes. Heparin, in its unfractionated form and as low-molecular-weight heparin, also reduces symptoms and prevents infarction in unstable angina. Thrombin inhibitors, such as hirudin or bivalirudin, directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors,
and function independently of antithrombin III. Thrombolytic agents, on the other hand, are of no benefit in unstable angina. Intravenous inhibitors of the platelet GPIIb/IIIa receptor (abciximab, tirofiban, and eptifibatide) are effective in preventing the complications of PCIs and in the treatment of some patients presenting with acute coronary syndromes.

**TREATMENT OF CLAUDICATION AND PERIPHERAL VASCULAR DISEASE**

Most patients with peripheral vascular disease also have coronary artery disease, and the therapeutic approaches for peripheral and coronary arterial diseases overlap. Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease, and treatment of coronary disease remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle \( O_2 \) demand exceeding blood flow impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies that are efficacious for treatment of coronary artery disease also have a salutary effect on progression of peripheral artery disease. Reductions in cardiovascular morbidity and mortality in patients with peripheral arterial disease have been documented with antiplatelet therapy using aspirin, clopidogrel, ticlopidine, ACE inhibitors, and treatment of hyperlipidemia. Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication: physical exercise, rehabilitation, and
smoking cessation have proven efficacy.

Drugs used specifically in the treatment of lower-extremity claudication include pentoxifylline and cilostazol. Pentoxifylline is a methylxanthine derivative that is called a *rheologic modifier* for its effects on increasing the deformability of red blood cells. The effects of pentoxifylline on lower-extremity claudication appear to be modest. Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular cyclic AMP in many cells, including blood platelets. Cilostazol-mediated increases in cyclic AMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized via this pathway (see *Chapter 6*). Cilostazol treatment improves symptoms of claudication but has no effect on cardiovascular mortality. As a PDE3 inhibitor, cilostazol is in the same drug class as milrinone, which had been used orally as an inotropic agent for patients with heart failure. Milrinone therapy was associated with an increase in sudden cardiac death, and the oral form of the drug was withdrawn from the market. Concerns about several other inhibitors of PDE3 (inamrinone, flosequinan) followed. Cilostazol, therefore, is labeled as being contraindicated in patients with heart failure, although it is not clear that cilostazol itself leads to increased mortality in such patients. Cilostazol has been reported to increase nonsustained ventricular tachycardia; headache is the most common side effect. Other treatments for claudication, including naftidrofuryl, propionyl levocarnitine, and prostaglandins, may also be efficacious.

**MECHANO-PHARMACOLOGY: DRUG-ELUTING ENDOVASCULAR STENTS**

Intracoronary stents can ameliorate angina and reduce adverse events in patients with acute coronary syndromes. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which occurs in a substantial minority of patients. The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding.

Two drugs are currently being used on intravascular stents as localized anti-proliferative therapy: paclitaxel and sirolimus. Paclitaxel is a tricyclic diterpene
that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12–sirolimus complex inhibits the mammalian kinase target of rapamycin (mTOR), thereby inhibiting cell-cycle progression (see Chapter 62). Stent-induced damage to the vascular endothelial cell layer can lead to thrombosis; patients typically are treated with antiplatelet agents, including clopidogrel (for up to 6 months) and aspirin (indefinitely), sometimes in conjunction with intravenous heparin and/or GPIIb/IIIa inhibitors. The inhibition of cellular proliferation by paclitaxel and sirolimus not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery. Therefore, antiplatelet therapy is continued for several months after intracoronary stenting with drug-eluting stents. The rate of restenosis with drug-eluting stents is reduced markedly compared with “bare metal” stents. Stent thrombosis can occur even many months after placement of the stent, sometimes temporally associated with discontinuation of antiplatelet therapy.

THERAPY OF HYPERTENSION

Hypertension is the most common cardiovascular disease; its prevalence increases with advancing age. Elevated arterial pressure causes pathological changes in the vasculature and hypertrophy of the left ventricle. Hypertension is the principal cause of stroke, a major risk factor for coronary artery disease and its complications, and a major contributor to cardiac failure, renal insufficiency, and dissecting aneurysm of the aorta.

Hypertension is defined conventionally as a sustained increase in blood pressure ≥140/90 mm Hg, a criterion that characterizes a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. Actually, the risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of <120 mm Hg and diastolic BP <80 mm Hg; these risks increase progressively with higher systolic and diastolic blood pressures (Table 27–4). Isolated systolic hypertension (sometimes defined as systolic BP > 140-160 mm Hg with diastolic BP <90 mm Hg) is largely confined to people older than 60 years of age. At very high blood pressures (systolic ≥210 mm Hg and/or diastolic ≥120 mm Hg), a subset of patients
develops fulminant arteriopathy characterized by endothelial injury and a marked proliferation of cells in the intima, leading to intimal thickening and ultimately to arteriolar occlusion. This is associated with rapidly progressive microvascular occlusive disease in the kidney (with renal failure), brain (hypertensive encephalopathy), congestive heart failure, and pulmonary edema. These patients typically require in-hospital management on an emergency basis for prompt lowering of blood pressure. Pharmacological treatment of patients with hypertension decreases morbidity and mortality from cardiovascular disease.

**PRINCIPLES OF ANTIHYPERTENSIVE THERAPY.**

Nonpharmacological therapy is an important component of treatment of all patients with hypertension. In some stage 1 hypertensives, blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake, increasing aerobic exercise, and moderating consumption of alcohol. These lifestyle changes may facilitate pharmacological control of blood pressure.

Antihypertensive drugs can be classified according to their sites or mechanisms of action (Table 27–5). Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both (recall that arterial pressure is the product of cardiac output and peripheral vascular resistance). Drugs may decrease the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling...
pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume via renal effects. Drugs can decrease peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels. In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated by changes in peripheral resistance but also via effects on large artery stiffness.

*Extended-release nifedipine is approved for hypertension.

The concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects. Hemodynamic consequences of longterm
antihypertensive therapy provide a rationale for multidrug therapy (Table 27–6).

**DIURETICS**

Diuretic agents (see Chapter 25) have antihypertensive effects when used alone, and they enhance the efficacy of virtually all other antihypertensive drugs.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. The drugs decrease extracellular volume by inhibiting the NaCl co-transporter (NCC) in the distal convoluted tubule, enhancing Na⁺ excretion in the urine, and leading to a fall in cardiac output. However, the hypotensive effect is maintained during long-term therapy due to decreased vascular resistance; cardiac output returns to pretreatment values and extracellular volume returns almost to normal due to compensatory responses such as activation of the RAS. *Hydrochlorothiazide* may open Ca²⁺-activated K⁺ channels, leading to
hyperpolarization of vascular smooth muscle cells, which leads in turn to closing of L-type Ca\(^{2+}\) channels and lower probability of opening, resulting in decreased Ca\(^{2+}\) entry and reduced vasoconstriction.

**BENZOTHIADIAZIDES AND RELATED COMPOUNDS.**

Benzothiadiazides ("thiazides") and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Following the discovery of *chlorothiazide*, a number of oral diuretics were developed that have an arylsulfonamide structure and block the NaCl co-transporter. Some of these are not benzothiadiazines but have structural features and molecular functions that are similar to the original benzothiadiazine compounds; consequently, they are designated as members of the thiazide class of diuretics. For example, chlorthalidone, one of the non-benzothiadiazines, is widely used in the treatment of hypertension, as is indapamide.

*Regimen for Administration of the Thiazide-Class Diuretics in Hypertension.*

Antihypertensive effects can be achieved in many patients with as little as 12.5 mg daily of chlorthalidone or hydrochlorothiazide. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Higher doses are not generally more efficacious in lowering blood pressure in patients with normal renal function. Urinary K\(^+\) loss can be a problem with thiazides. ACE inhibitors and angiotensin receptor antagonists will attenuate diuretic-induced loss of K\(^+\) to some degree, and this is a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretic alone. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs. Administration of ACE inhibitors or angiotensin receptor antagonists together with other K\(^+\)-sparing agents or with K\(^+\) supplements requires great caution; combining K\(^+\)-sparing agents with each other or with K\(^+\) supplementation can cause potentially dangerous hyperkalemia in some patients.

Treatment of severe hypertension that is unresponsive to 3 or more drugs may require larger doses of the thiazide-class diuretics. Hypertensive patients may
become refractory to drugs that block the sympathetic nervous system or to vasodilator drugs, because these drugs engender a state in which the blood pressure is very volume-dependent. Therefore, it is appropriate to consider the use of thiazide-class diuretics in doses of 50 mg of daily hydrochlorothiazide equivalent when treatment with appropriate combinations and doses of 3 or more drugs fails to yield adequate control of the blood pressure. Alternatively, there may be a need to use higher-capacity diuretics such as furosemide, especially if renal function is not normal, in some of these patients. Dietary Na\(^+\) restriction is a valuable adjunct to the management of such refractory patients and will minimize the dose of diuretic that is required. Because the degree of K\(^+\) loss relates to the amount of Na\(^+\) delivered to the distal tubule, such restriction of Na\(^+\) can minimize the development of hypokalemia and alkalosis. The effectiveness of thiazides as diuretics or antihypertensive agents is progressively diminished when the glomerular filtration rate falls below 30 mL/min. One exception is metolazone, which retains efficacy in patients with this degree of renal insufficiency.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within about 4-6 weeks. Therefore, doses should not be increased more often than every 4-6 weeks. Because the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. A wide range of fixed-dose combination products containing a thiazide are marketed for this purpose. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

Adverse Effects and Precautions. The adverse effects of diuretics are discussed in Chapter 25. Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics. Gout may be a consequence of the hyperuricemia induced by these diuretics. Precipitation of acute gout is relatively uncommon with low doses of diuretics. Hydrochlorothiazide may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca\(^{2+}\) excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients with primary hyperparathyroidism. The thiazide-induced decreased Ca\(^{2+}\) excretion may be used therapeutically in patients with
osteoporosis or hypercalciuria.

Two types of ventricular arrhythmias may be enhanced by K\(^+\) depletion. One of these is polymorphic ventricular tachycardia (*torsade de pointes*), which is induced by a number of drugs, including quinidine. Because K\(^+\) currents normally mediate repolarization, drugs that produce K\(^+\) depletion potentiate polymorphic ventricular tachycardia. The second is ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. There is a positive correlation between diuretic dose and sudden cardiac death, and an inverse correlation between the use of adjunctive K\(^+\)-sparing agents and sudden cardiac death. All of the thiazide-like drugs cross the placenta but they have not been shown to have direct adverse effects on the fetus. If administration of a thiazide is begun during pregnancy, there is a risk of transient volume depletion that may result in placental hypoperfusion. Because the thiazides appear in breast milk, they should be avoided by nursing mothers.

**OTHER DIURETIC ANTIHYPERTENSIVE AGENTS.** The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as furosemide and bumetanide in patients who have normal renal function. This differential effect likely relates to the short duration of action of loop diuretics, such that a single daily dose does not cause a significant net loss of Na\(^+\) for an entire 24-h period. Indeed, loop diuretics are frequently and inappropriately prescribed as a once-daily medication in the treatment of hypertension, congestive heart failure, and ascites. The spectacular efficacy of the loop diuretics in producing a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as minoxidil.

Amiloride is a K\(^+\)-sparing diuretic that has some efficacy in lowering blood pressure in patients with hypertension. Spironolactone lowers blood pressure but has some significant adverse effects, especially in men (e.g., erectile dysfunction, gynecomastia, benign prostatic hyperplasia). Eplerenone is a newer aldosterone receptor antagonist that does not have the sexually related adverse effects. Triamterene is a K\(^+\)-sparing diuretic that decreases the risk of
hypokalemia in patients treated with a thiazide diuretic but does not have efficacy in lowering blood pressure by itself. These agents should be used cautiously with frequent measurements of K\(^+\) concentrations in plasma in patients predisposed to hyperkalemia. Patients should be cautioned regarding the concurrent use of K\(^+\)-containing salt substitutes. Renal insufficiency is a relative contraindication to the use of K\(^+\)-sparing diuretics. Concomitant use of an ACE inhibitor or an angiotensin receptor antagonist magnifies the risk of hyperkalemia with these agents.

**DIURETIC-ASSOCIATED DRUG INTERACTIONS.** The K\(^+\)- and Mg\(^{2+}\)-depleting effects of the thiazides and loop diuretics can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. All diuretics can decrease the clearance of Li\(^+\), resulting in increased plasma concentrations of Li\(^+\) and potential toxicity. NSAIDs (see Chapter 34), including selective COX-2 inhibitors, that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics. NSAIDs, \(\beta\) receptor antagonists, and ACE inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K\(^+\)-sparing diuretic.

**SYMPATHOLYTIC AGENTS**

Antagonists of \(\alpha\) and \(\beta\) adrenergic receptors are mainstays of antihypertensive therapy (see Table 27–5).

**\(\beta\) ADRENERGIC RECEPTOR ANTAGONISTS**

\(\beta\) Adrenergic receptor antagonists have antihypertensive effects. Antagonism of \(\beta\) adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility, heart rate, and cardiac output. An important consequence is blockade of the \(\beta_1\) receptors of the juxtaglomerular complex, reducing renin secretion and thereby diminishing production of circulating AngII. Some \(\beta\) receptor antagonists may lower blood pressure by other mechanisms. For example, labetalol is also an \(\alpha_1\) receptor antagonist, and nebivolol promotes endothelium-dependent
vasodilation via activation of the NO pathway.

**Pharmacological Effects.** The β adrenergic blockers vary in their selectivity for the β₁ receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and vasodilating capacity. These differences do influence the clinical pharmacokinetics and spectrum of adverse effects of the various drugs. Drugs without intrinsic sympathomimetic activity produce an initial reduction in cardiac output and a reflex-induced rise in peripheral resistance, generally with no net change in arterial pressure. Persistently reduced cardiac output and possibly decreased peripheral resistance accounts for the reduction in arterial pressure. Drugs with intrinsic sympathomimetic activity produce lesser decreases in resting heart rate and cardiac output; the fall in arterial pressure correlates with a fall in vascular resistance below pretreatment levels, possibly because of stimulation of vascular β₂ receptors that mediate vasodilation.

**Adverse Effects and Precautions.** The adverse effects of β adrenergic blocking agents are discussed in Chapter 12. These drugs should be avoided in patients with asthma or with SA or AV nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as verapamil. The risk of hypoglycemic reactions may be increased in diabetics taking insulin. β Receptor antagonists without intrinsic sympathomimetic activity increase concentrations of triglycerides in plasma and lower those of HDL cholesterol without changing total cholesterol concentrations. β receptor blocking agents with intrinsic sympathomimetic activity have little or no effect on blood lipids or increase HDL cholesterol.

Sudden discontinuation of β adrenergic blockers can produce a withdrawal syndrome that is likely due to upregulation of β receptors causing enhanced tissue sensitivity to endogenous catecholamines; this can exacerbate the symptoms of coronary artery disease or cause rebound hypertension. Thus, β adrenergic blockers should be tapered gradually over 10-14 days.

NSAIDs such as indomethacin can blunt the antihypertensive effect of propranolol and probably other β receptor antagonists. This effect may be related to inhibition of vascular synthesis of prostacyclin, as well as to retention of Na⁺.

Epinephrine can produce severe hypertension and bradycardia when a nonselective β antagonist is present due to the unopposed stimulation of α
adrenergic receptors when vascular $\beta_2$ receptors are blocked. The bradycardia is the result of reflex vagal stimulation. Such hypertensive responses to $\beta$ receptor antagonists have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from clonidine, following administration of epinephrine as a therapeutic agent, or in association with the illicit use of cocaine.

**Therapeutic Uses.** The $\beta$ receptor antagonists provide effective therapy for all grades of hypertension. The antihypertensive effect of all the $\beta$ blockers is of sufficient duration to permit once- or twice-daily administration. Populations that tend to have a lesser antihypertensive response to $\beta$ blocking agents include the elderly and African Americans. However, intra-individual differences in antihypertensive efficacy are generally much larger than differences between racial or age-related groups. The $\beta$ receptor antagonists usually do not cause retention of salt and water, but do have additive antihypertensive effects when combined with diuretics. $\beta$ receptor antagonists are preferred drugs for hypertensive patients with conditions such as MI, ischemic heart disease, or congestive heart failure.

**$\alpha_1$ ADRENERGIC RECEPTOR ANTAGONISTS**

Drugs that selectively block $\alpha_1$ adrenergic receptors without affecting $\alpha_2$ adrenergic receptors are used in hypertension. Prazosin, terazosin, and doxazosin are the agents that are available for the treatment of hypertension.

**Pharmacological Effects.** Initially, $\alpha_1$ adrenergic receptor antagonists reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy. The $\alpha_1$ adrenergic blockers cause a variable amount of postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. $\alpha_1$ Receptor antagonists reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is
given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

**Adverse Effects.** The use of doxazosin as monotherapy for hypertension increases the risk for developing congestive heart failure. This may be an adverse effect of all of the $\alpha_1$ receptor antagonists. A major precaution regarding the use of the $\alpha_1$ receptor antagonists for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 30-90 min (or longer) of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic or an $\alpha$ receptor antagonist. After the first few doses, patients develop a tolerance to this marked hypotensive response.

**Therapeutic Uses.** $\alpha_1$ Receptor antagonists are not recommended as monotherapy for hypertensive patients but are used primarily in conjunction with diuretics, $\beta$ blockers, and other antihypertensive agents. $\beta$ Receptor antagonists enhance the efficacy of the $\alpha_1$ blockers. $\alpha_1$ Receptor antagonists are not the drugs of choice in patients with pheochromocytoma, because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular $\alpha_2$ adrenergic receptors. $\alpha_1$ Receptor antagonists improve urinary symptoms in hypertensive patients with benign prostatic hyperplasia.

**COMBINED $\alpha_1$ AND $\beta$ ADRENERGIC RECEPTOR ANTAGONISTS**

**Labetalol** (see Chapter 12) is an equimolar mixture of 4 stereoisomers. One isomer is an $\alpha_1$ antagonist (like prazosin), another is a nonselective $\beta$ antagonist with partial agonist activity (like pindolol), and the other 2 isomers are inactive. Because of its capacity to block $\alpha_1$ adrenergic receptors, labetalol given intravenously can reduce blood pressure sufficiently rapidly to be useful for the treatment of hypertensive emergencies. Labetalol has efficacy and adverse effects that would be expected with any combination of $\beta$ and $\alpha_1$ receptor antagonists.
Carvedilol (see Chapter 12) is a β receptor antagonist with α₁ receptor antagonist activity. The drug has been approved for the treatment of hypertension and symptomatic heart failure. The ratio of α₁ to β receptor antagonist potency for carvedilol is approximately 1:10. Carvedilol is oxidized by hepatic CYP2D6 and then glucuronidated. Carvedilol reduces mortality in patients with congestive heart failure associated with systolic dysfunction when used as an adjunct to therapy with diuretics and ACE inhibitors. It should not be given to those patients with decompensated heart failure who are dependent on sympathetic stimulation. As with labetalol, the side effects of carvedilol in hypertension are predictable based on its properties as a β and α₁ adrenergic receptor antagonist.

Nebivolol is a β₁-selective adrenergic antagonist that also promotes vasodilatation; nebivolol augments arterial smooth muscle relaxation via NO, and has agonist activity at β₃ receptors, although the clinical significance of this effect is not known.

**METHYLDOPA**

Methyldopa is a centrally acting antihypertensive agent. It is a prodrug that exerts its antihypertensive action via an active metabolite. Methyldopa’s significant adverse effects limit its current use largely to treatment of hypertension in pregnancy, where it has a record for safety.

Methyldopa is metabolized by the l-aromatic amino acid decarboxylase in adrenergic neurons to α-methyldopamine, which then is converted to α-methylnorepinephrine (α-CH₃-NE). α-CH₃-NE is stored in the secretory vesicles of adrenergic neurons, substituting for NE. Thus, when the adrenergic neuron discharges its neurotransmitter, α-CH₃-NE is released instead of NE. α-CH₃-NE acts in the CNS to inhibit adrenergic neuronal outflow from the brainstem and probably acts as an agonist at presynaptic α₂ adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of
vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

**ADME.** Because methyldopa is a prodrug that is metabolized in the brain to the active form, its concentration in plasma has less relevance for its effects than that for many other drugs. Peak concentrations in plasma occur after 2-3 h. The drug is eliminated with a $t_{1/2}$ of ~2 h but is prolonged to 4-6 h in patients with renal failure. The peak effect of methyldopa is delayed for 6-8 h, even after intravenous administration, and the duration of action of a single dose is usually about 24 h; this permits once- or twice-daily dosing. The discrepancy between the effects of methyldopa and the measured concentrations of the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite, storage of $\alpha$-CH$_3$-NE and its subsequent release at relevant $\alpha_2$ receptors in the CNS.

**Adverse Effects and Precautions.** Methyldopa produces sedation that is largely transient; depression occurs occasionally. Methyldopa may produce dryness of the mouth, diminished libido, parkinsonian signs, and hyper-prolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. Methyldopa may precipitate severe bradycardia and sinus arrest. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of methyldopa. At least 20% of patients who receive methyldopa for a year develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes; 1-5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of methyldopa, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Rarer adverse effects include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus–like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

**Therapeutic Uses.** Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus. The usual initial dose of methyldopa is 250 mg twice daily, and there is little additional effect with doses >2 g/day.
CLONIDINE, GUANABENZ, AND GUANFACINE

The detailed pharmacology of the $\alpha_2$ adrenergic agonists clonidine, guanabenz, and guanfacine is discussed in Chapter 12. These drugs stimulate the $\alpha_{2A}$ subtype of $\alpha_2$ adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS. Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central $\alpha_{2A}$ receptors, these drugs can activate $\alpha_2$ receptors of the $\alpha_{2B}$ subtype on vascular smooth muscle cells. This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken, and may be responsible for the loss of therapeutic effect that is observed with high doses.

**Pharmacological Effects.** The $\alpha_2$ adrenergic agonists lower arterial pressure by an effect on both cardiac output and peripheral resistance. In the supine position, when the sympathetic tone to the vasculature is low, the major effect is to reduce both heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature is normally increased, these drugs reduce vascular resistance and may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to a reduction in myocardial contractility and heart rate that could promote congestive heart failure in susceptible patients.

**Adverse Effects and Precautions.** Sedation and xerostomia are prominent adverse effects. The xerostomia may be accompanied by dry nasal mucosa, dry eyes, and parotid gland swelling and pain. Postural hypotension and erectile dysfunction may be prominent in some patients. Clonidine may produce a lower incidence of dry mouth and sedation when given transdermally. Less common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the SA node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15-20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related $\alpha_2$ adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. The arterial blood pressure may rise
to levels above those that were present prior to treatment. Symptoms typically occur 18-36 h after the drug is stopped and are associated with increased sympathetic discharge. The withdrawal syndrome is likely dose related and more dangerous in patients with poorly controlled hypertension. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of clonidine. If a more rapid effect is required, sodium nitroprusside or a combination of an α and β adrenergic blocker is appropriate. β Adrenergic blocking agents should not be used alone in this setting, because they may accentuate the hypertension by allowing unopposed α adrenergic vasoconstriction caused by activation of the sympathetic nervous system.

Surgical patients who are being treated with an α₂ adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose and/or transdermal clonidine prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being noncompliant with medications should not be given α₂ adrenergic agonists for hypertension. Adverse drug interactions with α₂ adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine, but the mechanism of this interaction is not known.

**Therapeutic Uses.** The CNS effects are such that this class of drugs is not a leading option for monotherapy of hypertension. They effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents.

**GUANADREL**

Guanadrel specifically inhibits the function of peripheral postganglionic adrenergic neurons. It is an exogenous false neurotransmitter that is accumulated, stored, and released like NE but is inactive at adrenergic receptors. In the neuron, guanadrel is concentrated within the adrenergic storage vesicle, where it replaces NE. Because guanadrel can promote NE release from pheochromocytomas, it is contraindicated in those patients.

**Pharmacological Effects.** The antihypertensive effect is achieved by a reduction in peripheral vascular resistance that results from inhibition of α receptor–
mediated vasoconstriction. Arterial pressure is reduced modestly in the supine position when sympathetic activity is usually low, but the pressure can fall to a greater extent during situations in which reflex sympathetic activation is an important mechanism for maintaining arterial pressure, particularly when standing.

**ADME.** The maximum effect on blood pressure is not seen until 4-5 h. The t\(_{1/2}\) of the pharmacological effect of guanadrel is determined by the drug’s persistence in this neuronal pool and is at least 10 h.

**Adverse Effects.** Guanadrel produces undesirable effects that are related to sympathetic blockade such as symptomatic hypotension during standing, exercise, ingestion of alcohol, or in hot weather. A general feeling of fatigue and lassitude is partially related to postural hypotension. Sexual dysfunction usually presents as delayed or retrograde ejaculation. Diarrhea also may occur. Drugs that block or compete for the catecholamine transporter on the presynaptic membrane (e.g., tricyclic antidepressants *cocaine, chlorpromazine, ephedrine, phenylpropanolamine*, and *amphetamine; see Chapter 8*) also will inhibit the effect of guanadrel.

**Therapeutic Uses.** Because of the availability of a number of drugs that lower blood pressure without producing similar adverse effects, guanadrel is used very rarely; the drug is no longer marketed in the U.S.

**RESERPINE**

*Reserpine* is an alkaloid extracted from the root of *Rauwolfia serpentina*. Reserpine inhibits the vesicular catecholamine transporter, VMAT2, so that nerve endings lose their capacity to concentrate and store NE and dopamine. Catecholamines leak into the cytoplasm, where they are metabolized. Consequently, little or no active transmitter is released from nerve endings, resulting in a pharmacological sympathectomy. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after discontinuation of the drug. Reserpine depletes amines in the CNS as well as in the peripheral adrenergic neuron and its antihypertensive effects may be related to both central and peripheral actions.

**Pharmacological Effects.** Both cardiac output and peripheral vascular resistance
are reduced during long-term therapy with reserpine.

**ADME.** Data available on the pharmacokinetic properties of reserpine are limited because of the lack of an assay capable of detecting low concentrations of the drug or its metabolites. Since reserpine binding is irreversible, the amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action. Free reserpine is entirely metabolized.

**Toxicity and Precautions.** Most adverse effects of reserpine are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Reserpine must be discontinued at the first sign of depression; reserpine-induced depression may last several months after the drug is discontinued. The risk of depression is likely dose related and is uncommon with doses of 0.25 mg/day or less. Other adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

**Therapeutic Uses.** The use of reserpine has diminished because of its CNS side effects. Reserpine is used once daily with a diuretic, and several weeks are necessary to achieve a maximum effect. The daily dose should be limited to 0.25 mg or less, and as little as 0.05 mg/day may be efficacious when a diuretic is also used.

**METYROSINE**

Metyrosine (DEMSER), α-methyl-L-tyrosine, inhibits tyrosine hydroxylase, the enzyme that catalyzes the conversion of tyrosine to DOPA and the rate-limiting step in catecholamine biosynthesis (see Chapter 8).

At a dose of 1-4 g/day, metyrosine decreases catecholamine biosynthesis by 35-80% in patients with pheochromocytoma. The maximal decrease in synthesis occurs only after several days and may be assessed by measurements of urinary catecholamines and their metabolites. Metyrosine is used as an adjuvant to phenoxybenzamine and other α adrenergic blocking agents for the management of pheochromocytoma and in the preoperative preparation of patients for
resection of pheochromocytoma. Metyrosine carries a risk of crystalluria, which can be minimized by maintaining a daily urine volume of >2 L. Other adverse effects include orthostatic hypotension, sedation, extrapyramidal signs, diarrhea, anxiety, and psychic disturbances. Doses must be titrated carefully to minimize these side effects.

CA$^{2+}$ CHANNEL ANTAGONISTS

Ca$^{2+}$ channel blocking agents are important drugs for the treatment of hypertension. The pharmacology of these drugs is presented earlier in this chapter. Because contraction of vascular smooth muscle is dependent on the free intracellular concentration of Ca$^{2+}$, inhibition of transmembrane movement of Ca$^{2+}$ through voltage-sensitive Ca$^{2+}$ channels can decrease the total amount of Ca$^{2+}$ that reaches intracellular sites. Ca$^{2+}$ channel blockers lower blood pressure by relaxing arteriolar smooth muscle and decreasing peripheral vascular resistance; however, this evokes a baroreceptor-mediated sympathetic discharge. With dihydropyridines, tachycardia may occur from the adrenergic stimulation of the SA node. Tachycardia is typically minimal to absent with verapamil and diltiazem because of the direct negative chronotropic effect of these 2 drugs. Indeed, the concurrent use of a β receptor antagonist drug may magnify negative chronotropic effects of these drugs or cause heart block in susceptible patients.

Ca$^{2+}$ channel blockers are effective when used alone or in combination with other drugs for the treatment of hypertension. However, there is no place in the treatment of hypertension for the use of nifedipine or other dihydropyridine Ca$^{2+}$ channel blockers with short half-lives, administered in a standard (immediate-release) formulation, because of the oscillation in blood pressure and concurrent surges in sympathetic reflex activity within each dosage interval. Parenteral administration of the dihydropyridine clevidipine may be useful in treating severe or perioperative hypertension. Compared with other classes of antihypertensive agents, there may be a greater frequency of achieving blood pressure control with Ca$^{2+}$ channel blockers as monotherapy in elderly subjects and in African Americans, population groups in which the low renin status is
more prevalent. Ca\textsuperscript{2+} channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated systolic hypertension.

**ANGIOTENSIN-CONVERTING ENZYME INHIBITORS**

Angiotensin II is an important regulator of cardiovascular function (see Chapter 26). ACE inhibitors include captopril, enalapril, lisinopril, quinapril, ramipril, benazepril, moexipril, fosinopril, trandolapril, and perindopril. Chapter 26 presents the pharmacology of ACE inhibitors in detail. The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis; many of these patients also have hypertension. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors; administration of ACE inhibitors in the immediate post-MI period has been shown to improve ventricular function and reduce morbidity and mortality (see Chapter 28).

Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na\textsuperscript{+} loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. Thus, even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and Na\textsuperscript{+} loss. The attenuation of aldosterone production by ACE inhibitors also influences K\textsuperscript{+} homeostasis; substantial retention of K\textsuperscript{+} can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause K\textsuperscript{+} retention, including the K\textsuperscript{+}-sparing diuretics (amiloride, triamterene, and spironolactone), NSAIDs, K\textsuperscript{+} supplements, and β receptor antagonists. Patients with diabetic nephropathy may be at greater risk of hyperkalemia. Angioedema is a rare but serious and
potentially fatal adverse effect of the ACE inhibitors. ACE inhibitors are contraindicated during pregnancy.

In most patients, there is no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by AngII. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate.

ACE inhibitors lower the blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial drop in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active RAS supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treatment is not strongly correlated with the pretreatment plasma renin activity. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients has a response that lasts <24 h and may require twice-daily dosing for adequate control of blood pressure.

**AT₁ RECEPTOR ANTAGONISTS**

Nonpeptide antagonists of the AT₁ AngII receptor approved for treatment of hypertension include losartan, candesartan, irbesartan, valsartan, telmisartan, olmesartan, eprosartan, and azilsartan. The pharmacology of AT₁ receptor antagonists is presented in detail in Chapter 26. By antagonizing the effects of AngII, these agents permit relaxation of smooth muscle and vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy.
There are 2 distinct subtypes of AngII receptors, AT$_1$ and AT$_2$. Because the AT$_1$ receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT$_1$ receptor antagonism. The clinical consequences of increased AngII effects on an uninhibited AT$_2$ receptor are unknown; however, emerging data suggest that the AT$_2$ receptor may elicit antigrowth and antiproliferative responses.

**Adverse Effects and Precautions.** Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions (see above and Chapter 26) also occur with AT$_1$ receptor antagonists. These include hypotension, hyperkalemia, and reduced renal function, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Cough, an adverse effect of ACE inhibitors, is less frequent with AT$_1$ receptor antagonists. Angioedema occurs very rarely.

**Therapeutic Uses.** When given in adequate doses, the AT$_1$ receptor antagonists appear to be as effective as ACE inhibitors in the treatment of hypertension. The full effect of AT$_1$ receptor antagonists on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an AT$_1$ receptor antagonist alone, a second drug acting by a different mechanism (e.g., a diuretic or Ca$^{2+}$ channel blocker) may be added. The combination of an ACE inhibitor and an AT$_1$ receptor antagonist is not recommended.

**DIRECT RENIN INHIBITORS**

*Aliskiren* is an orally effective direct renin inhibitor that lowers blood pressure in patients with hypertension. The detailed pharmacology of aliskiren is covered in Chapter 26.

**Pharmacological Effects.** Aliskiren directly and competitively inhibits the catalytic activity of renin, which leads to diminished production of AngI—and ultimately AngII and aldosterone—with a resulting fall in blood pressure. Aliskiren along with ACE inhibitors and AT$_1$ receptor antagonists lead to an adaptive increase in the plasma concentrations of renin; however, because aliskiren inhibits renin activity, plasma renin activity does not increase as occurs with these other classes of drugs (see Table 26–1).
Absorption, Metabolism, and Excretion. Aliskiren is poorly absorbed; bioavailability is <3%. High-fat meal may substantially decrease plasma concentrations of the drug. The $t_{1/2}$ is at least 24 h. Elimination of the drug may be primarily through hepatobiliary excretion with limited metabolism via CYP3A4.

Therapeutic Uses. Aliskiren (Tekturna) is effective as monotherapy in treating patients with hypertension with dose-dependent increasing efficacy at 150-300 mg/day. The combination of aliskiren with hydrochlorothiazide has a greater lowering effect on blood pressure than either drug alone. Aliskiren appears to have greater efficacy when added to other agents in the treatment of hypertension, including ACE inhibitors, AT$_1$ receptor antagonists, and Ca$^{2+}$ channel blockers. Combination therapy of aliskiren with ACE inhibitors or ARBs is contraindicated in patients with diabetes or kidney impairment due to increased risk of hyperkalemia, hypotension, and renal complications. Overall, aliskiren appears to be well tolerated.

VASODILATORS

HYDRALAZINE

Hydralazine directly relaxes arteriolar smooth muscle. The molecular mechanisms mediating this action are not clear but may ultimately involve a fall in intracellular Ca$^{2+}$ concentrations. The drug does not relax venous smooth muscle. Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, which results in increased heart rate and contractility, and increased plasma renin activity; all of these effects tend to counteract the antihypertensive effect of hydralazine.

The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilation of arterioles over veins, postural hypotension is not a common problem; hydralazine lowers blood pressure similarly in the supine and
upright positions.

**Absorption, Metabolism, and Excretion.** Hydralazine is well absorbed through the GI tract, but the systemic bioavailability is low (16% in fast acetylators and 35% in slow acetylators). Hydralazine is N-acetylated in the bowel and/or the liver. Although its $t_{1/2}$ in plasma is ~1 h, the duration of the hypotensive effect of hydralazine can last up to 12 h. Systemic clearance of the drug is ~50 mL/kg/min. The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly, and half do so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators (acetylation rate is genetically determined; see Figure 56–4). The peak concentration of hydralazine in plasma and the peak hypotensive effect of the drug occur within 30-120 min of ingestion.

**Toxicity and Precautions.** Adverse effects of the drug include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia can occur on account of increased O$_2$ demand induced by the baroreceptor reflex-induced stimulation of the sympathetic nervous system. Following parenteral administration to patients with coronary artery disease, the myocardial ischemia may be sufficiently severe and protracted to cause frank MI. For this reason, parenteral administration of hydralazine is not advisable in hypertensive patients with coronary artery disease, hypertensive patients with multiple cardiovascular risk factors, or older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a β adrenergic receptor blocker and a diuretic, hydralazine is better tolerated.

Other adverse effects are caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown. The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, sex, acetylator phenotype, and race. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome, but symptoms may persist in a few patients, and administration of corticosteroids may be necessary. Hydralazine also can produce a pyridoxine-responsive
polyneuropathy. The mechanism appears to be related to the ability of hydralazine to combine with pyridoxine to form a hydrazone. This side effect is very unusual with doses ≤200 mg/day.

**Therapeutic Uses.** Due to its relatively unfavorable adverse-effect profile, hydralazine is no longer a first-line drug in the treatment of hypertension. The drug is marketed as a combination pill containing isosorbide dinitrate (BiDil) that is used for the treatment of heart failure (see Chapter 28). Hydralazine may have utility in the treatment of some patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or AT₁ receptor antagonists), and may be useful in the treatment of hypertensive emergencies in pregnant women (especially preeclampsia). Hydralazine should be used with the great caution in elderly patients and in hypertensive patients with coronary artery disease because of the possibility of precipitation of myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25-100 mg twice daily. The maximum recommended dose of hydralazine is 200 mg/day to minimize the risk of drug-induced lupus syndrome.

**K<sub>ATP</sub> CHANNEL OPENERS: MINOXIDIL**

Minoxidil is efficacious in patients with the most severe and drug-resistant forms of hypertension. Minoxidil is metabolized by hepatic sulfotransferase to the active molecule, minoxidil N-O sulfate. Minoxidil sulfate activates the ATP-modulated K<sup>+</sup> channel. By opening K<sup>+</sup> channels in smooth muscle and thereby permitting K<sup>+</sup> efflux, it causes hyperpolarization and relaxation of smooth muscle. Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels.

Minoxidil increases blood flow to skin, skeletal muscle, the gastrointestinal tract, and the heart. The disproportionate increase in blood flow to the heart may have a metabolic basis, in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as 3- to 4-fold. The increased venous return probably results from enhancement of flow in the regional vascular beds, with a fast time constant for venous return to the heart. The adrenergic increase in
myocardial contractility contributes to the increased cardiac output but is not the predominant causal factor. Minoxidil is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension. Minoxidil is a very potent stimulator of renin secretion; this effect is mediated by a renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

**ADME.** Minoxidil is well absorbed from the GI tract. Although peak concentrations of minoxidil in blood occur 1 h after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed. The bulk of the absorbed drug is eliminated by hepatic metabolism; ~20% is excreted unchanged in the urine. Minoxidil has a plasma $t_{1/2}$ of 3-4 h, but its duration of action is 24 h or longer.

**Adverse Effects and Precautions.** The adverse effects of minoxidil can be severe and are divided into 3 major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis.

Retention of salt and water results from increased proximal renal tubular reabsorption, which is in turn secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular α adrenergic receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (e.g., diazoxide and hydralazine). Although administration of minoxidil causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during minoxidil therapy include increases in heart rate, myocardial contractility, and myocardial $O_2$ consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with coronary artery disease. The cardiac sympathetic responses are attenuated by concurrent administration of a β adrenergic blocker. The adrenergically-induced increase in renin secretion also can be ameliorated by a β receptor antagonist or an ACE inhibitor.
Minoxidil has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This likely contributes to the increased pulmonary artery pressure seen with minoxidil therapy in hypertensive patients and is compounded by the retention of salt and water. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of minoxidil. Although more commonly described in patients with cardiac and renal failure, pericardial effusion can occur in patients with normal cardiovascular and renal function. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K+ channels. Openers of the ATP-modulated K+ channel accelerate myocardial repolarization, shorten the refractory period, and one of them, pinacidil, lowers the ventricular fibrillation threshold and increases spontaneous ventricular fibrillation in the setting of myocardial ischemia. Hypertrichosis occurs in patients who receive minoxidil for an extended period and is probably a consequence of K+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly offensive to women. Topical minoxidil (ROGAINE) is used for male pattern baldness: It may have cardiovascular effects in some individuals. Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

**Therapeutic Uses.** Systemic minoxidil is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency. Minoxidil should be given concurrently with a diuretic to avoid fluid retention and with a sympatholytic drug (usually a β receptor antagonist) to control reflex cardiovascular effects. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be
increased gradually to 40 mg in 1 or 2 daily doses.

**SODIUM NITROPRUSSIDE**

Nitroprusside is a nitrovasodilator that acts by releasing NO that stimulates the guanylyl cyclase–cyclic GMP–PKG pathway, leading to vasodilation. Tolerance develops to nitroglycerin but not to nitroprusside. Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (see Chapter 28).

![Chemical Structure of Sodium Nitroprusside]

**SODIUM NITROPRUSSIDE**

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and glomerular filtration are maintained, and plasma renin activity increases. Sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial O₂ demand.

**Absorption, Metabolism, and Excretion.** Sodium nitroprusside is an unstable molecule that must be protected from light and given by continuous intravenous infusion to be effective. Its onset of action is within 30 sec; the peak hypotensive effect occurs within 2 min, and the effect disappears within 3 min after infusion is stopped. The metabolism of nitroprusside by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then NO. Cyanide is further metabolized by liver rhodanese to form thiocyanate, which is eliminated.
almost entirely in the urine. The mean elimination $t_{1/2}$ for thiocyanate is 3 days in patients with normal renal function, and it can be much longer in patients with renal insufficiency.

**Therapeutic Uses.** Sodium nitroprusside is used primarily to treat hypertensive emergencies but also can be used in many situations when short-term reduction of cardiac preload and/or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection; improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 28); and decrease myocardial oxygen demand after acute MI. In addition, nitroprusside is used to induce controlled hypotension during anesthesia in order to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a $\beta$ adrenergic receptor antagonist with nitroprusside, because reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2-3 mL of 5% dextrose in water. Addition of this solution to 250-1000 mL of 5% dextrose in water produces a concentration of 50-200 $\mu$g/mL. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. Most hypertensive patients respond to an infusion of 0.25-1.5 $\mu$g/kg/min. Higher rates of infusion are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Patients who are receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of 10 $\mu$g/kg/min do not produce adequate reduction of blood pressure within 10 min, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

**Toxicity and Precautions.** The short-term adverse effects of nitroprusside are due to excessive vasodilation. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug. Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading
to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate >5 μg/kg/min but also can occur in some patients receiving doses ~2 μg/kg/min for a prolonged period. The concomitant administration of sodium thiosulfate can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of sodium nitroprusside. The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for more than 24-48 h, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of nitroprusside and should not be allowed to exceed 0.1 mg/mL. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

NONPHARMACOLOGICAL THERAPY OF HYPERTENSION

Nonpharmacological approaches to the treatment of hypertension may be sufficient in patients with modestly elevated blood pressure and can augment the effects of antihypertensive drugs in patients with more marked initial elevations in blood pressure.

- Reduction in body weight for people who are modestly overweight or frankly obese may be useful.
- Restricting Na⁺ consumption lowers blood pressure in some patients. The Dietary Approaches to Stop Hypertension (DASH) diet may be particularly useful.
- For some patients, restriction of ethanol intake to modest levels may lower blood pressure.
- Increased physical activity may improve control of hypertension.

SELECTION OF ANTIHYPERTENSIVE DRUGS IN INDIVIDUAL
PATIENTS

National guidelines recommend diuretics as preferred initial therapy for most patients with uncomplicated stage 1 hypertension (see Table 27–4) who are unresponsive to nonpharmacological measures. Patients also are commonly treated with other drugs: β receptor antagonists, ACE inhibitors/AT₁ receptor antagonists, and Ca۲⁺ channel blockers. Patients with uncomplicated stage 2 hypertension will likely require the early introduction of a diuretic and another drug from a different class. Subsequently, doses can be titrated upward and additional drugs added to achieve goal blood pressures (blood pressure <140/90 mm Hg in uncomplicated patients).

An important and high-risk group of patients with hypertension are those with compelling indications for specific drugs on account of other underlying serious cardiovascular disease (heart failure, post-MI, or with high risk for coronary artery disease), chronic kidney disease, or diabetes. For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β receptor antagonist, ACE inhibitor/AT₁ receptor antagonist, and (in selected patients) spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension (see Chapter 28). Similarly, ACE inhibitors/AT₁ receptor antagonists should be first-line drugs in the treatment of diabetics with hypertension in view of these drugs’ well-established benefits in diabetic nephropathy.

Other patients may have less serious underlying diseases that could influence choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α₃ receptor antagonist as part of his or her therapeutic program, because α₃ antagonists are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β receptor antagonist because a number of drugs in this class are efficacious in preventing migraine attacks. Patients with isolated systolic hypertension benefit particularly from diuretics and also from Ca²⁺ channel blockers and ACE inhibitors. These should be first-line drugs in these patients in terms of efficacy, but compelling indications as noted earlier need to be taken into account.
chapter 28
Pharmacotherapy of Congestive Heart Failure

Congestive heart failure (CHF) is responsible for more than half a million deaths annually in the U.S., carries a 1-year mortality rate of more than 50% in patients with advanced forms of the condition. Substantive advances in CHF pharmacotherapy have altered clinical practice by shifting the paradigm of its management from exclusively symptom palliation to modification of disease progression and prolonged survival.

DEFINING CONGESTIVE HEART FAILURE. The onset and progression of clinically evident CHF from left ventricular (LV) systolic dysfunction follows a pathophysiologic sequence in response to an initial insult to myocardial dysfunction. A reduction in forward cardiac output leads to expanded activation of the sympathetic nervous system and the renin–angiotensin–aldosterone axis that, together, maintain perfusion of vital organs by increasing LV preload, stimulating myocardial contractility, and increasing arterial tone. Acutely, these mechanisms sustain cardiac output by allowing the heart to operate at elevated end-diastolic volumes, while peripheral vasoconstriction promotes regional redistribution of the cardiac output to the CNS, coronary, and renal vascular beds.

Unfortunately, these compensatory mechanisms over time propagate disease progression. Intravascular volume expansion increases diastolic and systolic wall stress that disrupts myocardial energetics and causes pathologic LV hypertrophy. By increasing LV afterload, peripheral arterial vasoconstriction also adversely affects diastolic ventricular wall stress, thereby increasing myocardial O2 demand. Finally, neurohumoral effectors such as NE and AngII are associated with myocyte apoptosis, abnormal myocyte gene expression, and pathologic changes in the extracellular matrix that increase LV stiffness.
Clinically, the term CHF describes a final common pathway for the expression of myocardial dysfunction. While some emphasize the clinical distinction between systolic versus diastolic heart failure, many patients demonstrate dysfunction in both contractile performance and ventricular relaxation/filling. Indeed, these physiologic processes are interrelated; for example, the rate and duration of LV diastolic filling are directly influenced by impairment in systolic contractile performance. The following definitions are useful for establishing a conceptual framework to describe this clinical syndrome:

*Congestive heart failure* is the pathophysiologic state in which the heart is unable to pump blood at a rate commensurate with the requirements of metabolizing tissues, or can do so only from an elevated filling pressure.

*Heart failure* is a complex of symptoms—fatigue, shortness of breath, and congestion—that are related to the inadequate perfusion of tissue during exertion and often to the retention of fluid. Its primary cause is an impairment of the heart’s ability to fill or empty the left ventricle properly.

One may consider CHF as a condition in which failure of the heart to provide adequate forward output at normal end-diastolic filling pressures results in a clinical syndrome of decreased exercise tolerance with pulmonary and systemic venous congestion. Numerous cardiovascular comorbidities are associated with CHF, including coronary artery disease, MI, and sudden cardiac death.

**PHARMACOLOGIC TREATMENT OF HEART FAILURE**

The abnormalities of myocardial structure and function that characterize CHF are often irreversible. These changes narrow the end-diastolic volume range that is compatible with normal cardiac
function. Although CHF is predominately a chronic disease, subtle changes to an individual’s hemodynamic status (e.g., increased circulating volume from high dietary sodium intake, increased systemic blood pressure from medication nonadherence) often provoke an acute clinical decompensation.

Not surprisingly, therefore, CHF therapy has for many years used diuretics to control volume overload and subsequent worsening in LV function. Other proven pharmacotherapies target ventricular wall stress, the renin–angiotensin–aldosterone axis, and the sympathetic nervous system to decrease pathologic ventricular remodeling, attenuate disease progression, and improve survival in selected patients with severe CHF and low LV ejection fraction. Figure 28–1 provides an overview of the sites of action for major drug classes commonly used to improve cardiac hemodynamics and function through preload reduction, afterload reduction, and enhancement of inotropy (i.e., myocardial contractility).
Pathophysiologic mechanisms of heart failure and major sites of drug action. Congestive heart failure is accompanied by compensatory neurohormonal responses, including activation of the sympathetic nervous and renin–angiotensin–aldosterone axis. Increased ventricular afterload, due to systemic vasoconstriction and chamber dilation, causes depression in systolic function. In addition, increased afterload and the direct effects of angiotensin and norepinephrine on the ventricular myocardium cause pathologic remodeling characterized by progressive chamber dilation and loss of contractile function. Key congestive heart failure medications and their targets of action are presented. ACE, angiotensin-converting enzyme; AT_1_ receptor, type 1 angiotensin receptor.

DIURETICS

Diuretics reduce extracellular fluid volume and ventricular filling pressure (or “preload”). Because CHF patients often operate on a “plateau” phase of the Frank-Starling curve (Figure 28–2), incremental preload reduction occurs under these conditions without a
reduction in cardiac output. Sustained natriuresis and/or a rapid decline in intravascular volume, however, may “push” one’s profile leftward on the Frank-Starling curve, resulting in an unwanted decrease in cardiac output. In this way, excessive diuresis is counterproductive secondary to reciprocal neurohormonal overactivation from volume depletion. Thus, it is preferable to avoid diuretics in patients with asymptomatic LV dysfunction and to only administer the minimal dose required to maintain euvoolemia in those patients symptomatic from hypervolemic state. Despite the efficacy of loop or thiazide diuretics in controlling congestive symptoms and improving exercise capacity, their use is not associated with a reduction in CHF mortality.

Figure 28–2 *Hemodynamic responses to pharmacologic interventions in heart failure*. The relationships between diastolic filling pressure (preload) and stroke volume (ventricular performance) are illustrated for a normal heart (*green line*; the Frank-Starling relationship) and for a patient with heart failure due to predominant systolic dysfunction (*red line*). Note that positive inotropic agents (I), such as cardiac glycosides or dobutamine, move patients to a higher ventricular function curve (*lower dashed line*), resulting in greater cardiac work for a given level of ventricular filling pressure. Vasodilators (V), such as
angiotensin-converting enzyme (ACE) inhibitors or nitroprusside, also move patients to improved ventricular function curves while reducing cardiac filling pressures. Diuretics (D) improve symptoms of congestive heart failure by moving patients to lower cardiac filling pressures along the same ventricular function curve.

**Dietary Na⁺ Restriction.** All patients with clinically significant LV dysfunction, regardless of symptom status, should be advised to limit dietary sodium intake to 2-3 g/day. More stringent salt restriction is seldom necessary and may be counterproductive, as it can lead to hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis when combined with loop diuretic.

**Loop Diuretics.** Furosemide (Lasix, others), bumetanide (Bumex, others), and torsemide (Demadex, others) are widely used in the treatment of CHF. Due to the increased risk of ototoxicity, ethacrynic acid (Edecrin) is recommended only for patients with sulfonamides allergies or who are intolerant to alternative options. Loop diuretics inhibit a specific ion transport protein, the Na⁺-K⁺-2Cl⁻ symporter on the apical membrane of renal epithelial cells in the ascending limb of the loop of Henle to increase Na⁺ and fluid delivery to distal nephron segments (see Chapter 25). These drugs also enhance K⁺ secretion, particularly in the presence of elevated aldosterone levels, as is typical in CHF.

The bioavailability of orally administered furosemide ranges from 40-70%. High drug concentrations often are required to initiate diuresis in patients with worsening symptoms or in those with impaired gastrointestinal absorption, as may occur in severely hypervolemic patients with CHF-induced gut edema. In contrast, the oral bioavailabilities of bumetanide and torsemide are >80%, and as a result, these agents are more consistently absorbed but are financially more costly. Furosemide and bumetanide are short-acting drugs, and rebound Na⁺ retention that occurs with sub-steady state drug levels make ≥2/day dosing an acceptable treatment strategy when using these agents, provided adequate monitoring of daily body weight and blood electrolyte level monitoring is possible.

**Thiazide Diuretics.** Monotherapy with thiazide diuretics (Diuril, Hydrodiuril, others) has a limited role in CHF. However, combination therapy with loop diuretics is often effective in those refractory to loop diuretics alone. Thiazide diuretics act on the Na⁺ Cl⁻ co-transporter in the distal convoluted tubule (see
Chapter 25) and are associated with a greater degree K+ wasting per fluid volume reduction when compared to loop diuretics.

**K+-Sparing Diuretics.** K+-spparing diuretics (see Chapter 25) inhibit apical membrane Na+-conductance channels in renal epithelial cells (e.g., amiloride, triamterene) or are mineralocorticoid (e.g., aldosterone) receptor antagonists (e.g., canrenone [not commercially available in the U.S.], spironolactone, and eplerenone). Collectively, these agents are weak diuretics, but have been used to achieve volume reduction with limited K+ and Mg2+ wasting.

**Diuretics in Clinical Practice.** The majority of CHF patients will require chronic administration of a loop diuretic to maintain euvoolemia. In patients with clinically evident fluid retention, furosemide typically is started at a dose of 40 mg once or twice daily, and the dosage is increased until an adequate diuresis is achieved. A larger initial dose may be necessary in patients with advanced CHF and azotemia. Serum electrolytes and renal function are monitored frequently. If present, hypokalemia from therapy may be corrected by oral or intravenous K+ supplementation or by the addition of a K+-sparing diuretic.

**Diuretics in the Decompensated Patient.** In patients with decompensated CHF warranting hospital admission, repetitive intravenously administered boluses or a constant infusion titrated to achieve a desired response may be needed to provide expeditious diuresis. A typical continuous furosemide infusion is initiated with a 40-mg bolus injection followed by a constant rate of 10 mg/h, with uptitration as necessary. If renal perfusion is reduced, drug efficacy may be enhanced by coadministration of drugs that increase cardiac output (e.g., dobutamine).

**Diuretic Resistance.** (Table 28–1). A compensatory increase in renal tubular Na+ reabsorption may prevent effective diuresis when dosed daily; as a result, reduction of diuretic dosing intervals may be warranted. In advanced CHF, invasive assessment of intracardiac filling pressures and cardiac output may be required to distinguish between low intravascular volume from aggressive diuresis versus low cardiac output states. Other factors can contribute to diuretic resistance (see Table 28–1).

| Table 28–1 |

**Causes of Diuretic Resistance in Heart Failure**
**Metabolic Consequences of Diuretic Therapy.** With regard to diuretic use in CHF, the most important adverse sequelae of diuretics are electrolyte abnormalities, including hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis.

**Adenosine A\textsubscript{1} Receptor Antagonists.** Adenosine A\textsubscript{1} receptor antagonists may provide a renal protective therapeutic strategy for enhanced volume loss in decompensated CHF. Adenosine is secreted from the macula densa in the renal arteriole in response to diuretic-induced increases in Na\textsuperscript{+} and Cl\textsuperscript{−} tubular flow concentrations. This results in increased Na\textsuperscript{+} resorption, a volume-loss counterregulatory mechanism (see Chapter 26). Na\textsuperscript{+} reabsorption, in addition to adenosine-induced renal arteriole vasoconstriction, appears responsible (in part) for the development of complications common to the use of diuretics in decompensated CHF patients, particularly prerenal azotemia. The role of adenosine in the macula densa and juxtaglomerular (granular) cells suggests other effects of A\textsubscript{1} antagonists on the renin-angiotensin system (see Figure 26–3). Administration of A\textsubscript{1} antagonists KW-3902 (Rolofylline) or BG9179 (Naxifylline), to patients with decompensated CHF already treated with loop diuretics, has been associated with increased volume reduction, improved renal function, and lower diuretic dosing, however, a clinical trial failed to show significant benefits of rolofylline in patients with CHF and clinical development of the drug was stopped in 2009. No A\textsubscript{1} antagonists are currently marketed in the U.S.

**ALDOSTERONE ANTAGONISTS AND CLINICAL OUTCOME**

LV systolic dysfunction decreases renal blood flow and results in overactivation of the renin–angiotensin–aldosterone axis and may
increase circulating plasma aldosterone levels in CHF to 20-fold above normal. The pathophysiologic effects of hyperaldosteronemia are diverse (Table 28–2) and extend beyond Na\(^+\) and fluid retention; however, the precise mechanism by which aldosterone receptor blockade improves outcome in CHF remains unresolved.

Aldosterone-receptor antagonists in combination with ACE inhibitor therapy have provided beneficial effects in clinical trials. In CHF patients with low LV ejection fraction, spironolactone (25 mg/day) decreased mortality by ~30% (from progressive heart failure or sudden cardiac death), and patients had fewer CHF-related hospitalizations compared with the placebo group. Treatment was well tolerated; however, 10% of men reported gynecomastia and 2% of all patients developed severe hyperkalemia (>6.0 mEq/L).

**ORAL VASODILATORS**

Although numerous vasodilators have been developed that improve CHF symptoms, only the hydralazine–isosorbide dinitrate combination, ACE inhibitors, and AT\(_1\) receptor blockers (ARBs) demonstrably improve survival. The therapeutic use of vasodilators in the treatment of hypertension and myocardial ischemia is considered in detail in Chapter 27. This chapter focuses on the uses for some of these same vasodilator drugs in the treatment of CHF, mainly through
their capacity to reduce preload and afterload (Table 28–3).

**NITROVASODILATORS.** Nitrovasodilators are *nitric oxide (NO) donors* that activate soluble guanylate cyclase in vascular smooth muscle cells, leading to vasodilation. Unlike *nitroprusside*, which is converted to NO• by cellular reducing agents such as glutathione, *nitroglycerin* and other organic nitrates undergo a more complex enzymatic biotransformation to NO• or bioactive S-nitrosothiols. The activities of specific enzyme(s) and cofactor(s) required for this biotransformation appear to differ by target organ and even by different
vasculature beds within a particular organ.

**Organic Nitrates.** Organic nitrates are available in a number of formulations that include rapid-acting nitroglycerin tablets or spray for sublingual administration, short-acting oral agents such as isosorbide dinitrate (ISORDIL, others), long-acting oral agents such as isosorbide mononitrate (ISMO, others), topical preparations such as nitroglycerin ointment and transdermal patches, and intravenous nitroglycerin. The principal action of these preparations in CHF is reducing LV filling pressure. This occurs, in part, by augmentation of peripheral venous capacitance that results in preload reduction. Additional effects of organic nitrates include pulmonary and systemic vascular resistance reduction, and coronary artery vasodilation for which systolic and diastolic ventricular function is enhanced by increased coronary blood flow. These beneficial physiologic effects translate into improved exercise capacity and CHF-symptom reduction. However, these drugs do not substantially influence systemic vascular resistance, and pharmacologic tolerance limits their utility over time. Organic nitrates are commonly used with other vasodilators (e.g., hydralazine) to increase the clinical effectiveness.

**Nitrate Tolerance.** *Nitrate tolerance may limit the long-term effectiveness of these drugs in the treatment of CHF. Blood nitrate levels may be permitted to fall to negligible levels for at least 6-8 h each day (see Chapter 27).* Patients with recurrent orthopnea or paroxysmal nocturnal dyspnea, e.g., might benefit from nighttime nitrate use. Likewise, co-treatment with hydralazine may decrease nitrate tolerance by an antioxidant effect that attenuates superoxide formation, thereby increasing the bioavailable NO levels.

**PARENTERAL VASODILATORS**

**Sodium Nitroprusside.** Sodium nitroprusside (NITRO-PRESS, others) is a direct NO donor and potent vasodilator that is effective in reducing both ventricular filling pressure and systemic vascular resistance (Figure 28–3). Onset to action is rapid (2-5 min) as the drug is quickly metabolized to NO. Nitroprusside is effective in treating critically ill patients with CHF who have elevated systemic vascular resistance or mechanical complications that follow acute MI (e.g., mitral regurgitation or ventricular septal defect-induced left-to-right shunts).
It increases cardiac output and renal blood flow, improving both glomerular filtration and diuretic effectiveness. The most common adverse side effect of nitroprusside is hypotension. Excessive reduction of systemic arterial pressure may limit or prevent an increase in renal blood flow in patients with more severe LV contractile dysfunction.

Figure 28–3 Relationship between ventricular outflow resistance and stroke volume in patients with systolic ventricular dysfunction. An increase in ventricular outflow resistance, a principal determinant of afterload, has little effect on stroke volume in normal hearts, as illustrated by the relatively flat curve. In contrast, in patients with systolic ventricular dysfunction, an increase in outflow resistance often is accompanied by a sharp decline in stroke volume. With more severe ventricular dysfunction, this curve becomes steeper. Because of this relationship, a reduction in systemic vascular resistance (1 component of outflow resistance) in response to an arterial vasodilator may markedly increase stroke volume in patients with severe myocardial dysfunction. The resultant increase in stroke volume may be sufficient to offset the decrease in systemic vascular resistance, thereby preventing a fall in systemic arterial pressure. (Adapted from Cohn and Franciosa, 1977.)

Cyanide produced during the biotransformation of nitroprusside is rapidly metabolized by the liver to thiocyanate, which is then renally excreted.
Thiocyanate and/or cyanide toxicity is uncommon but may occur in the setting of hepatic or renal failure, or following prolonged periods of high-dose drug infusion (see Chapter 27 for details). Typical symptoms include unexplained abdominal pain, mental status changes, convulsions, and lactic acidosis. Methemoglobinemia is another unusual complication and is due to the oxidation of hemoglobin by NO⁻.

Intravenous Nitroglycerin. Intravenous nitroglycerin is a vasoactive NO donor that is used in the intensive care unit setting. Unlike nitroprusside, nitroglycerin is relatively selective for venous capacitance vessels, particularly at low infusion rates. In CHF, intravenous nitroglycerin is most commonly used in the treatment of LV dysfunction due to an acute myocardial ischemia. Parenteral nitroglycerin also is used in the treatment of nonischemic cardiomyopathy when expeditious LV filling pressure reduction is desired. At higher infusion rates, this drug also may decrease systemic arterial resistance. Nitroglycerin therapy may be limited by headache and nitrate tolerance; tolerance may be partially offset by increasing the dosage.

Hydralazine. Hydralazine is a direct vasodilator whose mechanism of action is poorly understood. Hydralazine is an effective antihypertensive drug (see Chapter 27), particularly when combined with agents that blunt compensatory increases in sympathetic tone and salt and water retention. In CHF, hydralazine reduces right and LV afterload by reducing pulmonary and systemic vascular resistance. This results in an augmentation of forward stroke volume and a reduction in ventricular wall stress in systole. Hydralazine also appears to have moderate “direct” positive inotropic activity in cardiac muscle independent of its afterload-reducing effects. Hydralazine is effective in reducing renal vascular resistance and in increasing renal blood flow. Hydralazine often is used in CHF patients with renal dysfunction intolerant of ACE-inhibitor therapy. Combination therapy with isosorbide dinitrate and hydralazine reduces CHF mortality in patients with systolic dysfunction. Hydralazine provides additional hemodynamic improvement for patients with advanced CHF (with or without nitrates) already treated
with conventional doses of an ACE inhibitor, digoxin, and diuretics.

The oral bioavailability and pharmacokinetics of hydralazine are not altered significantly in CHF, unless severe hepatic congestion or hypoperfusion is present. Hydralazine is typically started at a dose of 10-25 mg 3 or 4 times per day and uptitrated to a maximum of 100 mg 3 or 4 times daily, as tolerated. At total daily doses >200 mg, hydralazine is associated with an increased risk of lupus-like effects.

There are several important considerations for hydralazine use. First, ACE inhibitors appear to be superior to hydralazine for mortality reduction in severe CHF. Second, side effects requiring dose adjustment of hydralazine withdrawal are common. The lupus-like side effects associated with hydralazine are relatively uncommon and may be more likely to occur in selected patients with the “slow-acetylator” phenotype (see Chapter 27). Finally, hydralazine is a medication taken 3 or 4 times daily, and adherence may be difficult for CHF patients, who are prescribed multiple medications concurrently.

TARGETING NEUROHORMONAL REGULATION: THE RENIN–ANGIOTENSIN–ALDOSTERONE AXIS AND VASOPRESSIN ANTAGONISTS

RENIN–ANGIOTENSIN–ALDOSTERONE AXIS ANTAGONISTS. The renin–angiotensin–aldosterone axis plays a central role in the pathophysiology of CHF (Figure 28–4).
Figure 28–4 The renin–angiotensin–aldosterone axis. Renin, excreted in response to β adrenergic stimulation of the juxtaglomerular (j-g) or granular cells of the kidney, cleaves plasma angiotensinogen to produce angiotensin I. Angiotensin-converting enzyme (ACE) catalyzes the conversion of angiotensin I to angiotensin II (AngII). Most of the known biologic effects of AngII are mediated by the type 1 angiotensin (AT₁) receptor. In general, the AT₂ receptor appears to counteract the effects of AngII that are mediated by activation of the AT₁ pathway. AngII also may be formed through ACE-independent pathways. These pathways, and possibly incomplete inhibition of tissue ACE, may account for persistence of AngII in patients treated with ACE inhibitors. ACE inhibition decreases bradykinin degradation, thus enhancing its levels and biologic effects, including the production of NO and PGI₂. Bradykinin may mediate some of the biological effects of ACE inhibitors.

AngII is a potent arterial vasoconstrictor and an important mediator of Na⁺ and water retention through its effects on glomerular filtration pressure and aldosterone secretion. AngII also modulates neural and adrenal medulla catecholamine release, is arrhythmogenic, promotes vascular hyperplasia and myocardial hypertrophy, and induces myocyte death. Consequently, reduction of the effects of AngII constitutes a cornerstone of CHF management.
ACE inhibitors suppress AngII (and aldosterone) production, decrease sympathetic nervous system activity, and potentiate the effects of diuretics in CHF. However, AngII levels frequently return to baseline values following chronic treatment with ACE inhibitors (see Chapter 26), due in part to AngII production via ACE-independent enzymes. This AngII “escape” suggests that alternate mechanisms contribute to the clinical benefits of ACE inhibitors in CHF. ACE is identical to kininase II, which degrades bradykinin and other kinins that stimulate production of NO, cyclic GMP, and vasoactive eicosanoids. These oppose AngII-induced vascular smooth muscle cell and cardiac fibroblasts proliferation and inhibit unfavorable extracellular matrix deposition.

ACE inhibitors are preferential arterial vasodilators. ACE-inhibitor–mediated decreases in LV afterload result in increased stroke volume and cardiac output. Heart rate typically is unchanged with treatment, often despite decreases in systemic arterial pressure, a response that probably is a consequence of decreased sympathetic nervous system activity from ACE inhibition. Most clinical actions of AngII are mediated through the AT₁ angiotensin receptor, whereas AT₂ receptor activation appears to counterbalance the downstream biologic effects of AT₁ receptor stimulation. Owing to enhanced target specificity, AT₁ receptor antagonists more efficiently block the effects of AngII than do ACE inhibitors. In addition, the elevated level of circulating AngII that occurs secondary to AT₁ receptor blockade results in a relative increase in AT₂ receptor activation. Unlike ACE inhibitors, AT₁ blockers do not influence bradykinin metabolism (see the next section).

**ANGIOTENSIN-CONVERTING ENZYME INHIBITORS.** The ACE inhibitors captopril, enalapril, ramipril, lisinopril, quinapril, trandolapril, and fosinopril (see Chapter 26) are FDA-approved for the treatment of CHF. Data from numerous clinical trials support ACE inhibition in the management of CHF of any severity, including those with asymptomatic LV dysfunction.

ACE-inhibitor therapy typically is initiated at a low dose (e.g., 6.25 mg of captopril, 5 mg of lisinopril) to avoid iatrogenic hypotension. ACE-inhibitor doses customarily are increased over several days in hospitalized patients or over weeks in ambulatory patients, with monitoring of blood pressure, serum electrolytes, and creatinine levels. In CHF patients with decreased renal blood flow, ACE inhibitors impair autoregulation of glomerular perfusion pressure,
reflecting their selective effect on efferent (over afferent) arteriolar tone. In the event of acute renal failure or a decrease in the glomerular filtration rate by >20%, ACE-inhibitor dosing should be reduced or the drug discontinued.

**ACE-Inhibitor Side Effects.** Elevated bradykinin levels from ACE inhibition are associated with angioedema, a potentially life-threatening drug side effect. If this occurs, immediate and permanent cessation of all ACE inhibitors is indicated. A characteristic, dry cough from the same mechanism is common; in this case, substitution of an AT₁ receptor antagonist for the ACE inhibitor often is curative. A small rise in serum K+ levels is common with ACE-inhibitor use. This increase may be substantial in patients with renal impairment or in diabetic patients with type IV renal tubular acidosis. Mild hyperkalemia is best managed by institution of a low-potassium diet or dose adjustment.

**ACE Inhibitors and Survival in CHF.** When compared with other vasodilators, ACE inhibitors appear superior in reducing mortality in CHF. ACE inhibitors improve survival in patients with CHF due to systolic dysfunction. ACE inhibitors also prevent the development of clinically significant LV dysfunction after acute MI. ACE inhibitors appear to confer these benefits by preventing postinfarction-associated adverse ventricular remodeling. In asymptomatic patients with LV dysfunction, ACE inhibitors slow the development of symptomatic CHF.

**AT₁ RECEPTOR ANTAGONISTS.** AT₁ receptor antagonism obviates AngII “escape” and decreases the probability of developing bradykinin-mediated side effects associated with ACE inhibition. Although rare, angioedema has been reported with AT₁ receptor antagonist use. AT₁ receptor blockers (ARBs) are effective antihypertensives, and their influence on mortality in acute or chronic CHF from systolic dysfunction after acute MI is akin to that of ACE-inhibitor therapy. Owing to their favorable side-effect profile, ARBs are an excellent alternative in CHF patients intolerant of ACE inhibitors. In the elderly, there is an increased probability of developing clinically significant hypotension, renal dysfunction, and hyperkalemia.
The role of combination ACE-inhibitor and ARB therapy in the treatment of CHF remains unresolved. Based on the hypothesis that ARB efficacy is at least in part a consequence of reduced circulating aldosterone levels, combined. Combined ARB treatment with aldosterone receptor inhibition has also been explored. Combination therapy is associated with a significant increase in LV ejection fraction and quality of life scores in patients with CHF from systolic dysfunction treated for 1 year with candesartan (8 mg daily) and spironolactone (25 mg daily) compared to those treated with candesartan alone. Data regarding mortality benefit attendant to combination therapy are not available at present.

**DIRECT RENIN INHIBITORS.** Maximal pharmacologic ACE inhibition alone may be insufficient for optimal attenuation of AngII-induced cardiovascular dysfunction in patients with CHF. Several molecular mechanisms may contribute:

- ACE-independent pathways that facilitate AngI → AngII conversion
- Suppression of the negative feedback exerted by AngII on renin secretion in the kidney

Thus, inhibition of renin to further suppress AngII synthesis in CHF has gained popularity. Renin-mediated conversion of angiotensinogen to AngI is the first and rate-limiting step in the biochemical cascade that generates AngII and aldosterone (see Figures 26–1 and 28–4).

Aliskiren (TEKTURNA, RASILEZ) is the first orally administered direct renin inhibitor to obtain FDA approval for use in clinical practice. The pharmacokinetic advantages of aliskiren over earlier direct renin inhibitor prototypes include an increased bioavailability (2.7%) and a long plasma $t_{1/2}$ (~23 h). Aliskiren induces a concentration-dependent decrease in plasma renin activity and AngI and AngII levels that are associated with a decrease in systemic blood pressure without significant reflex tachycardia (see Chapter 26).

Aliskiren is as effective as an ARB for monotherapy of mild-to-moderate hypertension. Aliskiren also appears to exert beneficial effects on myocardial remodeling by decreasing LV mass in hypertensive patients, suggesting that direct renin inhibition may attenuate hypertension-induced end-organ damage. Collectively, these observations provide evidence that aliskiren-mediated
reductions in plasma renin activity and circulating levels of AngII may have salutary effects on the cardiovascular system in hypertension. Combining aliskiren (150 mg/day) with a β receptor antagonist and an ACE inhibitor or ARB did not produce a significant increase in hypotension or hyperkalemia in a cohort that mainly included symptomatic CHF patients with a low LV ejection fraction (~30%). Results from this trial also demonstrated that aliskiren significantly decreased plasma N-terminal-proBNP levels, a clinically useful neurohumoral biomarker of active CHF. These findings affirm that inhibition of renin activity is an important potential target for improving symptoms and functional capacity in CHF.

**VASOPRESSIN RECEPTOR ANTAGONISTS.** Neurohumoral dysregulation in CHF includes abnormal arginine vasopressin (AVP) secretion, resulting in the perturbation of fluid balance. AVP is secreted into the systemic circulation in response to: (1) serum hypertonicity-induced activation of anterior pituitary osmoreceptors, and (2) a perceived drop in blood pressure detected by baroreceptors in the carotid artery, aortic arch, and left atrium (see Chapter 25).

The active form of AVP is a 9–amino acid peptide that interacts with 3 receptor subtypes: V\(_{1a}\), V\(_{1b}\), and V\(_2\). The AVP-V\(_2\) receptor interaction on the basolateral membrane of the renal collecting ducts stimulates de novo synthesis of aquaporin-2 water channels that mediate free water reabsorption, thereby impairing diuresis and, ultimately, correcting plasma hypertonicity. Additional cell signaling pathways important in the pathophysiology of CHF include vasoconstriction, cell hypertrophy, and increased platelet aggregation mediated by activation of V\(_{1a}\) receptors in vascular smooth muscle cells and cardiac myocytes. In addition, AngII-mediated activation of centrally located AT\(_1\) receptors is associated with increased AVP levels in CHF and may represent a mechanism by which the use of AT\(_1\)-receptor antagonists are effective in the clinical management of these patients.

AVP levels are nearly 2-fold above normal in CHF patients. This dysregulation of AVP synthesis in CHF may involve impaired atrial stretch receptor sensitivity, normally a counterregulatory mechanism for AVP secretion, and increased adrenergic tone. However, elevated levels of AVP have been observed in
asymptomatic patients with significantly decreased LV function. CHF may have a component of abnormal responsiveness to vasopressin rather than one of excessive vasopressin production alone. Vasopressin infusion in CHF patients decreases cardiac output and stroke volume and causes an exaggerated increase in systemic vascular resistance and pulmonary capillary wedge pressure. In turn, V₂ antagonists attenuate the adverse pathophysiologic effects of hypervasopressinemia by decreasing capillary wedge pressure, right atrial pressure, and pulmonary artery systolic blood pressure. These agents also restore and maintain normal serum sodium levels in decompensated CHF patients, but their long-term use has not yet been convincingly linked to a decrease in CHF-associated symptoms or mortality.

Tolvaptan (Samsca), which preferentially binds the V₂ receptor over the V₁a receptor (receptor selectivity ~29:1), is perhaps the most widely tested vasopressin receptor antagonist in patients with CHF and also is approved for hyponatremia. Due to the risk of overly rapid correction of hyponatremia causing osmotic demyelination, tolvaptan should be started only in a hospital setting where Na⁺ levels can be monitored closely and possible drug interactions mediated by CYP and P-gp can be considered (black box warning). Conivaptan, used mainly for the treatment of hyponatremia rather than for CHF per se, differs from tolvaptan in that it may be intravenously administered, has high affinity for both V₂ and V₁a receptors, and has a t₁/₂ nearly twice as long.

**β ADRENERGIC RECEPTOR ANTAGONISTS**

Long-term sympathomimetic use is associated with increased CHF mortality rates, whereas a survival benefit is associated with chronic administration of β receptor antagonists. β antagonists (e.g., metoprolol) improve symptoms, exercise tolerance, and are measures of LV function over several months in idiopathic dilated cardiomyopathy patients with CHF. Serial echocardiographic measurements in CHF patients indicate that a decrease in systolic function occurs immediately after initiation of a β antagonist treatment, but this recovers and improves beyond baseline over the ensuing 2-4 months.
**Mechanism of Action.** The mechanisms by which β receptor antagonists influence outcome in CHF patients are not fully delineated. By preventing myocardial ischemia without significantly influencing serum electrolytes, β receptor antagonists probably influence mortality, in part, by decreasing the frequency of unstable tachyarrhythmias to which CHF patients are particularly prone. In addition, these agents may influence survival by favorably affecting LV geometry, specifically by decreasing LV chamber size and increasing LV ejection fraction. Through inhibition of sustained sympathetic nervous system activation, these agents prevent or delay progression of myocardial contractile dysfunction by inhibiting maladaptive proliferative cell signaling in the myocardium, reducing catecholamine-induced cardiomyocyte toxicity, and decreasing myocyte apoptosis. β Receptor antagonists may also induce positive LV remodeling by decreasing oxidative stress in the myocardium.

**Metoprolol.** Metoprolol (LORPRESSOR, TOPROL XL, others) is a β₁-selective receptor antagonist. The short-acting form of this drug has a t₁/₂ of ~6 h. The extended-release formulation is sufficiently dosed once daily. A number of clinical trials have demonstrated the beneficial effects of β-antagonist therapy in CHF.

**Carvedilol.** Carvedilol (COREG, others) is a nonselective β receptor antagonist and α₁-selective antagonist that is FDA approved for the management of mild-to-severe CHF. In clinical trials, carvedilol (25 mg twice daily) was associated with a 65% reduction in all-cause mortality that was independent of age, sex, CHF etiology, or LV ejection fraction. The mortality benefit and improvement in LV ejection fraction was carvedilol concentration dependent. Exercise capacity (e.g., 6-min walk test) did not improve with carvedilol, but therapy did appear to slow the progression of CHF in a subgroup of patients with good exercise capacity and mild symptoms at baseline.

**CLINICAL USE OF β ADRENERGIC RECEPTOR ANTAGONISTS IN CHF**

Data from patients with mild-to-moderate chronic CHF establish that β receptor antagonists improve disease-associated symptoms, hospitalization, and mortality. Accordingly, β antagonists are recommended for use in patients with an LV ejection fraction <35% and NYHA class II or III symptoms in conjunction with an ACE
inhibitor or AT<sub>1</sub> receptor antagonist, and diuretics as required to palliate symptoms.

The role of β receptor antagonists in severe CHF or under circumstances of an acute clinical decompensation is not yet clear. Likewise, the utility of β blockade in patients with asymptomatic LV dysfunction has not been systematically evaluated. The marked heterogeneous pharmacologic characteristics (e.g., receptor selectivity, pharmacokinetics) of specific agents play a key role in predicting the overall efficacy of a particular β receptor antagonist. β receptor antagonist therapy is customarily initiated at very low doses, generally less than one-tenth of the final target dose, and titrated upward.

**CARDIAC GLYCOSIDES**

The benefits of cardiac glycosides in CHF are generally attributed to:

- Inhibition of the plasma membrane Na<sup>+</sup>, K<sup>+</sup>-ATPase in myocytes
- A positive inotropic effect on the failing myocardium
- Suppression of rapid ventricular rate response in CHF-associated atrial fibrillation
- Regulation of downstream deleterious effects of sympathetic nervous system overactivation

*Mechanism of the Positive Inotropic Effect.* With cardiac myocyte depolarization (Figure 28–5), Ca<sup>2+</sup> enters the cell via the L-type Ca<sup>2+</sup> channel and triggers the release of stored Ca<sup>2+</sup> from the sarcoplasmic reticulum via the ryanodine receptor (RyR). This Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release increases the level of cytosolic Ca<sup>2+</sup> available for interaction with myocyte contractile proteins, ultimately increasing myocardial contraction force. During myocyte repolarization and relaxation, cellular Ca<sup>2+</sup> is re-sequestered by the sarcoplasmic reticular Ca<sup>2+</sup>-ATPase and is removed from the cell by the Na<sup>+</sup> Ca<sup>2+</sup> exchanger and by the sarcolemmal Ca<sup>2+</sup>-ATPase.
Figure 28–5 Sarcolemmal exchange of \(Na^+\) and \(Ca^{2+}\) during cell depolarization and repolarization. \(Na^+\) and \(Ca^{2+}\) enter the cardiac myocyte via the \(Na^+\) channel and the L-type \(Ca^{2+}\) channel during each cycle of membrane depolarization, triggering the release, through the ryanodine receptor (RyR), of larger amounts of \(Ca^{2+}\) from internal stores in the sarcoplasmic reticulum (SR). The resulting increase in intracellular \(Ca^{2+}\) interacts with troponin C and activates interactions between actin and myosin that result in sarcomere shortening. The electrochemical gradient for \(Na^+\) across the sarcolemma is maintained by active transport of \(Na^+\) out of the cell by the sarcolemmal \(Na^+, K^+\)-ATPase. The bulk of cytosolic \(Ca^{2+}\) is pumped back into the SR by a \(Ca^{2+}\)-ATPase, SERCA2. The remainder is removed from the cell by either a sarcolemmal \(Ca^{2+}\)-ATPase or a high-capacity \(Na^+-Ca^{2+}\) exchanger, NCX. NCX exchanges 3 \(Na^+\) for a \(Ca^{2+}\), using the electrochemical potential of \(Na^+\) to drive \(Ca^{2+}\) extrusion. The direction of \(Na^+-Ca^{2+}\) exchange may reverse briefly during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. \(\beta\) adrenergic agonists and PDE inhibitors, by increasing intracellular cyclic AMP levels, activate PKA, which phosphorylates phospholamban (PL), the \(\alpha\) subunit of the L-type \(Ca^{2+}\) channel, and regulatory components of the RyR, as well as TnI, the
inhibitory subunit of troponin (not shown). As a result, the probabilities of opening of the L-type Ca\(^{2+}\) channel and the RyR2 Ca\(^{2+}\) channel are doubled; SERCA2 is uninhibited and accumulates Ca\(^{2+}\) into the SR faster, more avidly, and to a higher concentration; and relaxation occurs at slightly higher [Ca\(^{2+}\)], due to slightly reduced sensitivity of the troponin complex to Ca\(^{2+}\). The net effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation. ▲ indicates site of cardiac glycoside binding. See the text for the mechanism of positive inotropic effect of cardiac glycosides.

Cardiac glycosides bind and inhibit the phosphorylated α subunit of the sarcolemmal Na\(^{+}\), K\(^{+}\)-ATPase and thereby decreasing Na\(^{+}\) extrusion and increasing cytosolic [Na\(^{+}\)]. This decreases the transmembrane Na\(^{+}\) gradient that drives Na\(^{+}\)–Ca\(^{2+}\) exchange during myocyte repolarization. As a consequence, less Ca\(^{2+}\) is removed from the cell and more Ca\(^{2+}\) is accumulated in the sarcoplasmic reticulum (SR) by SERCA2. This increase in releasable Ca\(^{2+}\) (from the SR) is the mechanism by which cardiac glycosides enhance myocardial contractility. Elevated extracellular K\(^{+}\) levels (i.e., hyperkalemia) cause dephosphorylation of the ATPase α subunit, altering the site of action of the most commonly used cardiac glycoside, digoxin, and thereby reducing the drug’s effect.

*Electrophysiologic Actions.* At therapeutic plasma concentrations (i.e., 1-2 ng/mL), digoxin decreases automaticity and increases the maximal diastolic resting membrane potential in atrial and atrioventricular (AV) nodal tissues. This occurs via increases in vagal tone and sympathetic nervous system activity inhibition. In addition, digoxin prolongs the effective refractory period and decreases conduction velocity in AV nodal tissue. Collectively, these may contribute to sinus bradycardia, sinus arrest, prolongation of AV conduction, or high-grade AV block. At higher concentrations, cardiac glycosides may increase sympathetic nervous system activity that influences cardiac tissue automaticity, change associated with atrial and ventricular arrhythmias. Increased intracellular Ca\(^{2+}\) loading and sympathetic tone increases the spontaneous (phase 4) rate of diastolic depolarization as well as promoting delayed after depolarization; together, these decrease the threshold for generation of a propagated action potential and predisposes to malignant ventricular arrhythmias (see Chapter 29).
Regulation of Sympathetic Nervous System Activity. Sympathetic nervous system overactivation in CHF occurs, in part, from aberrant arterial baroreflex responses to low cardiac output. Specifically, a decline in baroreflex response to blood pressure results in a decline in baroreflex-mediated tonic suppression of CNS-directed sympathetic activity. This cascade contributes to the sustained elevation in plasma NE, renin, and vasopressin. Cardiac glycosides favorably influence carotid baroreflex responsiveness to changes in carotid sinus pressure. In patients with moderate-to-advanced CHF, cardiac glycoside infusion increases forearm blood flow and cardiac index and decreased heart rate. Digoxin also decreases centrally mediated sympathetic nervous system tone, although the mechanism to explain this is unresolved.

Pharmacokinetics. The elimination $t_{1/2}$ for digoxin is 36-48 h permitting once-daily dosing. Steady-state blood levels are achieved ~7 days after initiation of maintenance therapy. Digoxin is excreted by the kidney, and increases in cardiac output or renal blood flow from vasodilator therapy or sympathomimetic agents may increase renal digoxin clearance, necessitating adjustment of daily maintenance doses. The volume of distribution and drug clearance rate are both decreased in elderly patients. Digoxin is not removed effectively by hemodialysis due to the drug’s large (4-7 L/kg) volume of distribution. The principal tissue reservoir is skeletal muscle and dosing should be based on estimated lean body mass. Liquid-filled capsules of digoxin (LANOXICAPS) have a higher bioavailability than do tablets (LANOXIN). Digoxin is available for intravenous administration.

Chronic renal failure decreases the volume of distribution of digoxin and therefore requires a decrease in maintenance dosage of the drug. Drug interactions that may influence circulating serum digoxin levels include several commonly used cardiovascular medications such as verapamil, amiodarone, propafenone, and spironolactone. The rapid administration of Ca$^{2+}$ increases the risk of inducing malignant arrhythmias in patients already treated with digoxin. Electrolyte disturbances, especially hypokalemia, acid–base imbalances, and one’s form of underlying heart disease also may alter a patient’s susceptibility to digoxin side effects. Maximal increase in LV contractility becomes apparent at serum digoxin levels ~1.4 ng/mL (1.8 nmol). Higher serum concentrations are not associated with incrementally increased clinical benefit. The risk of death is greater with increasing serum concentrations and it is recommended to maintain
digoxin levels <1 ng/mL.

**Clinical Use of Digoxin in Heart Failure.** Overall, digoxin use usually is limited to CHF patients with LV systolic dysfunction in atrial fibrillation or to patients in sinus rhythm who remain symptomatic despite maximal therapy with ACE inhibitors and β adrenergic receptor antagonists. The latter agents are viewed as first-line therapies because of their proven mortality benefit.

**Digoxin Toxicity.** The incidence and severity of digoxin toxicity have declined substantially in the past 2 decades as a consequence of alternative drugs available for the treatment of supraventricular arrhythmias in CHF and increased understanding of digoxin pharmacokinetics. Common electrophysiologic manifestations of digoxin toxicity are ectopic beats originating from the AV junction or ventricle, first-degree AV block, abnormally slow ventricular rate response to atrial fibrillation, or an accelerated AV junctional pacemaker. Lidocaine or phenytoin, which have minimal effects on AV conduction, may be used for the treatment of digoxin-induced ventricular arrhythmias that threaten hemodynamic compromise (see Chapter 29). Electrical cardioversion carries an increased risk of inducing severe rhythm disturbances in patients with overt digitalis toxicity. Inhibition of the Na+, K+-ATPase activity of skeletal muscle can cause hyperkalemia. An effective antidote for digoxin toxicity is anti-digoxin immunotherapy. Purified Fab fragments from ovine anti-digoxin antisera (DIGIBIND) are usually dosed by the estimated total dose of digoxin ingested in order to achieve a fully neutralizing effect.

**β ADRENERGIC AND DOPAMINERGIC AGONISTS**

In decompensated CHF from reduced cardiac output, the principal focus of initial therapy is to increase myocardial contractility. Dopamine and dobutamine are positive inotropic agents most often used to accomplish this. These drugs stimulate cardiac myocyte dopamine (D₁) and β adrenergic receptors that stimulate the Gₛ-adenylyl cyclase-cyclic AMP–PKA pathway. PDE inhibitors slow degradation of cyclic AMP, thereby raising the steady-state level of cyclic AMP in cells. The catalytic subunit of PKA phosphorylates a number of substrates that enhance Ca²⁺-dependent myocardial
contraction and accelerate relaxation (see Figure 28–5). Isoproterenol, Epi, and NE have little role in routine CHF management. Indeed, inotropic agents that elevate cardiac cell cyclic AMP are consistently associated with increased risks of hospitalization and death. At the cellular level, enhanced cyclic AMP levels have been associated with apoptosis (see Chapter 12).

**Dopamine (DA).** The pharmacologic and hemodynamic effects of DA are concentration dependent. Low doses (≤2 μg/kg lean body mass/min) induces cyclic AMP–dependent vascular smooth muscle vasodilation. Activation of D₂ receptors on sympathetic nerves in the peripheral circulation at these concentrations also inhibits NE release and reduces α adrenergic stimulation of vascular smooth muscle, particularly in splanchnic and renal arterial beds. Low-dose DA infusion often is used to increase renal blood flow and thereby maintain an adequate glomerular filtration rate in hospitalized CHF patients with impaired renal function refractory to diuretics. DA also exhibits a pro-diuretic effect directly on renal tubular epithelial cells that contributes to volume reduction. At intermediate infusion rates (2-5 μg/kg/min), dopamine directly stimulates cardiac β receptors and vascular sympathetic neurons that enhance myocardial contractility and neural NE release. At higher infusion rates (5-15 μg/kg/min), α adrenergic receptor stimulation–mediated peripheral arterial and venous constriction occurs. This may be desirable in patients with critically reduced arterial pressure or in those with circulatory failure from severe vasodilation (e.g., sepsis, anaphylaxis), but has little role in the treatment of patients with primary cardiac contractile dysfunction. Tachycardia, which is more pronounced with DA than with dobutamine, may provoke ischemia in patients with coronary artery disease.

**Dobutamine.** Dobutamine is the β agonist of choice for the management of CHF patients with systolic dysfunction. For clinical use, dobutamine is available as a racemic mixture that stimulates both β₁ and β₂ receptor subtypes. In addition, the (−) enantiomer is an agonist for α adrenergic receptors, whereas the (+) enantiomer is a weak, partial agonist. At infusion rates that result in a positive inotropic effect in humans, the β₁ adrenergic effect in the myocardium predominates. In the vasculature, the α adrenergic agonist effect of the (−) enantiomer appears to be offset by the (+) enantiomer and vasodilating effects of
β₂ receptor stimulation. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume from positive inotropy, although β₂ receptor activation may cause a decrease in systemic vascular resistance and, therefore, mean arterial pressure. Despite increases in cardiac output, there is relatively little chronotropic effect. Continuous dobutamine infusions are typically initiated at 2-3 μg/kg/min and uptitrated until the desired hemodynamic response is achieved. Pharmacologic tolerance may limit infusion efficacy beyond 4 days, and, therefore, addition or substitution with a class III PDE inhibitor may be necessary to maintain adequate circulatory support. The major side effects of dobutamine are tachycardia and supraventricular or ventricular arrhythmias, which may require a reduction in dosage. Recent β receptor antagonist use is a common cause of blunted clinical responsiveness to dobutamine.

PHOSPHODIESTERASE INHIBITORS

The cyclic AMP–PDE inhibitors decrease cellular cyclic AMP degradation, resulting in elevated levels of cyclic AMP. The physiologic effects are positive myocardial inotropism and dilation of resistance and capacitance vessels. Collectively, PDE inhibition improves cardiac output through inotropy and by decreasing preload and afterload (thus giving rise to the term *inodilator*).

*Inamrinone and Milrinone.* Parenteral formulations of *inamrinone* (previously named amrinone) and *milrinone* are approved for short-term circulation support in advanced CHF. Both drugs are selective inhibitors of PDE3, the cyclic GMP–inhibited cyclic AMP PDE. By elevating cellular cyclic AMP levels, these drugs stimulate myocardial contractility and accelerate myocardial relaxation. In addition, they cause balanced arterial and venous dilation with a consequent fall in systemic and pulmonary vascular resistances and left and right-heart filling pressure. As a result of its effect on LV contractility, the increase in cardiac output from milrinone is superior to that from nitroprusside. Conversely, the arterial and venodilatory effects of milrinone are greater than those of dobutamine at concentrations that produce similar increases in cardiac output.

For inamrinone, a 0.75-mg/kg bolus injection administered over 2-3 min is typically followed by a 2-20-μg/kg/min infusion. The loading dose of milrinone is ordinarily 50 μg/kg, and the continuous infusion rate ranges from 0.25-1
μg/kg/min. The elimination half-lives of inamrinone and milrinone in normal individuals are 2-3 h and 0.5-1 h, respectively, but are nearly doubled in patients with severe CHF. Clinically significant thrombocytopenia occurs in b10% of those receiving inamrinone but is rare with milrinone. Because of enhanced selectivity for PDE3, short $t_{1/2}$, and favorable side-effect profile, milrinone is the agent of choice among currently available PDE inhibitors for short-term, parenteral inotropic support.

*Sildenafil.* In contrast to inamrinone and milrinone, sildenafil (REVATIO) inhibits PDE5, which is the most common PDE isoform in lung tissue. This characteristic of PDE5 likely accounts for the enhanced pulmonary artery specificity observed with sildenafil use. In fact, until recently, the primary clinical application of sildenafil in CHF has mainly been limited to those with isolated right ventricular systolic failure from pulmonary artery hypertension. However, recently published reports suggest that sildenafil favorably influences exercise capacity and right-heart hemodynamics in patients with pulmonary hypertension from LV systolic dysfunction as well. The pharmacology of PDE5 inhibitors is presented in Chapter 27.

**CHRONIC POSITIVE INOTROPIC THERAPY**

Although improvements in CHF symptoms, functional status, and hemodynamic profile have been reported, the effect of long-term therapy on mortality is disappointing. In fact, the dopaminergic agonist ibopamine; PDE inhibitors milrinone, inamrinone, and vesnarinone; and pimobendan are associated with increased mortality. At present, digoxin remains the only oral inotropic agent available for CHF patient use.

**DIASTOLIC HEART FAILURE**

Up to 40% of CHF patients have preserved LV systolic function. The pathogenesis of diastolic CHF includes structural and functional abnormalities of the ventricle(s) that are associated with impaired ventricular relaxation and LV distensibility. These abnormalities are reflected in the LV pressure-volume relationship during diastole,
which is shifted upward and to the left relative to normal subjects (Figure 28–6). Diastolic CHF is diagnosed when the LV is unable to maintain adequate cardiac output without filling at an abnormally elevated end-diastolic filling pressure.

![Pressure-volume relationships](image)

**Figure 28–6** Pressure–volume relationships in normal heart and heart with diastolic dysfunction. Normal P-V loop (*green*) based on normal end-diastolic pressure–volume relationship (EDPVR). P-V loop with diastolic dysfunction is shown in red. ESPVR, end-systolic pressure–volume relationship.

In patients with *primary* diastolic dysfunction, the myocardial abnormality that accounts for abnormal filling is intrinsic to the myocardium; e.g., by infiltrative disorders including cardiac amyloidosis, hemochromatosis, sarcoidosis, and rarer conditions such as endomyocardial fibrosis and Fabry disease. Although not a disease of myocardium infiltration, CHF may occur despite intact LV systolic function in familial hypertrophic cardiomyopathy. *Secondary* diastolic dysfunction occurs as a consequence of excessive preload (e.g., renal failure), excessive afterload (e.g., systemic hypertension), or changes in LV geometry that occur in response to chronically abnormal loading conditions. Diastolic CHF also is observed in patients with long-standing epicardial coronary artery or pericardial disease. The prevalence of secondary diastolic dysfunction is higher...
in women and with advanced age. Reported annual mortality rates for diastolic CHF are 5-8%, likely represents an underestimation.

Patients with diastolic CHF are typically dependent on preload to maintain adequate cardiac output. Although hypervolemic patients generally benefit from careful intravascular volume reduction, this must be accomplished gradually with frequent reassessment of treatment goals. Maintaining synchronous atrial contraction (or at least ventricular rate response control) helps to maintain adequate LV filling during the latter phase of diastole and is therefore a paramount goal in the management of CHF from diastolic dysfunction. Treatment of predisposing conditions to impaired diastolic function, such as myocardial ischemia and poorly controlled systemic hypertension, are fundamental to the overall pharmacotherapeutic strategy of this complex form of CHF.

TARGETING VASCULAR DYSFUNCTION IN CHF

Vascular dysfunction is an established component of the CHF syndrome associated with poorer clinical outcome and has evolved into a novel pharmacotherapeutic target (Figure 28–7). Elevated levels of oxidant, nitrosative, and other forms of inflammatory stress observed in patients with CHF may impair vascular reactivity by disruption of cell signaling pathways that lead to vasodilation.
Preserving normal vascular reactivity is a target of evolving priority in the treatment of patients with chronic CHF. Increased levels of reactive oxygen species (ROS, e.g., superoxide [O$_2^-$] and hydrogen peroxide [H$_2$O$_2$]) that are generated in endothelial cells (EC) and vascular smooth muscle cells (VSMC) impair key signaling pathways necessary for normal vascular function. For example, excessive aldosterone can cause a reduction in antioxidant enzyme activity in EC, such as glucose-6-phosphate dehydrogenase (G6PD), resulting in increased ROS formation. Likewise, increased xanthine oxidase (XO) activity, AT$_1$ receptor activation, and upregulation of signaling pathways associated with cholesterol metabolism favor ROS formation. In EC, elevated levels of ROS impair vascular reactivity, in part, by decreasing endothelial nitric oxide synthase (eNOS) activity and increasing peroxynitrite (ONOO$^-$) formation (which will decrease bioavailable NO). In VSMC, oxidant stress decreases NO levels and impairs sensitivity of soluble guanylyl cyclase (sGC) to NO, reducing cyclic GMP-dependent VSMC relaxation.

Mineralocorticoid (MR)-receptor antagonists, XO inhibitors (XO-I), HMG-CoA-reductase inhibitors (statin), AT$_1$ receptor blockers (ARBs), and angiotensin-converting enzyme inhibitors (ACE-I) block various cellular
reactions associated with elevated levels of ROS and impaired vascular reactivity. The BAY compounds (e.g., BAY 58-2667; figure inset), are a novel group of direct sGC activators that increase enzyme activity despite oxidant stress-induced sGC modifications that convert the enzyme to an NO-insensitive state.

**Xanthine Oxidase and Vascular Dysfunction.** Xanthine oxidase (XO) is necessary for normal purine metabolism and catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid in a reaction that generates superoxide. Elevated levels of uric acid are associated with clinically evident CHF. Epidemiologic data support a positive, graded association between impaired exercise capacity and circulating uric acid levels. The myocardium and vascular endothelial cells contain high concentrations of XO. This lead to the hypothesis that increased XO-generated superoxide impairs vascular reactivity in CHF patients.

Allopurinol (300 mg/day), an XO inhibitor, effectively decreases generation of free oxygen radicals and improves peripheral arterial vasodilation and blood flow in hyperuricemic patients with mild-to-moderate CHF from systolic dysfunction. Interestingly, probenecid, which decreases circulating urate levels by enhancing its elimination rather than by inhibiting XO activity, has not been shown to influence vascular reactivity. In patients with advanced CHF, allopurinol-induced serum uric acid level reduction (over 24 weeks) is associated with functional class improvement, but only in those with baseline serum uric acid levels >9.5 mg/dL.

**Statins and Vascular Dysfunction.** HMG-CoA (3-hydroxy-3-methyl-glutaryl–coenzyme A) reductase catalyzes the formation of L-mevalonic acid, a key biochemical precursor in the cholesterol synthesis pathway. Current evidence suggests a role of crosstalk between mevalonate metabolism and cell signaling pathways involved in inflammation and oxidant stress. Intermediate by-products of mevalonate metabolism (i.e., isopenylated proteins that upregulate activation of Rho, RAS, and other G proteins) are linked to impaired vascular function by increasing levels of oxidant stress and decreasing bioavailable NO levels. Statins inhibit these intermediary pathways and appear to restore endothelium-dependent and endothelium-independent vascular function. A large number of population studies have demonstrated a favorable effect of statin therapy on outcome in CHF.
**Direct Activators of Soluble Guanylyl Cyclase.** Soluble guanylyl cyclase (sGC) is an enzyme that catalyzes the conversion of GTP to cyclic GMP, a second messenger necessary for normal vascular smooth muscle cell relaxation. Under physiologic conditions, NO is the primary biologically active stimulator of sGC. Elevated levels of oxidant stress deactivate sGC through various molecular mechanisms. Organic nitrates, which promote sGC activation by increasing bioavailable NO levels, are subject to pharmacologic tolerance that complicates long-term drug use, dosing, and administration frequency (see Chapter 27). BAY compounds (e.g., BAY 58-2667 [cinaciguat]) activate sGC by an NO-independent mechanism, thereby promoting normal sGC function despite conditions of oxidant stress. In healthy humans, BAY compound administration has not been associated with severe side effects, but hypotension and headaches have been reported. The utility of BAY 58-2667 in the clinical management of patients with CHF is a topic of ongoing investigation.

**PROGRESSION OF DISEASE AND THERAPY IN CHF**

CHF is a chronic and usually progressive illness. Therapy also needs to be progressive in response to the disease:

**Stage 1. Patient at risk but asymptomatic:**
- Identify and reduce risk factors, educate patient and family
- Manage measurable risk factors; treat hypertension, diabetes, dyslipidemias

**Stage 2. With structural remodeling but few symptoms:**
- Reduce effects of AngII (ACEI or AT₁ blocker); add β₁ blocker as appropriate

**Stage 3. Structural disease, symptoms of failure:**
- Add ACEI or AT₁ blocker and β₁ blocker
- Reduce dietary Na⁺ intake; add diuretics, digoxin
- Treat bundle-branch block (resynchronize), if needed
- Revascularize, replace mitral valve, as appropriate
- Add aldosterone antagonist

**Stage 4. Symptoms refractory to treatment:**
• Use inotropic agents
• Employ surgical interventions (ventricular assist device; heart transplant)

A few new treatments are advancing through clinical trials. The hormone relaxin, which acts via four GPCRs, has a complex physiology but appears to be useful in heart failure. In the near future, we may have treatments that correct some of the molecular contributors of heart failure, such as a SERCA2 transgene that enhances uptake, storage, and release of Ca\(^{2+}\) in cardiac myocytes (see Figure 28–5).
Cardiac cells undergo depolarization and repolarization to form cardiac action potentials ~60 times/min. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins now have been identified.

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. In some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically against those mechanisms. In other cases, mechanisms can be only inferred, and the choice of drugs is based largely on the results of prior experience. Anti-arrhythmic drug therapy can have 2 goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, anti-arrhythmic drugs not only help to control arrhythmias but also can cause them, especially during long-term therapy. Thus, prescribing anti-arrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise diagnosis of the type of arrhythmia be made, and that the risks of drug therapy can be minimized.

PRINCIPLES OF CARDIAC ELECTROPHYSIOLOGY

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. Most anti-arrhythmic drugs affect more than one ion current, and many exert ancillary effects such as modification of cardiac contractility or autonomic nervous system function. Thus, anti-arrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients.

THE CARDIAC CELL AT REST: A $K^+$-PERMEABLE MEMBRANE
The normal cardiac cell at rest maintains a transmembrane potential ~80-90 mV negative to the exterior; this gradient is established by pumps, especially the Na\(^+\), K\(^+\)-ATPase, and fixed anionic charges within cells. There are both an electrical and a concentration gradient that would move Na\(^+\) ions into resting cells (Figure 29–1). However, Na\(^+\) channels, which allow Na\(^+\) to move along this gradient, are closed at negative transmembrane potentials, so Na\(^+\) does not enter normal resting cardiac cells. In contrast, a specific type of K\(^+\) channel protein (the inward rectifier channel) is in an open conformation at negative potentials. Hence, K\(^+\) can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients.
**Figure 29–1** Electrical and chemical gradients for K⁺ and Na⁺ in a resting cardiac cell. Inward rectifier K⁺ channels are open (left), allowing K⁺ ions to move across the membrane and the transmembrane potential to approach $E_K$. In contrast, Na⁺ does not enter the cell despite a large net driving force because Na⁺ channel proteins are in the closed conformation (right) in resting cells.

For each individual ion, there is an equilibrium potential $E_x$ at which there is no net driving force for the ion to move across the membrane. $E_x$ can be calculated using the Nernst equation:

$$E_x = -(RT/FZ_x) \ln([x]/[x]_0)$$

where $Z_x$ is the valence of the ion, $T$ is the absolute temperature, $R$ is the gas constant, $F$ is Faraday’s constant, $[x]_0$ is the extracellular concentration of the ion, and $[x]_i$ is the intracellular concentration. For K⁺, $[K]_o = 4$ mM and $[K]_i = 140$ mM, the calculated K⁺ equilibrium potential $E_K$ is $-94$ mV. There is thus no net force driving K⁺ ions into or out of a cell when the transmembrane potential is $-94$ mV, close to the resting potential. Thus, at rest, the normal cardiac cell is permeable to K⁺ (because inward rectifier channels are open) and $[K]_o$ is the major determinant of resting potential. If $[K]_o$ is elevated to 10 mM, as might occur in diseases such as renal failure or myocardial ischemia, the calculated $E_K$ rises to $-70$ mV.

**THE CARDIAC ACTION POTENTIAL**

Na⁺ channels have a life cycle of openings and closings that help to regulate membrane excitability (Figure 29–2). To initiate an action potential, a cardiac myocyte at rest is depolarized above a threshold potential, usually via gap junctions by a neighboring myocyte. Upon membrane depolarization, Na⁺ channel proteins change from the “closed” (resting) state to the “open” (conducting) state, allowing up to $10^7$ Na⁺ ions/sec to enter each cell and moving the transmembrane potential toward $E_{Na}$ (+65 mV). This surge of Na⁺ ions lasts only about a millisecond, after which the Na⁺ channel protein rapidly moves to an “inactivated,” nonconducting state. The maximum
upstroke slope of phase 0 (dV/dt_{max}, or V_{max}) of the action potential (Figure 29–3) is largely governed by Na^+ current and plays a role in the conduction velocity of a propagating action potential. Under normal conditions, Na^+ channels, once inactivated, cannot reopen until they reassume the closed conformation.

**Figure 29–2** *Life cycle of a voltage-sensitive channel.* Voltage-dependent conformational changes determine current flow through Na^+ channels. At hyperpolarized potentials, the channel is in a closed conformation (C) and no current flows. As depolarization begins, the pore opens (O), allowing conduction. As depolarization is maintained, a nearby region of a channel subunit moves to block current flow, putting the channel into an inactivated, nonconducting state (I). Restoration of the normal resting E_m restores the conformation to the closed state (C). See Figure 20–2 for structural details.
Figure 29–3 The relationship between an action potential from the conducting system and the currents that generate it. The current magnitudes are not to scale; the Na⁺ current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca²⁺ current, transient outward current (I_{TO1} and I_{TO2}), and delayed rectifier (I_K) have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-AP (4-aminopyridine) is a widely used in vitro blocker of K⁺ channels. I_{TO2} may be a Cl⁻ current in some species. Components of I_K have been separated on the basis of how rapidly they activate: slowly (I_{Ks}), rapidly (I_{Kr}), or ultra-rapidly (I_{Kur}). The voltage-activated, time-independent current may be carried by Cl⁻ (I_{Cl}) or K⁺ (I_{KP}, p for plateau). The genes encoding the major pore-forming proteins have been cloned for most of the channels shown here and are included in the right-hand column. The right-hand column lists the primary genes coding for the various ion channels and transporters.

A small population of Na⁺ channels may continue to open during the action potential.

potential plateau in some cells, providing further inward current. Certain mutations in the cardiac isoform of the Na\(^+\) channel can further increase the number of channels that do not properly inactivate, thereby prolonging the action potential, and cause a form of the congenital long QT syndrome. In general, however, as the cell membrane repolarizes, the negative membrane potential moves Na\(^+\) channel proteins from inactivated to “closed” conformations. The relationship between Na\(^+\) channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells.

The changes in transmembrane potential generated by the inward Na\(^+\) current produce a series of openings (and in some cases subsequent inactivation) of other channels (see Figure 29–3). For example, when a cell is depolarized by the Na\(^+\) current, “transient outward” K\(^+\) channels quickly enter an open, or conducting, state; because the transmembrane potential at the end of phase 0 is positive to \(E_K\), the opening of transient outward channels results in an outward, or repolarizing, K\(^+\) current (termed \(I_{\text{T0}}\)), which contributes to the phase 1 “notch” seen in action potentials from these tissues. Transient outward K\(^+\) channels, like Na\(^+\) channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through Ca\(^{2+}\) channels, are balanced by outward, repolarizing currents primarily through K\(^+\) (“delayed-rectifier”) channels. Delayed-rectifier currents (collectively termed \(I_K\)) increase with time, whereas Ca\(^{2+}\) currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na\(^+\) channel opening. Mutations in the genes encoding repolarizing K\(^+\) channels are responsible for the most common forms of the congenital long QT syndrome.

**ACTION POTENTIAL HETEROGENEITY IN THE HEART.** The general description of the action potential and the currents that underlie it must be modified for certain cell types, primarily due to variability in the expression of ion channels and electrogentic ion transport pumps. In the ventricle, action potential duration (APD) and shape vary across the wall of each chamber, as well as apico-basally (Figure 29–4). Atrial cells have short action potentials, probably because \(I_{\text{T0}}\) is larger, and an additional repolarizing K\(^+\) current, activated by the neurotransmitter acetylcholine, is present. As a result, vagal stimulation further shortens atrial action potentials. Cells of the sinus and atrioventricular (AV) nodes lack substantial Na\(^+\) currents. In addition, these cells,
as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4 depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart.

**Figure 29–4 Normal impulse propagation.** A schematic of the human heart with example action potentials from different regions of the heart (top) for a normal beat and their corresponding contributions to the macroscopic ECG (bottom). AV, atrioventricular; LV, left ventricle; RV, right ventricle; SA, sinoatrial. (Used with permission from The Am Physiol Soc. Nerbonne JM, Kass RS. *Physiol Rev*, 2005;85:1205-1253.)

One of the pacemaking currents responsible for this automaticity is generated via specialized K+ channels, the hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels that are permeable to both potassium and sodium. Another mechanism responsible for automaticity is the repetitive spontaneous Ca^{2+} release from the sarcoplasmic reticulum (SR). The rise in cytosolic Ca^{2+} causes
membrane depolarizations when \( \text{Ca}^{2+} \) is extruded from the cell via the electrogenic Na-Ca exchanger (NCX). In addition, sinus node cells lack *inward rectifier K\(^+\) currents* that are primarily responsible for protecting working myocardium against spontaneous membrane depolarizations.

**MAINTENANCE OF INTRACELLULAR ION HOMEOSTASIS**

With each action potential, the cell interior gains Na\(^+\) ions and loses K\(^+\) ions. The Na\(^+\), K\(^+\)-ATPase (Na\(^+\) pump) is activated in most cells to maintain intracellular homeostasis, extruding 3 Na\(^+\) ions for every 2 K\(^+\) ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself generates a net outward (repolarizing) current.

Normally, basal intracellular Ca\(^{2+}\) is maintained at very low levels (<100 nM). In cardiac myocytes, the entry of Ca\(^{2+}\) during each action potential through L-type Ca\(^{2+}\) channels is a signal to the SR to release its Ca\(^{2+}\) stores. The efflux of Ca\(^{2+}\) from the SR occurs through ryanodine-receptor (RyR2) Ca\(^{2+}\) release channels, and the resulting increase in intracellular Ca\(^{2+}\) subsequently triggers Ca\(^{2+}\) dependent contractile processes (= excitation-contraction coupling). Removal of intracellular Ca\(^{2+}\) occurs by both Ca\(^{2+}\)-ATPase (which moves Ca\(^{2+}\) ions back into the SR) and NCX, which exchanges 3 Na\(^+\) ions from the exterior for each Ca\(^{2+}\) ion extruded (*see Figure 28–5*). Abnormal regulation of intracellular Ca\(^{2+}\) is increasingly well described in heart failure and contributes to arrhythmias in this setting. Furthermore, mutations that disrupt the normal activity of the RyR2 channels and the cardiac isoform of calsequestrin have been linked to catecholaminergic polymorphic ventricular tachycardia (CPVT), thereby demonstrating a direct link between spontaneous SR Ca\(^{2+}\) release and cardiac arrhythmias.

**IMPULSE PROPAGATION AND THE ELECTROCARDIOGRAM**

Normal cardiac impulses originate in the sinus node. Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface electrocardiogram (ECG; *see Figure 29–4*). Propagation slows
markedly through the AV node, where the inward current (through Ca\textsuperscript{2+} channels) is much smaller than the Na\textsuperscript{+} current in atria, ventricles, or the subendocardial conducting system. This conduction delay allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output. Once impulses exit the AV node, they enter the conducting system, where Na\textsuperscript{+} currents are larger than elsewhere and propagation is correspondingly faster, up to 0.75 m/s longitudinally. Activation spreads from the His–Purkinje system on the endocardium of the ventricles throughout the rest of the ventricles, stimulating coordinated ventricular contraction. This electrical activation manifests itself as the QRS complex on the ECG. The T wave of the ECG represents ventricular repolarization.

The ECG can be used as a rough guide to some cellular properties of cardiac tissue:

- Heart rate reflects sinus node automaticity.
- PR-interval duration reflects AV nodal conduction time.
- QRS duration reflects conduction time in the ventricle.
- The QT interval is a measure of ventricular APD.

**REFRACTORINESS AND CONDUCTION FAILURE**

If a single action potential is restimulated very early during the plateau, no Na\textsuperscript{+} channels are available to open, no inward current results, and no action potential is generated: the cell is termed refractory (Figure 29–5). Conversely, if a stimulus occurs after the cell has repolarized completely, Na\textsuperscript{+} channels have recovered, and a normal Na\textsuperscript{+} channel–dependent upstroke results (Figure 29–5A). When a stimulus occurs during phase 3 of the action potential, the magnitude of the resultant Na\textsuperscript{+} current depends on the number of Na\textsuperscript{+} channels that have recovered (Figure 29–5B). The recovery from inactivation is faster at more hyperpolarized membrane potentials. Thus, refractoriness is determined by the voltage-dependent recovery
of Na⁺ channels from inactivation. The *effective refractory period* (ERP) is the longest interval at which a premature stimulus fails to generate a propagated response.

**Figure 29–5** Qualitative differences in responses of nodal and conducting tissues to premature stimuli. **A.** With a very early premature stimulus (*black arrow*) in ventricular myocardium, all Na⁺ channels still are in the inactivated state, and no upstroke results. As the action potential repolarizes, Na⁺ channels recover from the inactivated to the resting state, from which opening can occur. The phase 0 upstroke slope of the premature action potentials (*purple*) are greater with later stimuli because recovery from inactivation is voltage dependent. **B.** The relationship between transmembrane potential and degree of recovery of Na⁺ channels from inactivation. The *dotted line* indicates 25% recovery. Most Na⁺ channel–blocking drugs shift this relationship to the left. **C.** In nodal tissues, premature stimuli delivered even after full repolarization of the action potential are depressed; recovery from inactivation is time dependent.

The situation is different in tissue whose depolarization is largely controlled by Ca²⁺ channel current such as the AV node. As Ca²⁺ channels have a slower
recovery from inactivation, these tissues often are referred to as slow response, in contrast to fast response in the remaining cardiac tissues (Figure 29–5C). Even after a Ca$^{2+}$ channel–dependent action potential has repolarized to its initial resting potential, not all Ca$^{2+}$ channels are available for re-excitation. Therefore, an extra stimulus applied shortly after repolarization is complete and generates a reduced Ca$^{2+}$ current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca$^{2+}$ current and faster propagation. Thus, in Ca$^{2+}$ channel–dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is prolonged and propagation occurs slowly. Slow conduction in the heart, a critical factor in the genesis of reentrant arrhythmias (see next section), also can occur when Na$^{+}$ currents are depressed by disease or membrane depolarization (e.g., elevated [K]o), resulting in decreased steady-state Na$^{+}$ channel availability (see Figure 29–5B).

MECHANISMS OF CARDIAC ARRHYTHMIAS

When the normal sequence of impulse initiation and propagation is perturbed, an arrhythmia occurs. Failure of impulse initiation, in the sinus node, may result in slow heart rates (bradyarrhythmias), whereas failure in the normal propagation of action potentials from atrium to ventricle results in dropped beats (commonly referred to as heart block) that usually reflect an abnormality in either the AV node or the His–Purkinje system. These abnormalities may be caused by drugs (Table 29–1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

</table>
Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with anti-arrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and reentry. These often are interrelated mechanisms, as the first 2 often serve to initiate reentry.

**ENHANCED AUTOMATICITY.** Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His–Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and accelerate pacemaker rate; acetylcholine reduces pacemaker rate both by decreasing phase 4 slope and through hyperpolarization (making the maximum diastolic potential more negative). Automatic behavior may also occur in sites that ordinarily lack
spontaneous pacemaker activity; e.g., depolarization of ventricular cells (e.g., by ischemia) may produce “abnormal” automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, more complex arrhythmias may result from the induction of functional reentry.

AFTERDEPOLARIZATIONS AND TRIGGERED AUTOMATICITY. Under some pathophysiologic conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 29–6). If this abnormal depolarization reaches threshold, it may give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and are termed triggered rhythms.

![Figure 29–6](image-url) Afterdepolarizations and triggered activity. A. Delayed afterdepolarization (DAD) arising after full repolarization. DADs are typically caused by spontaneous Ca\(^{2+}\) release from the sarcoplasmic reticulum under conditions of Ca\(^{2+}\) overload. The extra cytosolic Ca\(^{2+}\) is removed from the cytosol by the electrogenic Na-Ca exchanger (NCX), which produces Na\(^{+}\) influx and causes a cell membrane depolarization in the form of a DAD. A DAD that reaches threshold results in a triggered upstroke (black arrow, right). B. Early afterdepolarization (EAD) interrupting phase 3 repolarization. Multiple ion channels and transporters can contribute to EADs (e.g., Na\(^{+}\) channel, L-type Ca\(^{2+}\) channel, NCX). Under some conditions, triggered beat(s) can arise from an EAD (black arrow, right).

In the first form of triggered rhythm, under conditions of intracellular or SR Ca\(^{2+}\) overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, heart failure), a normal action potential may be followed by a delayed afterdepolarization (DAD; Figure 29–6A). If this afterdepolarization
reaches threshold, a secondary triggered beat or beats may occur. In the second
type of triggered activity, the key abnormality is marked prolongation of the
cardiac action potential. When this occurs, phase 3 repolarization may be
interrupted by an early afterdepolarization (EAD; Figure 29–6B). EAD-
mediated triggering in vitro and clinical arrhythmias are most common when the
underlying heart rate is slow, extracellular K⁺ is low, and certain drugs that
prolong APD are present. EAD-related triggered upstrokes probably reflect
inward current through Na⁺ or Ca²⁺ channels. EADs are induced much more
readily in Purkinje cells than in epicardial or endocardial cells. When cardiac
repolarization is markedly prolonged, polymorphous ventricular tachycardia with
a long QT interval, known as the torsade de pointes syndrome, may occur. This
arrhythmia is thought to be caused by EADs, which trigger functional reentry
owing to heterogeneity of APDs across the ventricular wall. Congenital long QT
syndrome, a disease in which torsade de pointes is common, can most often be
caused by mutations in the genes encoding the Na⁺ channels or the channels
underlying the repolarizing currents $I_{Kr}$ and $I_{Ks}$.

**REENTRY.** Reentry occurs when a cardiac impulse travels in a path such as to
return to its original site and reactivate the original site and self-perpetuate rapid
activation independent of the normal sinus node conduction. This abnormal
activation path (or reentrant circuit) requires an isotropic conduction slowing (or
failure) due to either an anatomic or functional barrier.

**ANATOMICALLY DEFINED REENTRY.** Reentry can occur when impulses
propagate by more than 1 pathway between 2 points in the heart, and those
pathways have heterogeneous electrophysiologic properties. Patients with
Wolff–Parkinson–White (WPW) syndrome have accessory connections between
the atrium and ventricle (Figure 29–7). With each sinus node depolarization,
impulses can excite the ventricle via the normal structures (AV node) or the
accessory pathway. However, the electrophysiologic properties of the AV node
and accessory pathways are different: Accessory pathways usually consist of
nonnodal tissue and consequently vastly differ in refractoriness with the AV
node. Thus, with a premature atrial beat, conduction may fail in the accessory
pathway but continue, albeit slowly, in the AV node and then through the His–
Purkinje system; there, the propagating impulse may encounter the ventricular
end of the accessory pathway when it is no longer refractory. The likelihood that
the accessory pathway is no longer refractory increases as AV nodal conduction
slows. When the impulse reenters the atrium, it then can reenter the ventricle via the AV node, reenter the atrium via the accessory pathway, and so on. Reentry of this type, referred to as *AV reentrant tachycardia*, is determined by:

![Diagram of AV reentrant tachycardia](image)

**Figure 29–7 Atrioventricular reentrant tachycardia in the Wolff–Parkinson–White syndrome.** In these patients, an accessory atrioventricular (AV) connection is present (light blue). A premature atrial impulse blocks in the accessory pathway (1) and propagates slowly through the AV node and conducting system. On reaching the accessory pathway (by now no longer refractory), the impulse reenters the atrium (2), where it then can reenter the ventricle via the AV node and become self-sustaining (see Figure 29–9C). AV nodal blocking drugs readily terminate this tachycardia. Recurrences can be prevented by drugs that prevent atrial premature beats, by drugs that alter the electrophysiologic characteristics of tissue in the circuit (e.g., they prolong AV nodal refractoriness), and by nonpharmacologic techniques that section the accessory pathway.

- The presence of an anatomically defined circuit
- Heterogeneity in refractoriness among regions in the circuit
- Slow conduction in one part of the circuit

Similar “anatomically defined” reentry commonly occurs in the region of the AV node (*AV nodal reentrant tachycardia*) and in the atrium (*atrial flutter*). The term *paroxysmal supraventricular tachycardia* (PSVT) includes both AV reentry and AV nodal reentry, which share many clinical features. It now is sometimes possible to identify and ablate critical segments of reentrant pathway (or automatic foci), thus curing the patient and obviating the need for long-term drug therapy.
FUNCTIONALLY DEFINED REENTRY. Reentry also may occur in the absence of a distinct, anatomically defined pathway (Figure 29–8). If ischemia or other electrophysiologic perturbations result in an area of sufficiently slow conduction in the ventricle, the impulses exiting from that area find the rest of the myocardium re-excitiable and reentry may ensue. Atrial or ventricular fibrillation (VF) is an extreme example of “functionally defined” (or “leading circle”) reentry. Cells are re-excited as soon as they are repolarized sufficiently to allow enough Na\(^+\) channels to recover from inactivation. In this setting, neither organized activation patterns nor coordinated contractile activity is present.

![Diagram of two types of reentry](image)

**Figure 29–8** Two types of reentry. The border of a propagating wavefront is denoted by a heavy black arrowhead. In anatomically defined reentry (top), a fixed pathway is present (e.g., Figure 29–7). The black area denotes tissue in the reentrant circuit that is completely refractory because of the recent passage of the propagating wavefront; the gray area denotes tissue in which depressed upstrokes can be elicited (see Figure 29–5A), and the red area represents tissue in which restimulation would result in action potentials with normal upstrokes.
The red area is termed an *excitable gap*. In functionally defined, or “leading circle,” reentry (*bottom*), there is no anatomic pathway and no excitable gap. Rather, the circulating wavefront creates an area of inexcitable tissue at its core. In this type of reentry, the circuit does not necessarily remain in the same anatomic position during consecutive beats, and multiple such “rotors” may be present.

**COMMON ARRHYTHMIAS AND THEIR MECHANISMS**

Table 29–2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence.

### MECHANISMS OF ANTI-ARRHYTHMIC DRUG ACTION

Anti-arrhythmic drugs almost invariably have multiple effects in patients, and their effects on arrhythmias can be complex. A drug can modulate additional targets in addition to its primary mode of action. A single arrhythmia may result from multiple underlying mechanisms. Drugs may be anti-arrhythmic by suppressing the initiating mechanism or by altering the reentrant circuit. In some cases, drugs may suppress the initiator but nonetheless promote reentry.

Drugs may slow automatic rhythms by altering any of the 4
determinants of spontaneous pacemaker discharge (Figure 29–9):

**Figure 29–9** Four ways to reduce the rate of spontaneous discharge. The blue horizontal line represents threshold potential.

- Decrease phase 4 slope
- Increase threshold potential
- Increase maximum diastolic potential
- Increase APD

*Adenosine* and *acetylcholine* may increase maximum diastolic potential, and
β-receptor antagonists may decrease phase 4 slope. Blockade of Na⁺ or Ca²⁺ channels usually results in altered threshold, and blockade of cardiac K⁺ channels prolongs the action potential.

Anti-arrhythmic drugs may block arrhythmias owing to DADs or EADs by 2 major mechanisms:

- Inhibition of the development of afterdepolarizations
- Interference with the inward current (usually through Na⁺ or Ca²⁺ channels), which is responsible for the upstroke

Thus, arrhythmias owing to digitalis-induced DADs may be inhibited by verapamil (which blocks the development of DAD by reducing Ca²⁺ influx and subsequent storage/release) or by quinidine (which blocks Na⁺ channels, thereby elevating the threshold required to produce the abnormal upstroke). Similarly, 2 approaches are used in arrhythmias related to EAD-triggered beats (see Tables 29–1 and 29–2). EADs can be inhibited by shortening APD; in practice, heart rate is accelerated by isoproterenol infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg²⁺, without normalizing repolarization in vitro or QT interval. In patients with a congenitally prolonged QT interval, torsade de pointes often occurs with adrenergic stress; therapy includes β-adrenergic blockade (which does not shorten the QT interval) as well as pacing.

In anatomically determined reentry, drugs may terminate the arrhythmia by blocking propagation of the action potential. In the example of the WPW-related arrhythmia, drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca²⁺ channel blockers, β-adrenergic receptor antagonists, or digitalis glycosides, are likely to be effective. Conversely, slowing conduction in functionally determined reentrant circuits may change the pathway without extinguishing the circuit. Slow conduction generally promotes the development of reentrant arrhythmias, whereas the most likely approach for terminating functionally determined reentry is prolongation of refractoriness. In atrial and ventricular myocytes, refractoriness can be prolonged by delaying the recovery of Na⁺ channels from inactivation. Drugs blocking Na⁺ channels generally shift the voltage dependence of recovery from block (see Figure 29–5B) and so prolong refractoriness (Figure 29–10). Drugs that increase APD without direct action on Na⁺ channels (e.g., by blocking delayed-rectifier currents) also will prolong refractoriness. In sinoatrial or AV nodal tissues, Ca²⁺ channel blockade
prolongs refractoriness.

Figure 29–10 Two ways to increase refractoriness. The black dot indicates the point at which a sufficient number of Na⁺ channels (an arbitrary 25%; see Figure 29–5B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na⁺ channels (A) shifts voltage dependence of recovery (Figure 29–5B) and delays the point at which 25% of channels have recovered (red diamond), prolonging refractoriness. If the drug also dissociates slowly from the channel (see Figure 29–11), refractoriness in fast-response tissues actually can extend beyond full repolarization (“postrepolarization refractoriness”). Drugs that prolong the action potential (B) also will extend the point at which an arbitrary percentage of Na⁺ channels have recovered from inactivation, even without directly interacting with Na⁺ channels. ERP, effective refractory period.
**Figure 29–11 Recovery from block of Na\(^+\) channels during diastole.** This recovery is the critical factor determining extent of steady-state Na\(^+\) channel block. Na\(^+\) channel blockers bind to (and block) Na\(^+\) channels in the open and/or inactivated states, resulting in phasic changes in the extent of block during the action potential. In the middle panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. Increasing heart rate, which results in relatively less time spent in the resting state, also increases the extent of block (right panel). (Modified from Roden DM, Echt DS, Lee JT, Murray KT. Clinical pharmacology of antiarrhythmic agents. In: Josephson ME, ed. Sudden Cardiac Death. London: Blackwell Scientific; 1993:182–185, with permission from Wiley-Blackwell Publishing.)

**STATE-DEPENDENT ION CHANNEL BLOCK**

A key concept is that ion channel–blocking drugs bind to specific sites on the ion channel proteins to modify function (e.g., decrease current) and that the affinity of the ion channel protein for the drug on its target site will vary as the ion channel protein shuttles among functional states (see Figure 29–2). Most useful agents of this type block open and/or inactivated Na\(^+\) channels and have very little affinity for channels in the resting state. Thus, with each action potential, drugs bind to Na\(^+\) channels and block them, and with each diastolic interval, drugs dissociate, and the block is released. When heart rate increases, the time available for dissociation decreases, and steady-state Na\(^+\) channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains
the finding that Na\(^+\) channel blockers depress Na\(^+\) current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open versus inactivated-state block also may be important in determining the effects of some drugs. Increased APD, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone.

The rate of recovery from block often is expressed as a time constant (\(\tau_{\text{recovery}}\), the time required for ~63% of an exponentially determined process to be complete). In the case of drugs such as lidocaine, \(\tau_{\text{recovery}}\) is so short (>>1 s) that recovery from block is very rapid, and substantial Na\(^+\) channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as flecainide have such long \(\tau_{\text{recovery}}\) values (>10 s) that roughly the same number of Na\(^+\) channels is blocked during systole and diastole. As a result, marked slowing of conduction occurs even in normal tissues at normal rates.

**CLASSIFYING ANTI-ARRHYTHMIC DRUGS**

To the extent that the clinical actions of drugs can be predicted, classifying drugs by their basic electrophysiologic properties is useful. However, differences in pharmacologic effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 29–3). Another way of approaching therapy is to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiologic mechanism most likely to terminate or prevent the arrhythmia (see Table 29–2).

**Table 29–3**

**Major Electrophysiologic Actions of Anti-Arrhythmic Drugs**
**Na⁺ Channel Block.** The extent of Na⁺ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine $\tau_{\text{recovery}}$ (Figure 29–11). When Na⁺ channels are blocked, excitability is decreased (i.e., greater membrane depolarization is required to bring Na⁺ channels from the resting to open state). This change in the threshold of excitability probably contributes to the clinical findings that Na⁺ channel blockers tend to increase both pacing threshold and the energy required for defibrillation.

These deleterious effects may be important if anti-arrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na⁺ channel block
decreases conduction velocity in nonnodal tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with $\tau_{\text{recovery}}$ values greater than 10 s (e.g., flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca$^{2+}$ channel block (see below) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, quinidine actually tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration either is unaffected or shortened by Na$^+$ channel block; some Na$^+$ channel–blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K$^+$ channel block (see Table 29–3).

Na$^+$ channel block decreases automaticity (Figure 29–9B) and can inhibit triggered activity arising from DADs or EADs. Many Na$^+$ channel blockers also decrease phase 4 slope (Figure 29–9A). In anatomically defined reentry, Na$^+$ channel blockers may decrease conduction sufficiently to extinguish the propagating reentrant wavefront. However, conduction slowing owing to Na$^+$ channel block may exacerbate reentry. Thus, whether a given drug exacerbates or suppresses reentrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular reentrant circuit. Lidocaine and mexiletine have short $\tau_{\text{recovery}}$ values and are not useful in atrial fibrillation or flutter, whereas quinidine, flecainide, propafenone, and similar agents are effective in some patients. Many of these agents owe part of their anti-arrhythmic activity to blockade of K$^+$ channels.

**Late Na$^+$ Channel Current Block.** The long QT syndrome variant 3 (LQT3) is characterized by late inward Na$^+$ current caused by defects in the inactivation of the cardiac isoform of the Na$^+$ channel. This late current prolongs the APD and predisposes to arrhythmia. Many drugs with local anesthetic effects, including mexiletine, preferentially block this late current and can be used to successfully treat LQT3 patients.

**Na$^+$ Channel–Blocker Toxicity.** Conduction slowing in potential reentrant circuits can account for toxicity of drugs that block the Na$^+$ channel (see Table 29–1). For example, Na$^+$ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV nodal function permits a greater number of
impulses to penetrate the ventricle, and heart rate actually may increase (see Figure 29–9). Thus, atrial flutter rate may drop from 300/min, with 2:1 or 4:1 AV conduction (i.e., a heart rate of 150 or 75 beats/min), to 220/min, but with 1:1 transmission to the ventricle (i.e., a heart rate of 220 beats/min), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with quinidine because the drug also increases AV nodal conduction through its vagolytic properties; flecainide and propafenone also have been implicated. Therapy with Na\(^+\) channel blockers in patients with reentrant ventricular tachycardia after a myocardial infarction (MI) can increase the frequency and severity of arrhythmic episodes. Slowed conduction allows the reentrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be very difficult to manage, and deaths owing to intractable drug-induced ventricular tachycardia have been reported. In this setting, Na\(^+\) infusion may be beneficial.

**Action Potential Prolongation.** Most drugs that prolong the action potential do so by blocking K\(^+\) channels, although enhanced inward Na\(^+\) current also can cause prolongation. Enhanced inward current may underlie QT prolongation (and arrhythmia suppression) by **ibutilide**. Block of cardiac K\(^+\) channels increases APD and reduces normal automaticity (Figure 29–9D). Increased APD, seen as an increase in QT interval, increases refractoriness (see Figure 29–10) and therefore should be an effective way of treating reentry. Experimentally, K\(^+\) channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of VF owing to acute ischemia, and increased contractility. Most K\(^+\) channel–blocking drugs also interact with β adrenergic receptors (sotalol) or other channels (e.g., amiodarone, quinidine) (see Table 29–3). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na\(^+\) channel–blocking properties in both atrial and ventricular arrhythmias. “Pure” action potential–prolonging drugs (e.g., **dofetilide**, **ibutilide**) also are available.

**Toxicity of Drugs That Prolong QT Interval.** Most of these agents disproportionately prolong cardiac action potentials when underlying heart rate is slow and can cause **torsade de pointes** (see Table 29–1). While this effect usually is seen with QT-prolonging anti-arrhythmic drugs, it can occur more rarely with drugs that are used for noncardiac indications. For such agents, the risk of **torsade de pointes** may become apparent only after widespread use
postmarketing. Sex hormones modify cardiac ion channels and may account for the clinically observed increased incidence of drug-induced torsade de pointes in women.

Ca\(^{2+}\) Channel Block. The major electrophysiologic effects resulting from block of cardiac Ca\(^{2+}\) channels are in nodal tissues. Dihydropyridines, such as nifedipine, which are used commonly in angina and hypertension, preferentially block Ca\(^{2+}\) channels in vascular smooth muscle; their cardiac electrophysiologic effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, diltiazem, and bepridil block Ca\(^{2+}\) channels in cardiac cells at clinically used doses. These drugs generally slow heart rate (Figure 29–9A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction, as well as increased AV nodal refractoriness. These latter effects form the basis of the anti-arrhythmic actions of Ca\(^{2+}\) channel blockers in reentrant arrhythmias whose circuit involves the AV node, such as AV reentrant tachycardia (see Figure 29–7).

Another important indication for anti-arrhythmic therapy is to reduce ventricular rate in atrial flutter or fibrillation. Rare forms of ventricular tachycardia appear to be DAD-mediated and respond to verapamil. Parenteral verapamil and diltiazem are approved for rapid conversion of PSVTs to sinus rhythm and for temporary control of rapid ventricular rate in atrial flutter or fibrillation. Oral verapamil may be used in conjunction with digoxin to control ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β adrenergic receptor antagonists, Ca\(^{2+}\) channel blockers have not been shown to reduce mortality after MI.

Verapamil and Diltiazem. The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This is a particular problem if the drugs are used mistakenly in patients with ventricular tachycardia (in whom Ca\(^{2+}\) channel blockers usually are not effective) misdiagnosed as AV nodal reentrant tachycardia. Hypotension also is frequent in patients receiving other vasodilators, including quinidine, and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block occurs, especially in patients also receiving β blockers. With oral therapy, these adverse effects tend to be less severe.
Verapamil (CALAN, ISOPTIN, VERELAN, COVERA-HS, and others) is supplied as a racemate. L-Verapamil is a more potent calcium channel blocker than is D-verapamil. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally. Diltiazem (CARDIZEM, TIAZAC, DILACOR XR, and others) also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca\(^{2+}\) channel–blocking actions. Adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation. Constipation can occur with oral verapamil.

**Blockade of \(\beta\) Adrenergic Receptors.** \(\beta\) Adrenergic stimulation increases the magnitude of the Ca\(^{2+}\) current and slows its inactivation, increases the magnitude of repolarizing K\(^+\) and Cl\(^–\) currents, increases pacemaker current (thereby increasing sinus rate), increases the Ca\(^{2+}\) stored in the SR, and under pathophysiologic conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (e.g., acute MI, resuscitation after cardiac arrest) lower serum K\(^+\), especially in patients receiving chronic diuretic therapy. \(\beta\) Adrenergic receptor antagonists inhibit these effects and can be anti-arrhythmic by reducing heart rate, decreasing intracellular Ca\(^{2+}\) overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by \(\alpha_2\) adrenergic receptors and is blocked by “noncardioselective” antagonists such as propranolol (see Chapter 12). In acutely ischemic tissue, blockers increase the energy required to fibrillate the heart, an anti-arrhythmic action. These effects may contribute to the reduced mortality observed in trials of chronic therapy with \(\beta\) blockers after MI.

As with Ca\(^{2+}\) channel blockers and digitalis, \(\beta\) blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence, they are useful in terminating reentrant arrhythmias that involve the AV
node and in controlling ventricular response in atrial fibrillation or flutter. In many patients with the congenital long QT syndrome and many other patients, arrhythmias are triggered by physical or emotional stress; β blockers may be useful in these cases. β Adrenergic receptor antagonists also reportedly are effective in controlling arrhythmias Na+ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na+ channel block. Adverse effects of β blockade include fatigue, bronchospasm, hypotension, impotence, depression, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (see Chapter 12). In patients with arrhythmias owing to excess sympathetic stimulation (e.g., pheochromocytoma, clonidine withdrawal), β blockers can result in unopposed α adrenergic stimulation, with resulting severe hypertension and/or α adrenergic–mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β adrenergic antagonists or with a drug such as labetalol that combines α and β blocking properties. Abrupt discontinuation of chronic β blocker therapy can lead to “rebound” symptoms; thus, β receptor antagonists are tapered over 2 weeks.

Selected β Adrenergic Receptor Blockers. It is likely that most β adrenergic antagonists share anti-arrhythmic properties. Some, such as propranolol, also exert Na+ channel–blocking effects at high concentrations. Acebutolol is as effective as quinidine in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. Sotalol is more effective for many arrhythmias than other β blockers, probably because of its K+ channel–blocking actions. Esmolol is a β₁-selective agent that has a very short elimination \( t_{1/2} \). Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired.

**PRINCIPLES IN THE CLINICAL USE OF ANTI-ARRHYTHMIC DRUGS**

Drugs that modify cardiac electrophysiology often have a small therapeutic index. Moreover, anti-arrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacologic treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions, are indicated for some arrhythmias; in other cases,
no therapy is required, even though an arrhythmia is detected. The fundamental principles of therapeutics described here must be applied to optimize anti-arrhythmic therapy.

1. IDENTIFY AND REMOVE PRECIPITATING FACTORS

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs.

For example, theophylline can cause multifocal atrial tachycardia, while torsade de pointes can arise not only during therapy with action potential–prolonging anti-arrhythmics but also with other drugs not ordinarily classified as having effects on ion channels, including erythromycin (see Chapter 55); the antiprotozoal pentamidine (see Chapter 50); some antipsychotics, notably thioridazine (see Chapter 16); some analgesics, notably methadone and celecoxib; some antiemetics (e.g., droperidol, dolasetron); antihistamines such as diphenhydramine; azole antifungals such as voriconazole and fluconazole; bronchodilators such as albuterol, formoterol, and salmeterol; prednisone; cisapride; famotidine; tacrolimus; some selective serotonin reuptake inhibitors (including citalopram, fluoxetine, paroxetine sertraline, and venlafaxine); haloperidol; trazodone; some serotonin 5HT\textsubscript{1} agonists (e.g., sumatriptan, zolmitriptan); some antiretrovirals (e.g., efavirenz); most quinolone antibiotics (e.g., levofloxacin); tizanidine; and certain tricyclic antidepressants (see Chapter 15).

2. ESTABLISH THE GOALS OF TREATMENT

SOME ARRHYTHMIAS SHOULD NOT BE TREATED. The mere detection of an abnormality does not equate with the need for therapy. In the Cardiac Arrhythmia Suppression Trial (CAST), patients whose ventricular ectopic beats were suppressed by the potent Na\textsuperscript{+} channel blockers encainide (no longer marketed) or flecainide were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was 2- to 3-fold higher among patients treated with the drugs than those treated with placebo. This pivotal clinical trial reemphasizes the concept that therapy should be initiated only when a clear benefit to the patient can be identified. When symptoms are obviously
attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater. Among the anti-arrhythmic drugs discussed here, only β adrenergic blockers and, to a lesser extent, amiodarone have been shown to reduce mortality during long-term therapy.
