SYMPTOMS DUE TO ARRHYTHMIAS. If patients with an arrhythmia are asymptomatic, establishing any benefit from treatment will be difficult. Some patients may present with presyncope, syncope, or even cardiac arrest, which may be due to brady- or tachyarrhythmias. The sensation of irregular heartbeats (i.e., palpitations) can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as atrial fibrillation (which results in an irregular ventricular rate). Finally, patients may present with symptoms owing to decreased cardiac output. The most common symptom is breathlessness either at rest or on exertion. Rarely, sustained tachycardias may produce no “arrhythmia” symptoms (such as palpitations) but will depress contractile function; these patients may present with congestive heart failure that can be controlled by treating the arrhythmia.

CHOOSING AMONG THERAPEUTIC APPROACHES. In selecting therapy, establish clear therapeutic goals. For example, 3 options are available in patients with atrial fibrillation: (1) reduce the ventricular response using AV nodal blocking agents such as digitalis, verapamil, diltiazem, or β adrenergic antagonists (see Table 29–1); (2) restore and maintain normal rhythm using drugs such as quinidine, flecainide, or amiodarone; or (3) decide not to implement anti-arrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with atrial fibrillation also benefit from anticoagulation to reduce stroke incidence regardless of symptoms. Factors that contribute to choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the coexistence of conduction system disease, and the presence of noncardiac diseases (Table 29–4). In the rare patient with the WPW syndrome and atrial fibrillation, the ventricular response can be extremely rapid and can be accelerated paradoxically by AV nodal blocking drugs such as digitalis or Ca2+ channel blockers; deaths owing to drug therapy have been reported.
The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective. A marked decrease in the duration of paroxysms of atrial fibrillation may be sufficient to render a patient asymptomatic.

3. MINIMIZE RISKS

ANTI-ARRHYTHMIC DRUGS CAN CAUSE ARRHYTHMIAS. One risk of anti-arrhythmic therapy is the provoking of new arrhythmias, with potentially life-threatening consequences. Anti-arrhythmic drugs can provoke arrhythmias by different mechanisms (see Table 29–1). These drug-provoked arrhythmias must be recognized because further treatment with anti-arrhythmic drugs often
exacerbates the problem. Targeting therapies at underlying mechanisms of the arrhythmias may be required.

**MONITORING OF PLASMA CONCENTRATION.** Some adverse effects of anti-arrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving anti-arrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease.

**PATIENT-SPECIFIC CONTRAINdicATIONS.** Another way to minimize the adverse effects of anti-arrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during disopyramide therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 29–4.

4. **CONSIDER THE ELECTROPHYSIOLOGY OF THE HEART AS A “MOVING TARGET”**

Cardiac electrophysiology varies dynamically in response to external influences such as changing autonomic tone, myocardial ischemia, and myocardial stretch. For example, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca\(^{2+}\) concentrations, and repolarization, any one of which then may create arrhythmias or alter response to anti-arrhythmic therapy.

**ANTI-ARRHYTHMIC DRUGS**

Summaries of important electrophysiologic and pharmacokinetic
features of the drugs considered here are presented in Tables 29–3 and 29–5, respectively. Ca²⁺ channel blockers and β adrenergic antagonists are discussed in Chapters 12, 27, and 28. The drugs are presented in alphabetical order.

**ADENOSINE.** Adenosine (ADENOCARD, others) is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of reentrant supraventricular arrhythmias. Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of adenosine.

**Pharmacologic Effects.** The effects of adenosine are mediated by its interaction with specific GPCRs. Adenosine activates acetylcholine-sensitive K⁺ current in the atrium and sinus and AV nodes, resulting in shortening of APD, hyperpolarization, and slowing of normal automaticity (Figure 29–9C). Adenosine also inhibits the electrophysiologic effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca²⁺ currents, it can be anti-arrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation. Administration of an intravenous bolus of adenosine to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors; a continuous infusion can cause hypotension.

**Adverse Effects.** A major advantage of adenosine therapy is that adverse effects are short lived because the drug is transported into cells and deaminated so rapidly. Transient asystole is common but usually lasts less than 5 sec and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6-12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate bronchospasm or atrial fibrillation.

**Clinical Pharmacokinetics.** Adenosine is eliminated with a t½ of seconds by carrier-mediated uptake and subsequent metabolism by adenosine deaminase. Adenosine probably is the only drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in
elimination of the drug prior to its arrival at the heart. The effects of adenosine are potentiated in patients receiving *dipyridamole*, an adenosine uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines such as theophylline and caffeine block adenosine receptors; therefore, larger than usual doses are required to produce an anti-arrhythmic effect in patients who have consumed these agents in coffee and sodas or as therapy.

**AMIODARONE.** Amiodarone (*CORDARONE, PACERONE, others*) exerts myriad pharmacologic effects, none of which is clearly linked to its arrhythmia-suppressing properties. Amiodarone is a structural analog of thyroid hormone, and some of its anti-arrhythmic actions and its toxicity are due to interaction with thyroid hormone receptors.

Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or fibrillation resistant to other drugs. Oral amiodarone also is effective in maintaining sinus rhythm in patients with atrial fibrillation. An intravenous form is indicated for acute termination of ventricular tachycardia or fibrillation and is supplanting lidocaine as first-line therapy for out-of-hospital cardiac arrest. Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone now is used very widely in the treatment of common arrhythmias such as atrial fibrillation.

**Pharmacologic Effects.** Amiodarone blocks inactivated Na\(^+\) channels and has a relatively rapid rate of recovery (time constant ~1.6 s) from block. It also decreases Ca\(^{2+}\) current and transient outward delayed-rectifier and inward rectifier K\(^+\) currents and exerts a noncompetitive adrenergic blocking effect. Amiodarone potently inhibits abnormal automaticity and, in most tissues, prolongs APD. Amiodarone decreases conduction velocity by Na\(^+\) channel block and by a poorly understood effect on cell–cell coupling that may be especially important in diseased tissue. Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na\(^+\) channel block, delayed repolarization owing to K\(^+\) channel block, and inhibition of cell–cell coupling all may contribute to this effect.
Adverse Effects. Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of amiodarone. Although depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasionally during the loading phase, patients develop nausea, which responds to a decrease in daily dose.

Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose, suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/day or more, and recent pulmonary insults such as pneumonia appear to be risk factors. Serial chest X-rays or pulmonary function studies may detect early amiodarone toxicity; monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/day or less used in atrial fibrillation, pulmonary toxicity is unusual. Other adverse effects during long-term therapy include corneal microdeposits (which often are asymptomatic), hepatic dysfunction, neuromuscular symptoms (peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids. Dose reduction may be sufficient if the drug is deemed necessary and the adverse effect is not life-threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, torsade de pointes and other drug-induced tachyarrhythmias are unusual.

Clinical Pharmacokinetics. Amiodarone’s oral bioavailability is ~30%, which is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacologic effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacologic effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a $t_{1/2}$ of weeks to months. The mechanism whereby amiodarone and desethyl-amiodarone are eliminated is not well established.
A therapeutic plasma amiodarone concentration range of 0.5-2 µg/mL has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity. Because of amiodarone’s slow accumulation in tissue, a high-dose oral loading regimen (e.g., 800-1600 mg/day) usually is administered for several weeks before maintenance therapy is started. If the presenting arrhythmia is life-threatening, dosages of >300 mg/day normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of ≤200 mg/day are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation. Because of its very slow elimination, amiodarone is administered once daily, and omission of 1 or 2 doses during chronic therapy rarely results in recurrence of arrhythmia. Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potently inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4, CYP2C9, and P-glycoprotein (see Chapters 5 and 6). Dosages of warfarin, other anti-arrhythmics (e.g., flecainide, procainamide, quinidine), or digoxin usually require reduction during amiodarone therapy.

**DIGOXIN.** Digitalis glycosides exert positive inotropic effects and are used in heart failure (see Chapter 28). Their inotropic action results from increased intracellular Ca\(^{2+}\) (Figure 28–5), which also forms the basis for arrhythmias related to cardiac glycoside intoxication.

**Pharmacologic Effects.** Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if \([K]_0\) is low. They also exert prominent vagotonic actions, resulting in inhibition of Ca\(^{2+}\) currents in the AV node and activation of acetylcholine-mediated K\(^+\) currents in the atrium. Thus, the major “indirect” electrophysiologic effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The latter action accounts for the utility of digoxin in terminating reentrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation.

Cardiac glycosides may be especially useful in atrial fibrillation because many such patients have heart failure, which can be exacerbated by other AV nodal blocking drugs such as Ca\(^{2+}\) channel blockers or β adrenergic receptor
antagonists. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; however, even a modest decrease in rate can ameliorate heart failure. Similarly, in other conditions in which high sympathetic tone drives rapid AV conduction (e.g., chronic lung disease, thyrotoxicosis), digitalis therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance. The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

**Adverse Effects.** Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (see Chapter 28). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of digitalis, hypoxia, and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, hypercalcemia) predispose patients to digitalis-induced arrhythmias. Although digitalis intoxication can cause virtually any arrhythmia, certain types of arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia (a very rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na\(^+\), K\(^+\)-ATPase and profound bradyarrhythmias are seen. In patients with elevated serum digitalis levels, the risk of precipitating VF by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine. Mg\(^{2+}\) has been used successfully in some cases of digitalis-induced tachycardia. Any
serious arrhythmia should be treated with antidigoxin Fab fragments (DIGIBIND, DigiFab), which are highly effective in binding digoxin and digitoxin and greatly enhance their renal excretion (see Chapter 28). Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digitalis exerts direct arterial vasoconstrictor effects, which can be deleterious in patients with advanced atherosclerosis who receive intravenous drug.

**Clinical Pharmacokinetics.** The only digitalis glycoside used in the U.S. is digoxin (Lanoxin). Digitoxin also is used for chronic oral therapy outside the U.S. Digoxin tablets are ~75% bioavailable. In some patients, intestinal microflora may metabolize digoxin, markedly reducing bioavailability. In these patients, higher than usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics that destroy intestinal microflora are administered. Inhibition of P-glycoprotein also may play a role in cases of toxicity. Digoxin is 20-30% protein bound. The anti-arrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable anti-arrhythmic effects such as PR-interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of ~0.6-1 mg digoxin is administered over 24 h. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.0625-0.5 mg) to maintain concentrations of 0.5-2 ng/mL are useful during chronic digoxin therapy (see Table 29–5). Some patients may require and tolerate higher concentrations but with an increased risk of adverse effects.

</table>
Digoxin is largely excreted unchanged by the kidney with an elimination $t_{1/2} \approx 36$ h, so maintenance doses are administered once daily. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction.

Digitoxin’s elimination $t_{1/2}$ is even longer than that of digoxin ($\approx 7$ days); it is highly protein bound, and its therapeutic range is 10-30 ng/mL. Digitoxin metabolism is accelerated by drugs such as phenytoin and rifampin that induce hepatic metabolism. Amiodarone, quinidine, verapamil, diltiazem, cyclosporine,itraconazole, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination. New steady-state digoxin concentrations are approached in about a week. Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose of digoxin if these drugs are started. In all cases, digoxin concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia will potentiate digitalis-induced arrhythmias.

**DISOPYRAMIDE.** Disopyramide (NORPACE, others) exerts electrophysiologic effects very similar to those of quinidine, but the drugs produce different adverse effects. Disopyramide is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF.
**Pharmacologic Actions and Adverse Effects.** The in vitro electrophysiologic actions of S-(–)-disopyramide are similar to those of quinidine. The R-(–)-enantiomer produces similar Na\(^+\) channel block but does not prolong cardiac action potentials. Unlike quinidine, racemic disopyramide is not an α adrenergic receptor antagonist, but it does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention. Disopyramide commonly depresses contractility, which can precipitate heart failure and also can cause *torsade de pointes*.

**Clinical Pharmacokinetics.** Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration. Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher than usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

**DOFETILIDE.** Dofetilide (TIKOSYN) is a potent and “pure” \(I_{Kr}\) blocker that has virtually no extracardiac effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. Dofetilide is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and in-hospital treatment initiation.

**Adverse Effects.** *Torsade de pointes* occurred in 1-3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. The incidence of this adverse effect during more widespread use of the drug postmarketing is unknown.

**Clinical Pharmacokinetics.** Most of a dose of dofetilide is excreted unchanged by the kidneys. In patients with mild to moderate renal failure, decreases in dosage based on creatinine clearance are required to minimize the risk of *torsade de pointes*. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor
hepatic metabolism.

**DRONEDARONE.** Dronedarone (MULTAQ) is a derivative of amiodarone approved for the treatment of atrial fibrillation and atrial flutter. Compared to amiodarone, dronedarone treatment is associated with significantly fewer adverse events, but it also is significantly less effective in maintaining sinus rhythm. Dronedarone reduces morbidity and mortality in patients with high-risk atrial fibrillation. However, dronedarone increases mortality in patients with severe heart failure and is contraindicated in patients with NYHA class 4 heart failure and in patients with a recent decompensation of heart failure requiring hospitalization.

**Pharmacologic Effects.** Similar to amiodarone, dronedarone is a potent blocker of multiple ion currents, including the rapidly activating delayed-rectifier K⁺ current (\(I_{Kr}\)), the slowly activating delayed-rectifier K⁺ current (\(I_{KS}\)), the inward rectifier K⁺ current (\(I_{K1}\)), the acetylcholine activated K⁺ current, the peak Na⁺ current, and the L-type Ca²⁺ current. It has stronger anti-adrenergic effects than amiodarone.

**Adverse Effects and Drug Interactions.** The most common adverse reactions are diarrhea, nausea, abdominal pain, vomiting, and asthenia. Dronedarone causes dose-dependent prolongation of QT interval, but *torsade de pointes* is rare. Dronedarone is metabolized by CYP3A and is a moderate inhibitor of CYP3A, CYP2D6, and P-glycoprotein. A potent CYP3A4 inhibitor such as ketoconazole may increase dronedarone exposure by as much as 25-fold. Dronedarone should not be coadministered with potent CYP3A4 inhibitors. Coadministration with other drugs metabolized by CYP2D6 (e.g., metoprolol) or transported by P-glycoprotein (e.g., digoxin) may result in increased drug concentrations.

**ESMOLOL.** (BREVIBLOC, others) is a \(\beta_1\)-selective agent that is metabolized by erythrocyte esterases and so has a very short elimination \(t_{1/2}\) (9 min). Intravenous esmolol is useful in clinical situations in which immediate \(\beta\) adrenergic blockade is desired (e.g., for rate control of rapidly conducted atrial fibrillation).
FLECAINIDE. The effects of flecainide (TAMBOCOR, others) are likely attributable to the drug’s very long recovery from Na+ channel block. It is approved for the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, in whom structural heart disease is absent.

Pharmacologic Effects. Flecainide blocks Na+ current, delayed-rectifier K+ current ($I_{Kr}$) and Ca$^{2+}$ currents. APD is shortened in Purkinje cells, probably owing to block of late-opening Na+ channels, but prolonged in ventricular cells, probably owing to block of delayed-rectifier current. Flecainide does not cause EADs in vitro but has been associated with rare cases of torsade de pointes. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable anti-arrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates. Flecainide prolongs the duration of PR, QRS, and QT intervals even at normal heart rates. Flecainide also is an open channel blocker of RyR2 Ca$^{2+}$ release channels and prevents arrhythmogenic Ca$^{2+}$ release from the SR in isolated myocytes. The blockade of the RyR2 channel by flecainide targets directly the underlying molecular defect in patients with mutations in the ryanodine receptor and cardiac calsequestrin, which may explain why flecainide suppresses ventricular arrhythmias in CPVT patients refractory to standard drug therapy.

Adverse Effects. Dose-related blurred vision is the most common noncardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of reentrant ventricular tachycardia, and increased mortality in patients convalescing from MI. These may be attributed to Na+ channel block. Flecainide also can cause heart block in patients with conduction system disease.

Clinical Pharmacokinetics. Flecainide is well absorbed. Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism by CYP2D6 to inactive metabolites. However, in patients who lack this pathway due to genetic polymorphism or inhibition by other drugs (i.e., quinidine, fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient
with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Some reports suggest that plasma flecainide concentrations greater than 1 µg/mL should be avoided to minimize the risk of flecainide toxicity; but the adverse electrophysiologic effects of flecainide therapy can occur at therapeutic plasma concentrations.

**IBUTILIDE.** Ibutilide (CORVERT) is an $I_{Kr}$ blocker that in some systems also activates an inward Na$^{+}$ current. The action potential–prolonging effect of the drug may arise from either mechanism.

Ibutilide is administered as a rapid infusion (1 mg over 10 min) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug’s efficacy rate is higher in patients with atrial flutter (50-70%) than in those with atrial fibrillation (30-50%). In atrial fibrillation, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with ibutilide is *torsade de pointes*, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism and so is not used orally. It is eliminated by hepatic metabolism with a $t_{1/2}$ of 2-12 h.

**LIDOCAINE.** Lidocaine (XYLOCAINE, others) is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias. Its pharmacology is presented in Chapter 20. See also mexiletine, below.

**Pharmacologic Effects.** Lidocaine blocks both open and inactivated cardiac Na$^{+}$ channels. Recovery from block is very rapid, so lidocaine exerts greater effects in depolarized (e.g., ischemic) and/or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias possibly because atrial action potentials are so short that the Na$^{+}$ channel is in the inactivated state only briefly compared with long diastolic (recovery) times. Lidocaine can hyperpolarize Purkinje fibers depolarized by low [K]$_{o}$ or stretch; the resulting increased conduction velocity may be anti-arrhythmic in reentry. Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. APD usually is unaffected or is shortened; such shortening may be due to block of the few Na$^{+}$
channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported in patients with very poor left ventricular function.

**Adverse Effects.** When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nystagmus is an early sign of lidocaine toxicity.

**Clinical Pharmacokinetics.** Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus, oral use is inappropriate and the intravenous route is preferred (see Table 29–5). Lidocaine’s metabolites, glycine xylidide (GX) and monoethyl GX, are less potent as Na+ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na+ channel, suggesting that with infusions during which GX accumulates, lidocaine’s efficacy may be diminished. With infusions lasting longer than 24 h, the clearance of lidocaine falls—an effect that has been attributed to competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes.

The initial drop in plasma lidocaine following intravenous administration occurs rapidly, with a $t_{1/2}$ of ~8 min, and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$, usually ~110 min, represents drug elimination by hepatic metabolism. Lidocaine’s efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3-4 mg/kg over 20-30 min is used—e.g., an initial 100 mg followed by 50 mg every 8 min for 3 doses. Subsequently, stable concentrations can be maintained in plasma with an infusion of 1-4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state lidocaine concentrations is ~18-10 h. Routine measurement of plasma lidocaine concentration at the time of expected steady
state is useful in adjusting the maintenance infusion rate to avoid toxicities (therapeutic range, 1.5-5 µg/mL). In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Lidocaine clearance also is reduced in hepatic disease, during treatment with *cimetidine* or β blockers, and during prolonged infusions. Lidocaine is bound to the acute-phase reactant α-1-acid glycoprotein. Diseases such as acute MI are associated with increases in α-1-acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher than usual total plasma lidocaine concentrations to maintain anti-arrhythmic efficacy.

**MAGNESIUM.** The intravenous administration of 1-2 g MgSO₄ reportedly is effective in preventing recurrent episodes of *torsade de pointes*, even if the serum Mg²⁺ concentration is normal. However, controlled studies of this effect have not been performed.

The mechanism of action is unknown because the QT interval is not shortened; an effect on the inward current, possibly a Ca²⁺ current, responsible for the triggered upstroke arising from EADs (*black arrow*, Figure 29–6B) is possible. Intravenous Mg²⁺ also has been used successfully in arrhythmias related to digitalis intoxication.

**MEXILETINE.** Mexiletine (MEXITIL, others) is an analog of lidocaine that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy. The electrophysiologic actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. In vitro studies and clinical case reports suggest a role for mexiletine (or flecainide) in correcting the aberrant late inward Na⁺ current in congenital LQT3.
**PROCAINAMIDE.** Procainamide (PROCAN SR, others) is an analog of the local anesthetic procaine (see Chapter 20). It exerts electrophysiologic effects similar to those of quinidine but lacks quinidine’s vagolytic and α adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias; long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

**Pharmacologic Effects.** Procainamide is a blocker of open Na+ channels with an intermediate $\tau_{\text{recovery}}$ from block. It also prolongs cardiac action potentials, probably by blocking outward K+ current(s). Procainamide decreases automaticity, increases refractory periods, and slows conduction. Its major metabolite, N-acetyl procainamide, lacks the Na+ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials. Because the plasma concentrations of N-acetyl procainamide often exceed those of procainamide, increased refractoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS-interval prolongation. Hypotension may occur at high plasma concentrations, this effect is attributable to ganglionic blockade rather than to any negative inotropic effect.

**Adverse Effects.** Hypotension and marked slowing of conduction are major adverse effects of high concentrations (>10 µg/mL) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of N-acetyl procainamide. *Torsade de pointes* can occur, particularly when plasma concentrations of N-acetyl procainamide rise to ~30 µg/mL. Procainamide produces potentially fatal bone marrow aplasia in 0.2% of patients. During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating antinuclear antibodies. Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25-50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although
renal involvement is unusual. The lupuslike symptoms resolve on cessation of therapy or during treatment with N-acetyl procainamide (see below).

**Clinical Pharmacokinetics.** Procainamide is eliminated rapidly ($t_{1/2} = 3-4$ h) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by N-acetyl transferase, to form N-acetyl procainamide. N-Acetyl procainamide is eliminated by renal excretion ($t_{1/2} = 6-10$ h). Oral procainamide usually is administered as a slow-release formulation. In patients with renal failure reduction dose and dosing frequency and monitoring of plasma concentrations of both compounds are required. Because the parent drug and metabolite exert different pharmacologic effects, the past practice of using the sum of their concentrations to guide therapy is inappropriate. In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators. In addition, the symptoms of procainamide-induced lupus resolve during treatment with N-acetyl procainamide. Both these findings suggest that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome.

**PROPafenONE.** Propafenone (RYTHMOL, others) is a Na+ channel blocker with a relatively slow time constant for recovery from block. Like flecainide, propafenone also blocks K+ channels. Its major electrophysiologic effect is to slow conduction in fast-response tissues.

The drug is prescribed as a racemate; although the enantiomers do not differ in their Na+ channel–blocking properties, S-(+)-propafenone is a β receptor antagonist. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation. It also can be used in ventricular arrhythmias, but with only modest efficacy.

**adverse effects.** Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of reentrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm.
Clinical Pharmacokinetics. Propafenone is well absorbed and is eliminated by both hepatic and renal routes. The activity of CYP2D6 is a major determinant of plasma propafenone concentration. In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxypropafenone, a metabolite equipotent to propafenone as a Na⁺ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, N-desalkyl propafenone, is formed by non–CYP2D6-mediated metabolism and is a less potent blocker of Na⁺ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable, so small increases in dose can increase plasma propafenone concentration disproportionately. In “poor metabolizer” subjects lacking functional CYP2D6, plasma propafenone concentrations will be much higher after an equal dose. The incidence of adverse effects of propafenone therapy is higher in poor metabolizers.

CYP2D6 activity can be inhibited markedly by a number of drugs, including quinidine and fluoxetine. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma propafenone concentrations of more than 1 µg/mL are associated with clinical effects of β receptor blockade, such as reduction of exercise heart rate. Patients with moderate to severe liver disease should be reduced to ~20-30% of the usual dose, with careful monitoring. Slow-release formulation allows twice-daily dosing.

QUINIDINE. Quinidine, a diastereomer of the antimalarial quinine, is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF.

Pharmacologic Effects. Quinidine blocks Na⁺ current and multiple cardiac K⁺ currents. It is an open-state blocker of Na⁺ channels, with a τ_recovery in the intermediate (~3 s) range; as a consequence, QRS duration increases modestly, usually by 10-20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval up to 25%, but the effect is highly variable. At concentrations as low as 1 µM, quinidine blocks Na⁺ current and the rapid component of delayed rectifier (I_{Kr}); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca²⁺ current.
Quinidine’s Na\textsuperscript{+} channel–blocking properties result in an increased threshold for excitability and decreased automaticity. Due to K\textsuperscript{+} channel–blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when [K]\textsubscript{o} is low. Quinidine prolongs refractoriness in most tissues, probably as a result of both prolongation of APD and Na\textsuperscript{+} channel blockade.

Quinidine also produces β receptor blockade and vagal inhibition. Thus, the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine’s vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, quinidine’s vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (see Table 29–1).

**Adverse Effects—Noncardiac.** Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30-50% of patients, usually within the first several days of quinidine therapy but can occur later. Diarrhea-induced hypokalemia may potentiate *torsade de pointes* due to quinidine. A number of immunologic reactions can occur during quinidined therapy. The most common is thrombocytopenia, which can be severe but resolves rapidly with drug discontinuation. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations. Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

**Adverse Effects—Cardiac.** Between 2-8% will develop marked QT-interval prolongation and *torsade de pointes*. In contrast to effects of sotalol, N-acetyl procainamide, and many other drugs, quinidine-associated *torsade de pointes* generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility are not known. At high plasma concentrations of quinidine, marked Na\textsuperscript{+} channel block can occur, with resulting ventricular tachycardia. Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, quinidine is well tolerated, perhaps because of its vasodilating actions.
Clinical Pharmacokinetics. Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and α-1-acid glycoprotein. As with lidocaine, greater than usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute MI. Quinidine undergoes extensive hepatic oxidative metabolism, and ~20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac Na⁺ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine are tolerated by some patients. There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2-5 µg/mL. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

Drug Interactions. Quinidine is a potent inhibitor of CYP2D6. Drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects. For example, inhibition of CYP2D6-mediated metabolism of codeine to its active metabolite morphine results in decreased analgesia. Conversely, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased β-adrenergic receptor blockade. Quinidine reduces the clearance of digoxin; inhibition of P-glycoprotein–mediated digoxin transport has been implicated. Quinidine metabolism is induced by drugs such as phenobarbital and phenytoin. In patients receiving these agents, very high doses of quinidine may be required to achieve therapeutic concentrations. Cimetidine and verapamil also elevate plasma quinidine concentrations, but these effects usually are modest.

SOTALOL. Sotalol (BETAPACE, BETAPACE AF) is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed-rectifier and possibly other K⁺ currents.

Sotalol is prescribed as a racemate; the L-enantiomer is a much more potent β adrenergic receptor antagonist than the D-enantiomer, but the 2 are equipotent as K⁺ channel blockers. In the U.S., sotalol is an orphan drug approved for use in patients with both ventricular tachyarrhythmias (BETAPACE) and atrial fibrillation
or flutter (Betapace AF). It is at least as effective as most Na+ channel blockers in ventricular arrhythmias. Sotalol prolongs QT interval, decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K+ channels and β adrenergic receptors; but it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity in vitro and can cause *torsade de pointes*, especially when the serum K+ concentration is low. The incidence of *torsade de pointes* seems to depend on the dose of sotalol. Occasional cases occur at low dosages, often in patients with renal dysfunction, because sotalol is eliminated by renal excretion. For adverse effects associated with β receptor blockade (see Chapter 12).
Blood must remain fluid within the vasculature and yet clot quickly when exposed to subendothelial surfaces at sites of vascular injury. Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhages. Alteration of this balance in favor of coagulation results in thrombosis. Thrombi, composed of platelet aggregates, fibrin, and trapped red blood cells, can form in arteries or veins. Antithrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation; anticoagulants, which attenuate fibrin formation; and fibrinolytic agents, which degrade fibrin. All antithrombotic drugs increase the risk of bleeding.

This chapter reviews the agents commonly used for controlling blood fluidity, including:

- The parenteral anticoagulant heparin and its derivatives, which activate a natural inhibitor of coagulant proteases
- The coumarin anticoagulants, which block multiple steps in the coagulation cascade
- Fibrinolytic agents, which degrade thrombi
- Antiplatelet agents, including aspirin, thienopyridines, and glycoprotein (GP) IIb/IIIa inhibitors

OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel, where they become activated. Adherent platelets release substances that activate nearby platelets, thereby
recruiting them to the site of injury. Activated platelets then aggregate to form the primary hemostatic plug.

Vessel wall injury also exposes tissue factor (TF), which initiates the coagulation system. Platelets enhance activation of the coagulation system by providing a surface onto which clotting factors assemble and by releasing stored clotting factors. This results in a burst of thrombin (factor IIa) generation. Thrombin then converts fibrinogen to fibrin and amplifies platelet activation and aggregation.

Later, as wound healing occurs, the platelet aggregates and fibrin clots are degraded. The processes of platelet aggregation and blood coagulation are summarized in Figures 30–1 and 30–2 (see also the animation on the Goodman & Gilman website). The pathway of clot removal, fibrinolysis, is shown in Figure 30–3, along with sites of action of fibrinolytic agents. Coagulation involves a series of zymogen activation reactions, as shown in Figure 30–2. At each stage, a precursor protein, or zymogen, is converted to an active protease by cleavage of 1 or more peptide bonds in the precursor molecule. The final protease generated is thrombin.
Figure 30–1 Platelet adhesion and aggregation. GPIa/IIa and GPIb are platelet receptors that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR1 and PAR4 are protease-activated receptors that respond to thrombin (IIa); P2Y1 and P2Y12 are receptors for ADP; when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and cyclooxygenase-1 (COX-1) to promote platelet aggregation and secretion. Thromboxane A2 (TxA2) is the major product of COX-1 involved in platelet activation. Prostaglandin I2 (prostacyclin, PGI2), synthesized by endothelial cells, inhibits platelet activation.
Figure 30–2 Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (tissue factor and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important in vivo. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. TF, tissue factor. Activated coagulation factors are followed by the letter “a”: II, prothrombin; IIa, thrombin.
Figure 30–3 Fibrinolysis. Endothelial cells secrete tissue plasminogen activator (t-PA) at sites of injury. t-PA binds to fibrin and converts plasminogen to plasmin, which digests fibrin. Plasminogen activator inhibitors-1 and -2 (PAI-1, PAI-2) inactivate t-PA; α₂-antiplasmin (α₂-AP) inactivates plasmin.

CONVERSION OF FIBRINOGEN TO FIBRIN. Fibrinogen, a 340,000-Da protein, is a dimer, each half of which consists of 3 pairs of polypeptide chains (designated Aα, Bβ, and γ). Disulfide bonds covalently link the chains and the 2 halves of the molecule together. Thrombin converts fibrinogen to fibrin monomers by releasing fibrinopeptide A (a 16–amino acid fragment) and fibrinopeptide B (a 14–amino acid fragment) from the amino termini of the Aα and Bβ chains, respectively. Removal of the fibrinopeptides creates new amino termini, which fit into preformed holes on other fibrin monomers to form a fibrin gel, which is the end point of in vitro tests of coagulation (see “Coagulation in vitro”). Initially, the fibrin monomers are bound to each other noncovalently. Subsequently, factor XIII, a transglutaminase that is activated by thrombin, catalyzes interchain covalent cross-links between adjacent fibrin monomers, which enhance the strength of the clot.

STRUCTURE OF COAGULATION FACTORS. In addition to factor XIII, the coagulation factors include factors II (prothrombin), VII, IX, X, XI, XII, and
prekallikrein. A stretch of ~200 amino acid residues at the carboxyl-termini of each of these zymogens exhibits homology to trypsin and contains the active site of the proteases. In addition, 9-12 glutamate residues near the amino termini of factors II, VII, IX, and X are converted to t-carboxyglutamate (Gla) residues that bind Ca$^{2+}$ and are necessary for the coagulant activities of these proteins.

**NONENZYMATIC PROTEIN COFACTORs.** Factors V and VIII serve as cofactors. Factor VIII circulates in plasma bound to von Willebrand factor. Factor V circulates in plasma, is stored in platelets in a partially activated form, and is released when platelets are activated. Thrombin cleaves factors V and VIII to yield activated cofactors (factors Va and VIIIa).

Factors Va and VIIIa serve as cofactors by binding to the surface of activated platelets and acting as receptors for factors Xa and IXa, respectively. The activated cofactors also help localize prothrombin and factor X, the respective substrates for these enzymes, on the activated platelet surface. These coagulation factor complexes increase the catalytic efficiency of factors Xa and IXa by ~10$^9$-fold.

TF is a nonenzymatic lipoprotein cofactor; it initiates coagulation by enhancing the catalytic efficiency of factor VIIa. Not normally present on blood-contacting cells, TF is constitutively expressed on the surface of subendothelial smooth muscle cells and fibroblasts, which are exposed when the vessel wall is damaged. Another plasma protein, high-molecular-weight kininogen, also serves as a cofactor.

**ACTIVATION OF PROTHROMBIN.** By cleaving 2 peptide bonds on prothrombin, factor Xa converts it to thrombin. In the presence of factor Va, a negatively charged phospholipid surface, and Ca$^{2+}$, factor Xa activates prothrombin with 10$^9$-fold greater efficiency. The maximal rate of activation only occurs when prothrombin and factor Xa contain Gla residues, which endow them with the capacity to bind to phospholipids.

**Initiation of Coagulation.** TF exposed at sites of vessel wall injury initiates coagulation via the *extrinsic pathway*. The small amount of factor VIIa circulating in plasma binds subendothelial TF and the TF-factor VIIa complex, then activates factors X and IX (see Figure 30–2). TF, in the presence of phospholipids and Ca$^{2+}$, increases the activity of factor VIIa by 30,000-fold.
The intrinsic pathway is initiated in vitro when factor XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another surface to generate small amounts of factor XIIa. Activation of factor XI to factor Xla and factor IX to factor IXa follows. Factor IXa then activates factor X in a reaction accelerated by factor VIIIa, anionic phospholipids, and Ca²⁺. Optimal thrombin generation depends on the formation of this factor IXa complex because it activates factor X more efficiently than the TF-factor VIIa complex.

Activation of factor XII is not essential for hemostasis, as evidenced by the fact that patients deficient in factor XII, prekallikrein, or high-molecular-weight kininogen do not have excessive bleeding. Factor XI deficiency is associated with a variable and usually mild bleeding disorder.

Fibrinolysis. The pathway of fibrinolysis is summarized in Figure 30–3. The fibrinolytic system dissolves intravascular fibrin through the action of plasmin. To initiate fibrinolysis, plasminogen activators first convert single-chain plasminogen, an inactive precursor, into 2-chain plasmin by cleavage of a specific peptide bond. There are 2 distinct plasminogen activators: tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), or urokinase. Although both activators are synthesized by endothelial cells, t-PA predominates under most conditions and drives intravascular fibrinolysis, while synthesis of u-PA mainly occurs in response to inflammatory stimuli and promotes extravascular fibrinolysis.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds is preserved to maintain hemostasis. t-PA is released from endothelial cells in response to various stimuli. Released t-PA is rapidly cleared from blood or inhibited by plasminogen activator inhibitor-1 (PAI-1) and, to a lesser extent, plasminogen activator inhibitor-2 (PAI-2); t-PA thus exerts little effect on circulating plasminogen in the absence of fibrin. α₂-antiplasmin rapidly inhibits any plasmin that is generated. The catalytic efficiency of t-PA activation of plasminogen increases more than 300-fold in the presence of fibrin, which promotes plasmin generation on its surface.

Plasminogen and plasmin bind to lysine residues on fibrin via 5 loop-like regions near their amino termini, which are known as kringle domains. To inactivate plasmin, α₂-antiplasmin binds to the first of these kringle domains and then blocks the active site of plasmin. Because the kringle domains are occupied
when plasmin binds to fibrin, plasmin on the fibrin surface is protected from inhibition by α2-antiplasmin and can digest the fibrin. Once the fibrin clot undergoes degradation, α2-antiplasmin rapidly inhibits any plasmin that escapes from this local milieu. To prevent premature clot lysis, factor XIIIa mediates the covalent cross-linking of small amounts of α2-antiplasmin onto fibrin.

When thrombi occlude major arteries or veins, therapeutic doses of plasminogen activators sometimes are administered to degrade the fibrin and rapidly restore blood flow. In high doses, these plasminogen activators promote the generation of so much plasmin that the inhibitory controls are overwhelmed. Plasmin is a relatively nonspecific protease; it also degrades several coagulation factors. Reduction in the levels of these coagulation proteins impairs the capacity for thrombin generation, which can contribute to bleeding. In addition, unopposed plasmin tends to dissolve fibrin in hemostatic plugs as well as that in pathological thrombi, a phenomenon that also increases the risk of bleeding. Therefore, fibrinolytic drugs can be toxic, producing hemorrhage as their major side effect.

Coagulation in vitro. Whole blood normally clots in 4-8 min when placed in a glass tube. Clotting is prevented if a chelating agent such as ethylenediaminetetraacetic acid (EDTA) or citrate is added to bind Ca2+. Recalcified plasma normally clots in 2-4 min. The clotting time after recalcification is shortened to 26-33 seconds by the addition of negatively charged phospholipids and a particulate substance, such as kaolin (aluminum silicate) or celite (diatomaceous earth), which activates factor XII; the measurement of this is termed the activated partial thromboplastin time (aPTT). Alternatively, recalcified plasma clots in 12-14 seconds after addition of “thromboplastin” (a mixture of TF and phospholipids); the measurement of this is termed the prothrombin time (PT).

Natural Anticoagulant Mechanisms. Platelet activation and coagulation do not normally occur within an intact blood vessel. Thrombosis is prevented by several regulatory mechanisms that require a healthy vascular endothelium. NO and PGI2, synthesized by endothelial cells, inhibit platelet activation (see Chapter 33).

Antithrombin is a plasma protein that inhibits coagulation enzymes of the
intrinsic and common pathways. Heparan sulfate proteoglycans synthesized by endothelial cells enhance the activity of antithrombin by m1000-fold. Another regulatory system involves protein C, a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of Ca$^{2+}$ to Gla residues within its amino-terminal domain. Protein C binds to endothelial protein C receptor (EPCR), which presents protein C to the thrombin–thrombomodulin complex for activation. Activated protein C then dissociates from EPCR and, in combination with protein S, its nonenzymatic Gla-containing cofactor, activated protein C degrades factors Va and VIIIa. Without these activated cofactors, the rates of activation of prothrombin and factor X are greatly diminished. Deficiency of protein C or protein S is associated with an increased risk of pathological thrombus formation.

Tissue factor pathway inhibitor (TFPI), is a natural anticoagulant found in the lipoprotein fraction of plasma. TFPI first binds and inhibits factor Xa, and this binary complex then inhibits factor VIIa. By this mechanism, factor Xa regulates its own generation.

PARENTERAL ANTICOAGULANTS

HEPARIN AND ITS DERIVATIVES

Heparin, a glycosaminoglycan found in the secretory granules of mast cells, is synthesized from UDP-sugar precursors as a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues.

Heparin is commonly extracted from porcine intestinal mucosa, which is rich in mast cells, and preparations may contain small amounts of other glycosaminoglycans. The biological activities among different commercial preparations of heparin are similar (~150 USP units/mg). A USP unit reflects the quantity of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 h after the addition of 0.2 mL of 1% CaCl$_2$. European manufacturers measure potency with an antifactor Xa assay. To determine heparin potency, residual factor Xa activity in the sample is compared with that detected in controls containing known concentrations of an international heparin standard. When assessed this way, heparin potency is expressed in international units per mg. Effective October 1, 2009, the new USP unit dose has been harmonized to the
international unit dose. As a result, the new USP unit dose is less potent than the old USP unit dose by ~10%, and heparin doses using the new USP units will have to increase slightly to achieve the same level of anticoagulation.

HEPARIN DERIVATIVES. Derivatives of heparin in current use include low-molecular-weight heparins (LMWHs) and fondaparinux (see their comparison in Table 30–1).

Mechanism of Action. Heparin, LMWHs, and fondaparinux have no intrinsic anticoagulant activity; rather, these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Synthesized in the liver, antithrombin circulates in plasma at an approximate concentration of 2.6 μM. Antithrombin inhibits activated coagulation factors involved in the intrinsic and common pathways but has relatively little activity against factor VIIa. Antithrombin is a “suicide substrate” for these proteases; inhibition occurs when the protease attacks a specific Arg–Ser peptide bond in the reactive center loop of antithrombin and becomes trapped as a stable 1:1 complex. Heparin binds to antithrombin via a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 30–4). Pentasaccharide binding to antithrombin induces a conformational change in antithrombin that renders its reactive site more accessible to the target protease (Figure 30–5). This conformational change accelerates the rate of factor Xa inhibition by at least 2 orders of magnitude but has no effect on the rate of thrombin inhibition. To enhance the rate of thrombin inhibition by antithrombin, heparin serves as a catalytic template to which both the inhibitor and the protease bind. Only heparin molecules composed of 18 or more saccharide units (molecular weight
>5400 Da) are of sufficient length to bridge antithrombin and thrombin together. Consequently, by definition, heparin catalyzes the rates of factor Xa and thrombin to a similar extent, as expressed by an antifactor Xa to antifactor IIa (thrombin) ratio of 1:1. In contrast, at least half of LMWH molecules (mean molecular weight of 5000 Da, ~17 saccharide units) are too short to provide this bridging function and have no effect on the rate of thrombin inhibition by antithrombin. Because these shorter molecules still induce the conformational change in antithrombin that accelerates inhibition of factor Xa, LMWHs have greater antifactor Xa activity than antifactor IIa activity, and the ratio ranges from 3:1 to 2:1 depending on the preparation. Fondaparinux, an analog of the pentasaccharide sequence in heparin or LMWHs that mediates their interaction with antithrombin, has only antifactor Xa activity because it is too short to bridge antithrombin to thrombin (see Figure 30–5).

Figure 30–4 The antithrombin-binding pentasaccharide structure of heparin. Sulfate groups required for binding to antithrombin are indicated in red.
Figure 30–5 Mechanism of action of heparin, low-molecular-weight heparin (LMWH), and fondaparinux, a synthetic pentasaccharide. A. Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units (MW ~5,400 Da) are of sufficient length to perform this bridging function. With a mean MW ~15,000 Da, virtually all of the heparin chains are long enough to do this. B. LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains (mean MW ~4,500-5,000 Da) are too short to bridge...
antithrombin to thrombin. C. The pentasaccharide accelerates only factor Xa inhibition by antithrombin; the pentasaccharide is too short to bridge antithrombin to thrombin.

Heparin, LMWHs, and fondaparinux act in a catalytic fashion. After binding to antithrombin and promoting the formation of covalent complexes between antithrombin and target proteases, the heparin, LMWH, or fondaparinux dissociates from the complex and can then catalyze other antithrombin molecules.

Platelet factor 4, a cationic protein released from the α granules during platelet activation, binds heparin and prevents it from interacting with antithrombin. This phenomenon may limit the activity of heparin in the vicinity of platelet-rich thrombi. Because LMWH and fondaparinux have a lower affinity for platelet factor 4, these agents may retain their activity in the vicinity of such thrombi to a greater extent than heparin.

**Miscellaneous Pharmacological Effects.** High doses of heparin can interfere with platelet aggregation and prolong bleeding time. In contrast, LMWHs and fondaparinux have little effect on platelets. Heparin “clears” lipemic plasma in vivo by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect.

**Clinical Use.** Heparin, LMWH, and fondaparinux can be used to initiate treatment of venous thrombosis and pulmonary embolism because of their rapid onset of action. An oral vitamin K antagonist, such as warfarin, usually is started concurrently, and the heparin or heparin derivative is continued for at least 5 days to allow warfarin to achieve its full therapeutic effect. Heparin, LMWH, or fondaparinux also can be used in the initial management of patients with unstable angina or acute myocardial infarction. For most of these indications, LMWHs and fondaparinux have replaced continuous heparin infusions because of their pharmacokinetic advantages, which permit subcutaneous administration once or twice daily in fixed or weight-adjusted doses without coagulation monitoring. Thus, LMWHs or fondaparinux can be used for out-of-hospital management of patients with venous thrombosis or pulmonary embolism.
Heparin and LMWH are used during coronary balloon angioplasty with or without stent placement to prevent thrombosis. Fondaparinux is not used in this setting because of the risk of catheter thrombosis, a complication caused by catheter-induced activation of factor XII; longer heparin molecules are better than shorter ones for blocking this process. Cardiopulmonary bypass circuits also activate factor XII, which can cause clotting of the oxygenator. Heparin remains the agent of choice for surgery requiring cardiopulmonary bypass. Heparin also is used to treat selected patients with disseminated intravascular coagulation. Subcutaneous administration of low-dose heparin remains the recommended regimen for the prevention of postoperative deep venous thrombosis (DVT) and pulmonary embolism in patients undergoing major abdominothoracic surgery or who are at risk of developing thromboembolic disease.

Unlike warfarin, heparin, LMWH, and fondaparinux do not cross the placenta and have not been associated with fetal malformations, making them the drugs of choice for anticoagulation during pregnancy. Heparin, LMWH, and fondaparinux do not appear to increase fetal mortality or prematurity. If possible, the drugs should be discontinued 24 h before delivery to minimize the risk of postpartum bleeding.

**ADME.** Heparin, LMWHs, and fondaparinux are not absorbed through the GI mucosa and must be given parenterally. Heparin is given by continuous intravenous infusion, intermittent infusion every 4-6 h, or subcutaneous injection every 8-12 h. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed 1-2 h. LMWH and fondaparinux are absorbed more uniformly after subcutaneous injection. The $t_{1/2}$ of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives of the anticoagulant activities are ~1, 2.5, and 5 h. Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of undegraded heparin appears in the urine.

LMWHs and fondaparinux have longer biological half-lives than heparin, 4-6 h and L17 h, respectively. Because these smaller heparin fragments are cleared almost exclusively by the kidneys, the drugs can accumulate in patients with
renal impairment and lead to bleeding. Both LMWH and fondaparinux are contraindicated in patients with a creatinine clearance $<30$ mL/min. In addition, fondaparinux is contraindicated in patients with body weight $<50$ kg undergoing hip fracture, hip replacement, knee replacement surgery, or abdominal surgery.

**Administration and Monitoring.** Full-dose heparin therapy usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a fixed-dose bolus injection of 5000 units or with a weight-adjusted bolus, followed by 800-1600 units/h delivered by an infusion pump. Therapy routinely is monitored by measuring the aPTT. The therapeutic range for heparin is considered to be that which is equivalent to a plasma heparin level of 0.3-0.7 units/mL, as determined with an antifactor Xa assay. An aPTT 2-3 times the normal mean aPTT value generally is assumed to be therapeutic. The aPTT should be measured initially and the infusion rate adjusted every 6 h. Once a steady dosage schedule has been established in a stable patient, daily laboratory monitoring usually is sufficient. Very high doses of heparin are required to prevent coagulation during cardiopulmonary bypass. The aPTT is infinitely prolonged over the dosage range used. A less sensitive coagulation test, such as the activated clotting time, is employed to monitor therapy in this situation.

For therapeutic purposes, heparin also can be administered subcutaneously on a twice-daily basis. A total daily dose of ~35,000 units administered as divided doses every 8-12 h usually is sufficient to achieve an aPTT of twice the control value (measured midway between doses). For low-dose heparin therapy (to prevent DVT and thromboembolism in hospitalized medical or surgical patients), a subcutaneous dose of 5000 units is given 2-3 times daily.

**LMWH PREPARATIONS** include Enoxaparin (LOVENOX), dalteparin (FRAGMIN), tinzaparin (INNOHEP, others), ardeparin (NORMIFLO), nadroparin (FRAXIPARINE, others), and reviparin (CLIVARINE) (the latter 3 are not currently available in the United States). These agents differ considerably; do not assume that 2 preparations that have similar antifactor Xa activity will have equivalent antithrombotic effects. Because LMWHs produce a relatively predictable anticoagulant response, monitoring is not done routinely. Patients with renal impairment may require monitoring with an antifactor Xa assay because this condition may prolong the $t_{1/2}$ and slow the elimination of LMWHs. Obese
patients and children given LMWHs also may require monitoring.

**FONDAPARINUX (Arixtra)** is administered by subcutaneous injection, reaches peak plasma levels in 2 h, and is excreted in the urine ($t_{1/2}$ 17 h). It should not be used in patients with renal failure. Fondaparinux can be given once a day at a fixed dose without coagulation monitoring. Fondaparinux appears to be much less likely than heparin or LMWH to trigger the syndrome of heparin-induced thrombocytopenia. Fondaparinux is approved for thromboprophylaxis in patients undergoing hip or knee surgery or surgery for hip fracture, and for initial therapy in patients with pulmonary embolism or DVT.

**IDRAPARINUX**, a hypermethylated version of fondaparinux with a $t_{1/2}$ of 80 h; it is given subcutaneously once-weekly. To overcome the lack of an antidote, a biotin moiety was added to idraparinux to generate idrabiotaaparinux, which can be neutralized with intravenous avidin. Ongoing phase III clinical trials are comparing idrabiotaaparinux with warfarin for treatment of pulmonary embolism or for stroke prevention in patients with atrial fibrillation. Idraparinux, idrabiotaaparinux, and avidin are not available for routine clinical use.

**Heparin Resistance.** The dose of heparin required to produce a therapeutic aPTT varies due to differences in the concentrations of heparin-binding proteins in plasma that competitively inhibit binding of heparin to antithrombin. Some patients do not achieve a therapeutic aPTT unless very high doses of heparin (>50,000 units/day) are administered. Such patients may have “therapeutic” concentrations of heparin in plasma at the usual dose when measured using an antifactor Xa assay. This “pseudo” heparin resistance occurs because these patients have short aPTT values prior to treatment, as a result of increased concentrations of factor VIII. Other patients may require large doses of heparin because of accelerated clearance of the drug, as may occur with massive pulmonary embolism. Patients with inherited antithrombin deficiency ordinarily have 40-60% of the usual plasma concentration of this inhibitor and respond normally to intravenous heparin. However, acquired antithrombin deficiency, where concentrations may be ≤25% of normal, may occur in patients with hepatic cirrhosis, nephrotic syndrome, or disseminated intravascular coagulation; large doses of heparin may not prolong the aPTT in these individuals.

Because LMWHs and fondaparinux exhibit reduced binding to plasma proteins other than antithrombin, heparin resistance rarely occurs with these agents. For
this reason, routine coagulation monitoring is unnecessary.

**TOXICITY AND ADVERSE EVENTS**

**BLEEDING.** Bleeding is the primary untoward effect of heparin. Major bleeding occurs in 1-5% of patients treated with intravenous heparin for venous thromboembolism. The incidence of bleeding is somewhat less in patients treated with LMWH for this indication. Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction.

The anticoagulant effect of heparin disappears within hours of discontinuation of the drug. Mild bleeding due to heparin usually can be controlled without the administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by the intravenous infusion of *protamine sulfate* (a mixture of basic polypeptides isolated from salmon sperm) that binds tightly to heparin and neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is 41 mg of protamine for every 100 units of heparin remaining in the patient; protamine (up to a maximum of 50 mg) is given intravenously at a slow rate (over 10 min). Protamine binds only long heparin molecules. Therefore, protamine only partially reverses the anticoagulant activity of LMWHs and has no effect on that of fondaparinux.

**Heparin-Induced Thrombocytopenia.** Heparin-induced thrombocytopenia (platelet count H150,000/mL or a 50% decrease from the pretreatment value) occurs in 10.5% of medical patients 5-10 days after initiation of therapy with heparin. Although the incidence may be lower, thrombocytopenia also occurs with LMWHs and fondaparinux, and platelet counts should be monitored. Thrombotic complications that can be life-threatening or lead to amputation occur in about one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. Women are twice as likely as men to develop this condition.

Venous thromboembolism occurs most commonly, but arterial thromboses
causing limb ischemia, myocardial infarction, and stroke also occur. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of IgG antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) appears to cause all of these reactions.

Heparin, LMWH, and fondaparinux should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned above occur 5 or more days after beginning therapy, regardless of the dose or route of administration. The diagnosis of heparin-induced thrombocytopenia can be confirmed by a heparin-dependent platelet activation assay or an assay for antibodies that react with heparin/platelet factor IV complexes. Because thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as lepirudin, argatroban (see the next section), or fondaparinux should be administered to patients with heparin-induced thrombocytopenia. LMWH preparations should be avoided, because these drugs often cross-react with heparin. Warfarin may precipitate venous limb gangrene or multicentric skin necrosis in patients with heparin-induced thrombocytopenia and should not be used.

Other Toxicities. Abnormalities of hepatic function tests occur frequently in patients who are receiving heparin or LMWHs. Osteoporosis resulting in spontaneous vertebral fractures can occur, albeit infrequently, in patients who have received therapeutic doses of heparin (20,000 units/day) for extended periods (e.g., 3–6 months). Risk of osteoporosis is lower with LMWHs or fondaparinux than it is with heparin. Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia. Allergic reactions to heparin are rare.

OTHER PARENTERAL ANTICOAGULANTS

LEPIRUDIN. Lepirudin (REFLUDAN) is a recombinant derivative of hirudin, a direct thrombin inhibitor present in the salivary glands of the medicinal leech. Lepirudin is a 65–amino acid polypeptide that binds tightly to both the catalytic site and the extended substrate recognition site of thrombin. Lepirudin is approved in the U.S. for
treatment of patients with heparin-induced thrombocytopenia.

Lepirudin is administered intravenously at a dose adjusted to maintain the aPTT at 1.5-2.5 times the median of the laboratory’s normal range for aPTT. The drug is excreted by the kidneys and has a $t_{1/2}$ of 1.3 h. Lepirudin should be used cautiously in patients with renal failure. Patients may develop antibodies against hirudin that occasionally prolong the $t_{1/2}$ and cause a paradoxical increase in the aPTT; therefore, daily monitoring of the aPTT is recommended. There is no antidote for lepirudin.

**DESIRUDIN.** Desirudin (IPRIVASK) is a recombinant derivative of hirudin that differs only by the lack of a sulfate group on Tyr$^{63}$.

Desirudin is indicated for the prophylaxis of DVT in patients undergoing elective hip replacement surgery. The recommended dose is 15 mg every 12 h by subcutaneous injection. It is eliminated by the kidney; the $t_{1/2}$ is 2 h following subcutaneous administration. The drug should be used cautiously in patients with decreased renal function, and serum creatinine and aPTT should be monitored daily.

**BIVALIRUDIN.** Bivalirudin (ANGIOMAX) is a synthetic 20–amino acid polypeptide that directly inhibits thrombin by a mechanism similar to that of lepirudin.

Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty or cardiopulmonary bypass surgery. Patients with heparin-induced thrombocytopenia or a history of this disorder also can be given bivalirudin instead of heparin during coronary angioplasty. The $t_{1/2}$ of bivalirudin is 25 min; dosage reductions are recommended for patients with renal impairment.

**ARGATROBAN.** Argatroban, a synthetic compound based on the structure of l-arginine, binds reversibly to the catalytic site of thrombin.

Argatroban is administered intravenously. Its $t_{1/2}$ is 40-50 min. It is metabolized
by hepatic CYPs and is excreted in the bile. Dosage reduction is required for patients with hepatic insufficiency. Argatroban can be used as an alternative to lepirudin for prophylaxis or treatment of patients with, or at risk of developing, heparin-induced thrombocytopenia. In addition to prolonging the aPTT, argatroban also prolongs the PT, which can complicate the transitioning of patients from argatroban to warfarin. A chromogenic factor X assay can be used instead of the PT to monitor warfarin in these patients.

**ANTITHROMBIN.** Antithrombin (ATRYN) is a recombinant form of human antithrombin produced from the milk of genetically modified goats. It is approved as an anticoagulant for patients with hereditary antithrombin deficiency undergoing surgical procedures.

**DROTRECOGIN ALFA.** Drotrecogin alfa (XIGRIS) is a recombinant form of human-activated protein C that inhibits coagulation by proteolytic inactivation of factors Va and VIIIa. It also has anti-inflammatory effects. Xigris was withdrawn from the U.S. market in October, 2011, after a major clinical study showed no improvement in 28-day survival in adult patients with sepsis.

**ORAL ANTICOAGULANTS**

**WARFARIN**

Investigating a hemorrhagic disorder in cattle resulting from ingestion of spoiled sweet clover silage, Campbell and Link, in 1939, identified the hemorrhagic agent as bishydroxycoumarin (dicoumarol). Subsequently, a more potent synthetic congener was introduced as a rodenticide; the compound was named warfarin after the patent holder, Wisconsin Alumni Research Foundation (WARF). These anticoagulants have become mainstays for prevention of thromboembolic disease.

**MECHANISM OF ACTION.** The oral anticoagulants are antagonists of vitamin K. Coagulation factors II, VII, IX, and X and the anticoagulant proteins C and S are synthesized mainly in the liver and are biologically inactive unless 9-13 of the amino-terminal glutamate residues are carboxylated to form the Ca\(^{2+}\)-binding
Gla residues. This reaction of the decarboxy precursor protein requires CO₂, O₂, and reduced vitamin K and is catalyzed by γ-glutamyl carboxylase (Figure 30–6). Carboxylation is coupled to the oxidation of vitamin K to its corresponding epoxide. Reduced vitamin K must be regenerated from the epoxide for sustained carboxylation and synthesis of biologically competent proteins. The enzyme that catalyzes this, vitamin K epoxide reductase (VKOR), is inhibited by therapeutic doses of warfarin.

**Figure 30–6** The vitamin K cycle and mechanism of action of warfarin. In the racemic mixture of S- and R-enantiomers, S-warfarin is more active. By blocking vitamin K epoxide reductase encoded by the VKORC1 gene, warfarin inhibits the conversion of oxidized vitamin K epoxide into its reduced form, vitamin K hydroquinone. This inhibits vitamin K-dependent α-carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a c-glutamyl carboxylase that catalyzes the a-carboxylation process whereby prozymogens are converted to zymogens capable of binding Ca²⁺ and interacting...
with anionic phospholipids. S-warfarin is metabolized by CYP2C9; common genetic polymorphisms in this enzyme increase warfarin metabolism. Polymorphisms in the C1 subunit of vitamin K reductase (VKORC1) increase the susceptibility of the enzyme to warfarin-induced inhibition. Thus, patients expressing polymorphisms in these 2 enzymes require reduction of warfarin dosage (see Table 30–2).

Therapeutic doses of warfarin decrease by 30-50% the total amount of each vitamin K-dependent coagulation factor made by the liver; in addition, the secreted molecules are under-carboxylated, resulting in diminished biological activity (10-40% of normal). Congenital deficiencies of the procoagulant proteins to these levels cause mild bleeding disorders. Vitamin K antagonists have no effect on the activity of fully carboxylated molecules in the circulation. The approximate $t_{1/2}$ (in hours) are as follows: factor VII, 6; factor IX, 24; factor X, 36; factor II, 50; protein C, 8; and protein S, 30. Because of the long $t_{1/2}$ of some of the coagulation factors, in particular factor II, the full antithrombotic effect of warfarin is not achieved for several days, even though the PT may be prolonged soon after administration due to the more rapid reduction of factors with a shorter $t_{1/2}$, in particular factor VII.

DO\-SAGE. The usual adult dosage of warfarin is 2-5 mg/day for 2-4 days, followed by 1-10 mg/day as indicated by measurements of the international normalized ratio (INR), a value derived from the patient’s PT (see the functional definition of INR in the section on “Laboratory Monitoring”). As presented later, common genetic polymorphisms render patients more or less sensitive to warfarin. A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly. Warfarin usually is administered orally. Warfarin also can be given intravenously without modification of the dose. Intramuscular injection is not recommended.

ADME. The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Different commercial preparations of warfarin tablets vary in their rate of dissolution, and this causes some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Plasma concentrations peak in 2-8 h. Warfarin is administered as a racemic mixture of S- and R-warfarin. S-warfarin is 3- to 5-fold more potent than R-warfarin and is metabolized principally by CYP2C9.
Inactive metabolites of warfarin are excreted in urine and stool. The $t_{1/2}$ varies (25-60 h); the duration of action of warfarin is 2-5 days.

Table 30–2 summarizes the effects of known genetic factors on warfarin dose requirements. Polymorphisms in 2 genes, CYP2C9 and VKORC1 (vitamin K epoxide reductase complex, subunit 1) account for most of the genetic contribution to variability in warfarin response. CYP2C9 variants affect warfarin pharmacokinetics, whereas VKORC1 variants affect warfarin pharmacodynamics. Common variations in the CYP2C9 gene (designated CYP2C9*2 and *3), encode an enzyme with decreased activity, and thus are associated with higher drug concentrations and reduced warfarin dose requirements. VKORC1 is the target of coumarin anticoagulants such as warfarin (see Figure 30–6). VKORC1 variants are more prevalent than those of CYP2C9. The prevalence of VKORC1 genetic variants is higher in Asians, followed by European Americans and African Americans. The warfarin dose requirement is decreased in these variants. Based on evidence that genetic variations affect warfarin dose requirements and responses to therapy, the FDA amended the prescribing information for warfarin to indicate that lower warfarin initiation doses be considered for patients with CYP2C9 and VKORC1 genetic variations. Efforts to facilitate the rational incorporation of genetic information into patient care include the development of a warfarin-dosing algorithm and point-of-care methods for CYP2C9 and VKORC1 genotyping.

**Table 30–2**

**Effect of CYP2C9 Genotypes and VKORC1 Haplotypes on Warfarin Dosing**
DRUG AND OTHER INTERACTIONS WITH ORAL ANTICOAGULANTS. Any substance or condition is potentially dangerous if it alters:

- The uptake or metabolism of the oral anticoagulant or vitamin K
- The synthesis, function, or clearance of any factor or cell involved in hemostasis or fibrinolysis
- The integrity of any epithelial surface

Patients must be educated to report the addition or deletion of any medication, including nonprescription drugs and food supplements. Some of the more commonly described factors that cause a decreased effect of oral anticoagulants include:

- Reduced absorption of drug caused by binding to cholestyramine in the GI tract
- Increased volume of distribution and a short $t_{1/2}$ secondary to hypoproteinemia, as in nephrotic syndrome
- Increased metabolic clearance of drug secondary to induction of hepatic enzymes, especially CYP2C9, by barbiturates, carbamazepine, or rifampin

*Polymorphisms in 2 genes, CYP2C9, and VKORC1, largely account for the genetic contribution to the variability in warfarin response. CYP2C9 variants affect warfarin pharmacokinetics. CYP2C9 metabolizes warfarin and the non-*1/*1 variants are less active than CYP2C9*1/*1, necessitating a reduction in dose. VKORC1 variants affect warfarin pharmacodynamics. VKORC1 is the target of coumarin anticoagulants such as warfarin. The non-A/A and A/A forms have decreased requirements for warfarin.*

• Ingestion of large amounts of vitamin K-rich foods or supplements
• Increased levels of coagulation factors during pregnancy

The PT can be shortened in any of these cases.

Frequently cited interactions that enhance the risk of hemorrhage in patients taking oral anticoagulants include decreased metabolism due to \textit{CYP2C9} inhibition by amiodarone, azole antifungals, cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfinpyrazone, tolcapone, or zafirlukast, and displacement from protein-binding sites caused by loop diuretics or valproate. Relative deficiency of vitamin K may result from inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause excessive PT prolongation in patients adequately controlled on warfarin. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions increase the prolongation of the PT. Serious interactions that do not alter the PT include inhibition of platelet function by agents such as aspirin and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than 1 effect; e.g., clofibrate increases the rate of turnover of coagulation factors and inhibits platelet function.

\textbf{SENSITIVITY TO WARFARIN.} \~10\% of patients require 11.5 mg/day of warfarin to achieve an INR of 2-3. These patients often possess variant alleles of \textit{CYP2C9} or variant \textit{VKORC1} haplotypes, which affect the pharmacokinetics or pharmacodynamics of warfarin, respectively.

\textbf{TOXICITIES}

\textbf{BLEEDING.} Bleeding is the major toxicity of warfarin. The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of a potential anatomical source of bleeding. The incidence of major bleeding episodes is generally \~3\% per year in patients treated with a target INR of 2-3. The risk of intracranial
hemorrhage increases dramatically with an INR of 4.

If the INR is above the therapeutic range but the patient is not bleeding or in need of a surgical procedure, warfarin can be discontinued temporarily and restarted at a lower dose once the INR is within the therapeutic range. If the INR is >5, vitamin K₁ (phytonadione, Mephyton, Aquamephyton) can be given orally at a dose of 1-2.5 mg (for INR 5) or 3-5 mg (for INR 9). These doses of oral vitamin K₁ generally cause the INR to fall substantially within 24-48 h without rendering the patient resistant to further warfarin therapy. Higher doses or parenteral administration may be required if more rapid correction of the INR is necessary. The effect of vitamin K₁ is delayed for at least several hours because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound warfarin overdosage (INR >20), adequate concentrations of vitamin K₁-dependent coagulation factors can be restored by transfusion of fresh frozen plasma (10-20 mL/kg), supplemented with 10 mg of vitamin K₁, given by slow intravenous infusion. Transfusion of plasma may need to be repeated because the transfused factors (particularly factor VII) are cleared from the circulation more rapidly than the residual oral anticoagulant. Vitamin K₁ administered intravenously carries the risk of anaphylactoid reactions and therefore should be used cautiously. Patients who receive high doses of vitamin K₁ may become unresponsive to warfarin for several days, but heparin can be used if continued anticoagulation is required.

**Birth Defects.** Administration of warfarin during pregnancy causes birth defects and abortion. CNS abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal PT values are in the therapeutic range. Vitamin K antagonists should not be used during pregnancy, but heparin, LMWH, or fondaparinux can be used safely in this circumstance.

**Skin Necrosis.** Warfarin-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3-10 days after treatment is initiated. The lesions typically are on the extremities, but adipose tissue, the penis, and the female breast also may be involved.

**Other Toxicities.** A reversible, sometimes painful, blue-tinged discoloration of
the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3-8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

**CLINICAL USE.** Vitamin K antagonists are used to prevent the progression or recurrence of acute DVT or pulmonary embolism following an initial course of heparin. They also are effective in preventing venous thromboembolism in patients undergoing orthopedic or gynecological surgery, recurrent coronary ischemia in patients with acute myocardial infarction, and systemic embolization in patients with prosthetic heart valves or chronic atrial fibrillation.

Prior to initiation of therapy, laboratory tests are used in conjunction with the history and physical examination to uncover hemostatic defects that might make the use of vitamin K antagonists more dangerous (e.g., congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular abnormalities). Thereafter, the INR calculated from the patient’s PT is used to monitor the extent of anticoagulation and compliance. Therapeutic INR ranges for various clinical indications have been established empirically and reflect dosages that reduce the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications, the target INR is 2-3. A higher target INR (e.g., 2.5-3.5) generally is recommended for patients with high-risk mechanical prosthetic heart valves.

For treatment of acute venous thromboembolism, heparin, LMWH, or fondaparinux usually is continued for at least 5 days after warfarin therapy is begun and until the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of the vitamin K-dependent coagulation factors with long $t_{1/2}$, especially factor II. Frequent INR measurements are indicated at the onset of therapy to guard against excessive anticoagulation in the unusually sensitive patient.

**OTHER VITAMIN K ANTAGONISTS**

**PHENPROCOUMON AND ACENOCOUMAROL.** These agents
generally are not available in the U.S. but are prescribed in the E.U. and elsewhere. Phenprocoumon (MARUMAR) has a longer plasma $t_{1/2}$ (5 days) than warfarin, as well as a somewhat slower onset of action and a longer duration of action (7-14 days). It is administered in daily maintenance doses of 0.75-6 mg. Acenocoumarol (SINTHROME) has a shorter $t_{1/2}$ (10-24 h), a more rapid effect on the PT, and a shorter duration of action (2 days). The maintenance dose is 1-8 mg daily.

**INDANDIONE DERIVATIVES.** Anisindione (MIRADON) is available for clinical use in some countries. It is similar to warfarin in its kinetics of action but offers no clear advantages and may have a higher frequency of untoward effects. Phenindione (DINDEVAN) still is available in some countries. Serious hypersensitivity reactions, occasionally fatal, can occur within a few weeks of starting therapy with this drug.

**RODENTICIDES.** Bromadoline, brodifacoum, diphenadione, chlorophacinone, and pindone are long-acting agents (prolongation of the PT may persist for weeks). They are of interest because they sometimes are agents of accidental or intentional poisoning. In this setting, reversal of the coagulopathy can require very large doses of vitamin K (i.e., 1100 mg/day) for weeks or months.

**NEW ORAL ANTICOAGULANTS**

**DABIGATRAN ETEXILATE (PRADAXA, PRADAX).** Dabigatran etexilate is a prodrug that is rapidly converted to dabigatran, which reversibly blocks the active site of thrombin.

The drug has oral bioavailability of T6%, a peak onset of action in 2 h, and a plasma $t_{1/2}$ of 12-14 h. When given in fixed doses, dabigatran etexilate produces such a predictable anticoagulant response that routine coagulation monitoring is unnecessary. Dabigatran etexilate is approved for stroke prevention in patients with atrial fibrillation.

**RIVAROXABAN (XARELTO).** Rivaroxaban is an oral factor Xa inhibitor.
It has 80% oral bioavailability, a peak onset of action in 3 h, and a plasma $t_{1/2}$ of 7-11 h. About one-third of the drug is excreted unchanged in the urine, the remainder is metabolized by the liver, and inactive metabolites are excreted in the urine or feces. This drug is given in fixed doses and does not require coagulation monitoring. Rivaroxaban is approved for prophylaxis of venous thromboembolism in patients undergoing hip or knee replacement surgery and for stroke prevention in patients with non-valvular atrial fibrillation.

**APIXABAN (ELIQUIS).** Apixaban is an oral factor Xa inhibitor.

Apixaban is indicated for the prevention of stroke and embolism in patients with non-valvular fibrillation. The recommended oral dose is 5 mg taken twice daily, and half that in patients ≥80 years old, ≤60 kg, or whose serum creatinine ≥1.5 mg/dL. Apixaban has 50% oral bioavailability, peak onset 3-4 h, and an apparent $t_{1/2}$ of 12 h due to prolonged absorption from the GI tract. The drug is metabolized mainly by CYP3A4 and is a substrate for P-gp. Thus, coadministration with other inhibitors/substrates of these enzymes (e.g., ketoconazole, itraconazole, ritonavir, clarithromycin) requires halving the dose rate for apixaban.

**FIBRINOLYTIC DRUGS**

The fibrinolytic pathway is summarized by Figure 30–3. The action of fibrinolytic agents is best understood in conjunction with an understanding of the characteristics of its components.

**PLASMINOGEN.** Plasminogen is a single-chain glycoprotein that is converted to the active protease plasmin by proteolytic cleavage.

Plasminogen’s 5 kringle domains mediate the binding of plasminogen (or plasmin) to carboxyl-terminal lysine residues in partially degraded fibrin; this enhances fibrinolysis. A plasma carboxypeptidase termed *thrombin-activatable fibrinolysis inhibitor* (TAFI) can remove these lysine residues and thereby attenuate fibrinolysis. The lysine-binding kringle domains of plasminogen also promote formation of complexes of plasmin with $\alpha_2$-antiplasmin, the major physiological plasmin inhibitor. A degraded form of plasminogen termed *lys-
plasminogen binds to fibrin with higher affinity than intact plasminogen.

**α2-ANTIPLASMIN.** α2-Antiplasmin, a glycoprotein, forms a stable complex with plasmin, thereby inactivating it.

Plasma concentrations of P2-antiplasmin (1 -M) are sufficient to inhibit about 50% of potential plasmin. When massive activation of plasminogen occurs, the inhibitor is depleted, and free plasmin causes a “systemic lytic state” in which hemostasis is impaired. In this state, fibrinogen is degraded and fibrinogen degradation products impair fibrin polymerization and therefore increase bleeding from wounds. c2-Antiplasmin inactivates plasmin nearly instantaneously, as long as the first kringle domain on plasmin is unoccupied by fibrin or other antagonists, such as aminocaproic acid (see “Inhibitors of Fibrinolysis” section).

**TISSUE PLASMINOGEN ACTIVATOR.** t-PA is a serine protease and a poor plasminogen activator in the absence of fibrin. t-PA binds to fibrin and activates fibrin-bound plasminogen several hundredfold more rapidly than it activates plasminogen in the circulation.

Because it has little activity except in the presence of fibrin, physiological t-PA concentrations of 5-10 ng/mL do not induce systemic plasmin generation. During therapeutic infusions of t-PA, however, when concentrations rise to 300-3000 ng/mL, a systemic lytic state can occur. Clearance of t-PA primarily occurs by hepatic metabolism, and its \( t_{1/2} \) is 5 min. t-PA is effective in lysing thrombi during treatment of acute myocardial infarction or acute ischemic stroke.

t-PA (alteplase, Activase) is produced by recombinant DNA technology. The currently recommended (“accelerated”) regimen for coronary thrombolysis is a 15-mg intravenous bolus, followed by 0.75 mg/kg of body weight over 30 min (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant variants of t-PA now are available (reteplase, Retavase and tenecteplase, TNKase). They differ from native t-PA by having longer plasma half-lives that allow convenient bolus dosing. They also are relatively resistant to inhibition by PAI-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity.
**STREPTOKINASE.** Streptokinase (STREPTASE) is a 47,000-Da protein produced by β-hemolytic streptococci.

It has no intrinsic enzymatic activity but forms a stable, noncovalent 1:1 complex with plasminogen. This produces a conformational change that exposes the active site on plasminogen and facilitates the formation of plasmin. Streptokinase is rarely used clinically for fibrinolysis.

**HEMORRHAGIC TOXICITY OF THROMBOLYTIC THERAPY.** The major toxicity of all thrombolytic agents is hemorrhage, which results from 2 factors:

1. The lysis of fibrin in hemostatic plugs at sites of vascular injury
2. The systemic lytic state that results from systemic plasmin generation, which produces fibrinogenolysis and degradation of other coagulation factors (especially factors V and VIII)

The contraindications to fibrinolytic therapy are listed in Table 30–3. Patients with these conditions should not receive such treatment.

**Table 30–3**

*CPR, cardiopulmonary resuscitation; INR, international normalized ratio.*
If heparin is used concurrently with t-PA, serious hemorrhage will occur in 2-4% of patients. Intracranial hemorrhage is by far the most serious problem. Hemorrhagic stroke occurs with all regimens and is more common when heparin is used. The efficacies of t-PA and streptokinase in treating myocardial infarction are essentially identical. Both agents reduce death and reinfarction by ~30% in regimens containing aspirin.

**INHIBITORS OF FIBRINOLYSIS**

**AMINOCAPROIC ACID.** Aminocaproic acid (AMICAR) is a lysine analog that competes for lysine binding sites on plasminogen and plasmin, blocking the interaction of plasmin with fibrin. Aminocaproic acid is thereby a potent inhibitor of fibrinolysis and can reverse states that are associated with excessive fibrinolysis.

The main problem with its use is that thrombi that form during treatment with the drug are not lysed. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with aminocaproic acid. Aminocaproic acid has been used to reduce bleeding after prostatic surgery or after tooth extractions in hemophiliacs. Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 h. For intravenous use, a loading dose of 4-5 g is given over 1 h, followed by an infusion of 1-1.25 g/h until bleeding is controlled. No more than 30 g should be given in a 24-h period. Rarely, the drug causes myopathy and muscle necrosis.

**TRANEXAMIC ACID.** Tranexamic acid (CYKLOKAPRON, LYSTEDA) is a lysine analog that competes for lysine binding sites on plasminogen and plasmin, thus blocking their interaction with fibrin.

Tranexamic acid is used for the same indications as aminocaproic acid and given intravenously or orally. Tranexamic acid is excreted in the urine; dose reductions are necessary in patients with renal impairment. Oral tranexamic acid is approved for treatment of heavy menstrual bleeding, usually given at a dose of 1 g 4 times a day for 4 days.

**ANTIPLATELET DRUGS**
Platelets provide the initial hemostatic plug at sites of vascular injury. They also participate in pathological thromboses that lead to myocardial infarction, stroke, and peripheral vascular thromboses. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms (Figure 30–7); thus, in combination, their effects are additive or even synergistic.

Figure 30–7 Sites of action of antiplatelet drugs. Aspirin inhibits thromboxane A₂ (TxA₂) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TxA₂ release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block P2Y₁₂.
a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of P2Y_{12}. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor (vWF) from binding to activated glycoprotein (GP) IIb/IIIa. SCH530348 and E5555 inhibit thrombin-mediated platelet activation by targeting protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

**ASPIRIN.** In platelets, the major cyclooxygenase product is TxA$_2$, a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of TxA$_2$ by acetylating a serine residue near the active site of platelet cyclooxygenase-1 (COX-1). Because platelets do not synthesize new proteins, the action of aspirin on platelet COX-1 is permanent, lasting for the life of the platelet (7-10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function.

Complete inactivation of platelet COX-1 is achieved with a daily aspirin dose of 75 mg. Therefore, aspirin is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicate that aspirin, when used as an antithrombotic drug, is maximally effective at doses of 50-320 mg/day. Higher doses do not improve efficacy and potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding. Other NSAIDs that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and in fact may even interfere with low-dose aspirin regimens (see Chapters 33 and 34).

**DIPYRIDAMOLE.** Dipyridamole (PERSANTINE) interferes with platelet function by increasing the cellular concentration of cyclic AMP.

This effect is mediated by inhibition of cyclic nucleotide phosphodiesterases and/or by blockade of uptake of adenosine, thereby increasing the dwell time of adenosine at cell surface adenosine A$_2$ receptors that link to the stimulation of
platelet adenylyl cyclase. Dipyridamole is a vasodilator that, in combination with warfarin, inhibits embolization from prosthetic heart valves.

**TICLOPIDINE (TICLID, others).** Ticlopidine is a thienopyridine prodrug that inhibits the P2Y12 receptor.

Platelets contain 2 purinergic receptors, P2Y₁ and P2Y₁₂; both are GPCRs for ADP. The ADP-activated platelet P2Y₁ receptor couples to the Gq–PLC–IP₃–Ca²⁺ pathway and induces a shape change and aggregation. The P2Y₁₂ receptor couples to Gi and, when activated by ADP, inhibits adenylyl cyclase, resulting in lower levels of cyclic AMP and thereby less cyclic AMP–dependent inhibition of platelet activation. Both receptors must be stimulated to result in platelet activation.

Ticlopidine is converted to the active thiol metabolite by a hepatic CYP. It is rapidly absorbed and highly bioavailable. It permanently inhibits the P2Y₁₂ receptor by forming a disulfide bridge between the thiol on the drug and a free cysteine residue in the extracellular region of the receptor; thus the effect is prolonged effect, even though the free drug has a short t₁/₂. Maximal inhibition of platelet aggregation is not seen until 8-11 days after starting therapy. The usual dose is 250 mg twice daily. Loading doses of 500 mg sometimes are given to achieve a more rapid onset of action. Inhibition of platelet aggregation persists for a few days after the drug is stopped.

**Adverse Effects.** The most common side effects are nausea, vomiting, and diarrhea. The most serious is severe neutropenia (absolute neutrophil count <500/5L), which occurred in 2.4% of stroke patients given the drug during premarketing clinical trials. Fatal agranulocytosis with thrombocytopenia has occurred within the first 3 months of therapy; therefore, frequent blood counts should be obtained during the first few months of therapy, with immediate discontinuation of therapy should cell counts decline. Platelet counts also should be monitored, as thrombocytopenia has been reported. Rare cases of thrombotic thrombocytopenic purpura hemolytic uremic syndrome (TTP-HUS) have been associated with ticlopidine, with high incidence (1 in 1600-4800 patients) when the drug is used after cardiac stenting and high mortality among those affected. Remission of TTP-HUS has been reported when the drug is stopped.
**Therapeutic Uses.** Because ticlopidine is associated with life-threatening blood dyscrasias and a relatively high rate of TTP-HUS, it has largely been replaced by clopidogrel.

**CLOPIDOGREL (PLAVIX).** Clopidogrel is closely related to ticlopidine. Clopidogrel also is an irreversible inhibitor of platelet P2Y$_{12}$ receptors but is more potent and has a more favorable toxicity profile than ticlopidine, with thrombocytopenia and leukopenia occurring only rarely.

Clopidogrel is a prodrug with a slow onset of action. The usual dose is 75 mg/day with or without an initial loading dose of 300 or 600 mg. The drug is somewhat better than aspirin in the secondary prevention of stroke, and the combination of clopidogrel plus aspirin is superior to aspirin alone for prevention of recurrent ischemia in patients with unstable angina. The FDA-approved indications for clopidogrel are to reduce the rate of stroke, myocardial infarction, and death in patients with recent myocardial infarction or stroke, established peripheral arterial disease, or acute coronary syndrome.

**PRASUGREL (EFFIENT).** The newest member of the thienopyridine class, prasugrel also is a prodrug that requires metabolic activation. Its onset of action is more rapid than that of ticlopidine or clopidogrel, and prasugrel produces greater and more predictable inhibition of ADP-induced platelet aggregation.

Prasugrel is rapidly and completely absorbed from the gut. Virtually all of the absorbed prasugrel undergoes activation; by comparison, only 15% of absorbed clopidogrel undergoes metabolic activation. Because the active metabolites of prasugrel and the other thienopyridines bind irreversibly to the P2Y$_{12}$ receptor, these drugs have a prolonged effect after discontinuation. This can be problematic if patients require urgent surgery.

Prasugrel was compared with clopidogrel in patients with acute coronary syndromes scheduled to undergo a coronary intervention. The incidence of cardiovascular death, myocardial infarction, and stroke was significantly lower with prasugrel than with clopidogrel mainly reflecting a reduction in the
incidence of nonfatal myocardial infarction. The incidence of stent thrombosis also was lower with prasugrel than with clopidogrel. However, these advantages were at the expense of significantly higher rates of fatal and life-threatening bleeding. Because patients with a history of a prior stroke or transient ischemic attack are at particularly high risk of bleeding, the drug is contraindicated in those with a history of cerebrovascular disease. Caution is required if prasugrel is used in patients weighing <60 kg or in those with renal impairment. After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. Patients >75 years of age or weighing <60 kg may do better with a daily prasugrel dose of 5 mg.

GLYCOPROTEIN IIB/IIIA INHIBITORS. Glycoprotein IIb/IIIa is a platelet-surface integrin, designated αIbβ3 by the integrin nomenclature. This dimeric glycoprotein undergoes a conformational transformation when platelets are activated to serve as a receptor for fibrinogen and von Willebrand factor, which anchor platelets to foreign surfaces and to each other, thereby mediating aggregation. Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or the thienopyridine platelet inhibitors. Three agents are approved for use at present; their features are highlighted in Table 30–4.

*KGD, Lysine - Glycine - Aspartate; RGD, Arginine - Glycine - Aspartate.*

**ABCIXIMAB.** Abciximab (REOPRO) is the Fab fragment of a humanized monoclonal antibody -directed against the mIb β3
receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells.

The antibody is administered to patients undergoing percutaneous angioplasty for coronary thromboses, and when used in conjunction with aspirin and heparin, has been shown to prevent restenosis, recurrent myocardial infarction, and death. The $t_{1/2}$ of the unbound antibody is ~30 min, but antibody remains bound to the $\alpha_{IIb}\beta_3$ receptor and inhibits platelet aggregation as measured in vitro for 18-24 h after infusion. It is given as a 0.25 to mg/kg bolus followed by 0.125 $\mu$g/kg/min for 12 h or longer.

**Adverse Effects.** The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for the fibrinolytic agents listed in Table 30–3. The frequency of major hemorrhage in clinical trials varies from 1-10%, depending on the intensity of anticoagulation with heparin. Thrombocytopenia with a platelet count <50,000 occurs in about 2% of patients and may be due to development of neo-epitopes induced by bound antibody. Since the duration of action is long, if major bleeding or emergent surgery occurs, platelet transfusions can reverse the aggregation defect because free antibody concentrations fall rapidly after cessation of infusion. Readministration of antibody has been performed in a small number of patients without evidence of decreased efficacy or allergic reactions. The expense of the antibody limits its use.

**EPTIFIBATIDE.** Eptifibatide (INTEGRILIN) is a cyclic peptide inhibitor of the fibrinogen binding site on $\alpha_{IIb}\beta_3$. It is administered intravenously and blocks platelet aggregation.

Eptifibatide is given as a bolus of 180 $\mu$g/kg followed by 2 $\mu$g/kg/min for up to 96 h. It is used to treat acute coronary syndrome and for angioplastic coronary interventions (myocardial infarction and death have been reduced by ~20%). The benefit of the drug is somewhat less than that obtained with abciximab, perhaps because eptifibatide is specific for $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. Platelet aggregation is restored within 6-12 h after cessation of infusion. Eptifibatide generally is administered in conjunction with aspirin and heparin.
Adverse Effects. The major side effect is bleeding, as is the case with abciximab. The frequency of major bleeding in trials was about 10%, compared with ~9% in a placebo group, which included heparin. Thrombocytopenia has been seen in 0.5-1% of patients.

TIROFIBAN. Tirofiban (AGGRASTAT) is a nonpeptide, small-molecule inhibitor of αIIbβ3 that appears to have a mechanism of action similar to eptifibatide.

Tirofiban has a short duration of action and has efficacy in non-Q-wave myocardial infarction and unstable angina. Reductions in death and myocardial infarction have been ~20% compared to placebo. Side effects also are similar to those of eptifibatide. The agent is specific to αIIbβ3 and does not react with the vitronectin receptor. Meta-analysis of trials using αIIbβ3 inhibitors suggests that their value in antiplatelet therapy after acute myocardial infarction is limited. Tirofiban is administered intravenously at an initial rate of 0.4 μg/kg/min for 30 min, and then continued at 0.1 μg/kg/min for 12-24 h after angioplasty or atherectomy. It is used in conjunction with heparin.

NEWER ANTIPLATELET AGENTS

TICAGRELOR (BRILINTA). Ticagrelor is an orally active, reversible inhibitor of P2Y12. The drug is given twice daily and not only has a more rapid onset and offset of action than clopidogrel, but also produces greater and more predictable inhibition of ADP-induced platelet aggregation. Ticagrelor is FDA approved for the prevention of thrombotic events. It is the first new antiplatelet drug to demonstrate a reduction in cardiovascular death compared with clopidogrel in patients with acute coronary syndromes.

Other new agents in advanced stages of development include cangrelor, reversible P2Y12 antagonist, and SCH530348 and E5555, orally effective inhibitors of the protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

THE ROLE OF VITAMIN K
Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ-carboxylation of multiple glutamate residues of several clotting factors and anticoagulant proteins. The vitamin K-dependent formation of Gla residues permits the appropriate interactions of clotting factors, Ca\(^{2+}\), and membrane phospholipids and modulator proteins (see Figures 30–1, 30–2, and 30–3). Vitamin K antagonists (coumarin derivatives) block Gla (γ-carboxyglutamate) formation and thereby inhibit clotting; excess vitamin K\(_1\) can reverse the effects.

Vitamin K activity is associated with at least 2 distinct natural substances, designated as vitamin K\(_1\) and vitamin K\(_2\). Vitamin K\(_1\), or phytonadione (also referred to as phylloquinone), is 2-methyl-3-phytyl-1, 4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K\(_2\) actually is a series of compounds (the menaquinones) in which the phytanyl side chain of phytonadione has been replaced by a side chain built up of 2-13 prenyl units. Considerable synthesis of menaquinones occurs in gram-positive bacteria; indeed, intestinal flora synthesize the large amounts of vitamin K contained in human and animal feces. Menadione is at least as active on a molar basis as phytonadione.

![Phytonadione](image)

**PHYSIOLOGICAL FUNCTIONS AND PHARMACOLOGICAL ACTIONS.** Phytonadione and menaquinones promote the biosynthesis of:

- The Gla forms of factors II (prothrombin), VII, IX, and X
- Anticoagulant proteins C and S; protein Z (a cofactor to the inhibitor of Xa)
- The bone Gla protein osteocalcin
• The matrix Gla protein
• The growth arrest–specific protein 6 (Gas6)
• Four transmembrane monospans of unknown function

Figure 30–6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. The γ-glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and function as a multicomponent complex. With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ-carboxylation of glutamate also occurs in lung, bone, and other cell types. Two natural mutations in γ-glutamyl carboxylase lead to bleeding disorders.

HUMAN REQUIREMENTS. In patients made vitamin K deficient by a starvation diet and antibiotic therapy for 3–4 weeks, the minimum daily requirement is estimated to be 0.03 μg/kg of body weight and possibly as high as 1 μg/kg, which is approximately the recommended intake for adults (70 μg/day).

SYMPTOMS OF DEFICIENCY. The chief clinical manifestation of vitamin K deficiency is an increased tendency to bleed. Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptyisis is uncommon. The discovery of a vitamin K-dependent protein in bone suggests that the fetal bone abnormalities associated with the administration of oral anticoagulants during the first trimester of pregnancy (“fetal warfarin syndrome”) may be related to a deficiency of the vitamin. Vitamin K plays a role in adult skeletal maintenance and the prevention of osteoporosis. Low concentrations of the vitamin are associated with deficits in bone mineral density and fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and also improves bone mineral density, but the relationship of these 2 effects is unclear. Bone mineral density in adults is not changed by therapeutic use of vitamin K antagonists, but new bone formation may be affected.

TOXICITY. Phytonadione and the menaquinones are nontoxic. Menadione and its derivatives (synthetic forms of vitamin K) have been implicated in producing hemolytic anemia and kernicterus in neonates, and should not be used as a therapeutic form of vitamin K.

ADME. The mechanism of intestinal absorption of compounds with vitamin K
activity varies with their solubility. In the presence of bile salts, phytonadione and the menaquinones are adequately absorbed from the intestine, phytonadione by an energy-dependent, saturable process in proximal portions of the small intestine, menaquinones by diffusion in the distal portions of the small intestine and in the colon. Following absorption, phytonadione is incorporated into chylomicrons in close association with triglycerides and lipoproteins. The extremely low phytonadione levels in newborns may be partly related to very low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phytonadione and menaquinones are concentrated in the liver, but the concentration of phytonadione declines rapidly. Menaquinones, produced in the lower bowel, are less biologically active due to their long side chain. Very little vitamin K accumulates in other tissues. There is only modest storage of vitamin K in the body: under circumstances in which lack of bile interferes with absorption of vitamin K, hypoprothrombinemia develops slowly over several weeks.

**THERAPEUTIC USES.** Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin, or as a consequence of the action of a vitamin K antagonist.

Phytonadione (AQUAMEPHYTON, KONAKION, Mephyton) is available as tablets and in a dispersion with buffered polysorbate and propylene glycol (KONAKION) or polyoxyethylated fatty acid derivatives and dextrose (AQUAMEPHYTON). KONAKION is administered only intramuscularly. AQUAMEPHYTON may be given by any route; however, oral or subcutaneous injection is preferred because severe reactions resembling anaphylaxis have followed its intravenous administration.

**Inadequate Intake.** After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare. The vitamin is present in many foods and is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce a hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation. It is recommended to give 1 mg of phytonadione per week (the equivalent of about 150 μg/day) to patients on total parenteral nutrition.

**HYPOPROTHROMBINEMIA OF THE NEWBORN**
Healthy newborn infants show decreased plasma concentrations of vitamin K-dependent clotting factors for a few days after birth, the time required to obtain an adequate dietary intake of the vitamin and to establish a normal intestinal flora. Measurements of non-γ-carboxylated prothrombin suggest that vitamin K deficiency occurs in about 3% of live births.

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K. In addition, the intestinal flora of breast-fed infants may lack microorganisms that synthesize the vitamin. Commercial infant formulas are supplemented with vitamin K. In the neonate with hemorrhagic disease of the newborn, the administration of vitamin K raises the concentration of these clotting factors to the level normal for the newborn infant and controls the bleeding tendency within about 6 h. The routine administration of 1 mg phytonadione intramuscularly at birth is required by law in the U.S. This dose may have to be increased or repeated if the mother has received anticoagulant or anticonvulsant drug therapy or if the infant develops bleeding tendencies. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg/day for 2 weeks).

Inadequate Absorption. Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with either intrahepatic or extrahepatic biliary obstruction or a severe defect in the intestinal absorption of fat from other causes.

BILIARY OBSTRUCTION OR FISTULA
Bleeding that accompanies obstructive jaundice or biliary fistula responds promptly to the administration of vitamin K. Oral phytonadione administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin activity of the blood rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual dose is 10 mg/day of vitamin K.

MALABSORPTION SYNDROMES
Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are cystic fibrosis, sprue, Crohn disease and enterocolitis, ulcerative colitis, dysentery, and extensive resection of bowel. Because drugs
that greatly reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. For immediate correction of the deficiency, parenteral therapy should be used.

**Inadequate Utilization.** Hepatocellular disease may be accompanied or followed by hypoprothrombinemia. Hepatocellular damage also may be secondary to long-lasting biliary obstruction. If an inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of phytonadione daily. Paradoxically, the administration of large doses of vitamin K or its analogs in an attempt to correct the hypoprothrombinemia associated with severe hepatitis or cirrhosis actually may result in a further depression of the concentration of prothrombin.

**Drug- and Venom-Induced Hypoprothrombinemia.** Anticoagulant drugs such as warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants is above. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom destroys or inactivates prothrombin.
chapter 31
Drug Therapy for Hypercholesterolemia and Dyslipidemia

Hyperlipidemia is a major cause of atherosclerosis and atherosclerosis-induced conditions, such as coronary heart disease (CHD), ischemic cerebrovascular disease, and peripheral vascular disease. These conditions cause morbidity or mortality in a majority of middle-aged or older adults. Dyslipidemias, including hyperlipidemia (hypercholesterolemia) and low levels of high-density-lipoprotein cholesterol (HDL-C), are major causes of increased atherogenic risk; both genetic disorders and lifestyle contribute to the dyslipidemias seen in countries around the world.

Classes of drugs that modify cholesterol levels include:

- Statins, inhibitors of 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase
- Bile acid–binding resins
- Nicotinic acid (niacin)
- Fibric acid derivatives
- Ezetimibe, an inhibitor of cholesterol absorption

These drugs provide benefit in patients across the entire spectrum of cholesterol levels, primarily by reducing levels of low-density-lipoprotein cholesterol (LDL-C). Drug regimens that reduce LDL-C levels moderately (30-40%) can reduce fatal and nonfatal CHD events and strokes by as much as 30-40%. In patients with low HDL-C and average LDL-C levels, appropriate drug therapy reduces CHD endpoint events by 20-35%. Because two-thirds of patients with CHD in the U.S. have low HDL-C levels (<40 mg/dL in men, <50 mg/dL in women), low-HDL-C patients should be treated for dyslipidemia, even if their LDL-C levels are in the normal range.

Severe hypertriglyceridemia (i.e., triglyceride levels of >1000 mg/dL) requires therapy to prevent pancreatitis. Moderately elevated triglyceride levels (150-400
mg/dL) are of concern because they often occur as part of the metabolic syndrome, which includes insulin resistance, obesity, hypertension, low HDL-C levels, a procoagulant state, and substantially increased risk of CVD. Atherogenic dyslipidemia in patients with metabolic syndrome also is characterized by lipid-depleted LDL (sometimes referred to as “small, dense LDL”). Metabolic syndrome affects ~25% of adults and is common in CVD patients; hence, identification of moderate hypertriglyceridemia in a patient, even if the total cholesterol level is normal, should trigger an evaluation to identify insulin-resistant patients with this disorder.

PLASMA LIPOPROTEIN METABOLISM

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as apolipoproteins or apoproteins, provide structural stability to the lipoproteins and also may function as ligands in lipoprotein–receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. The major classes of lipoproteins and their properties are summarized in Table 31–1. Apoproteins have well-defined roles in plasma lipoprotein metabolism (Table 31–2).

In all spherical lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apolipoproteins, phospholipids, and unesterified cholesterol) are located on the surface. Except for apo(a), the lipid-binding regions of all apoproteins contain amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non–lipid-binding regions determine the functional specificities of the apolipoproteins.

Figure 31–1 summarizes the pathways involved in the uptake and transport of
dietary fat and cholesterol, pathways that involve the lipoprotein structures described below.

Figure 31–1 The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. “Remnant receptors” include the LDL receptor–related protein (LRP), LDL receptors, and perhaps other receptors. Free fatty acid (FFA) released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue. HL, hepatic lipase; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

CHYLOMICRONS. Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed by epithelial cells in the small intestine. Chylomicrons are the largest and lowest density plasma lipoproteins. In normolipidemic individuals, chylomicrons are present in plasma for 3-6 h after a fat-containing meal has been ingested. Intestinal cholesterol absorption is mediated by Niemann-Pick C1–Like 1 protein (NPC1L1), which appears to be
the target of ezetimibe, a cholesterol absorption inhibitor.

After their synthesis in the endoplasmic reticulum, triglycerides are transferred by microsomal triglyceride transfer protein (MTP) to the site where newly synthesized apoB-48 is available to form chylomicrons. ApoB-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons and functions primarily as a structural component of chylomicrons. Dietary cholesterol is esterified by the type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase (ACAT-2). ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins (chylomicrons and very-low-density lipoproteins [VLDL]) are assembled.

After entering the circulation via the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize lipoprotein lipase (LPL), (see Figure 31–1), including adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. The resulting free fatty acids are taken up and used by the adjacent tissues. The interaction of chylomicrons and LPL requires apoC-II as a cofactor.

**CHYLOMICRON REMNANTS.** After LPL-mediated removal of much of the dietary triglycerides, the chylomicron remnants, with all of the dietary cholesterol, detach from the capillary surface and within minutes are removed from the circulation by the liver (see Figure 31–1). First, the remnants are sequestered by the interaction of apoE with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by hepatic lipase (HL), further reducing the remnant triglyceride content. Next, apoE mediates remnant uptake by interacting with the hepatic LDL receptor or the LDL receptor–related protein (LRP).

During the initial hydrolysis of chylomicron triglycerides by LPL, apoA-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (precursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor–mediated catabolism of LDL by the liver.
**VERY-LOW-DENSITY LIPOPROTEINS.** VLDL are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased de novo synthesis of fatty acids by the liver.

ApoB-100, apoE, and apoC-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDL (see Table 31–2). Triglycerides are synthesized in the endoplasmic reticulum, and along with other lipid constituents, are transferred by MTP to the site in the endoplasmic reticulum where newly synthesized apoB-100 is available to form nascent (precursor) VLDL. Small amounts of apoE and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDL are secreted by the liver. Mutations of MTP that result in the inability of triglycerides to be transferred to either apoB-100 in the liver or apoB-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder *abetalipoproteinemia*.

Plasma VLDL is catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (see Figure 31–1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed *IDL*, are released from the capillary endothelium and reenter the circulation. ApoB-100 containing small VLDL and IDL, which have a $t_{1/2} < 30$ min, have 2 potential fates. About 40-60% are cleared from the plasma by the liver via apoB-100 and apoE-mediated interaction with LDL receptors and LRP. LPL and HL convert the remainder of the IDL to LDL by removal of additional triglycerides. The C apoproteins, apoE, and apoA-V redistribute to HDL.

ApoE plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDL, and IDL). About half of the apoE in the plasma of fasting subjects is associated with triglyceride-rich lipoproteins, and the other half is a constituent of HDL.

**LOW-DENSITY LIPOPROTEINS.** Virtually all of the LDL particles in the circulation are derived from VLDL. The LDL particles have a $t_{1/2}$ of 1.5-2 days. In subjects without hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL. Plasma clearance of LDL is
mediated primarily by LDL receptors (ApoB-100 binds LDL to its receptor); a small component is mediated by nonreceptor clearance mechanisms.

The most common cause of autosomal dominant hypercholesterolemia involves mutations of the LDL receptor gene. Defective or absent LDL receptors cause high levels of plasma LDL and familial hypercholesterolemia. LDL becomes atherogenic when modified by oxidation, a required step for LDL uptake by the scavenger receptors of macrophages. This process leads to foam-cell formation in arterial lesions. At least 2 scavenger receptors (SRs) are involved (SR-AI/II and CD36). SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression is greater as foam cells form during lesion progression. The liver expresses a large complement of LDL receptors and removes ~75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor gene expression is a most effective way to modulate plasma LDL-C levels. Thyroxine and estrogen enhance LDL receptor gene expression, which explains their LDL-C–lowering effects. The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression.

**HIGH-DENSITY LIPOPROTEINS.** HDL are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion. HDL effects also include putative anti-inflammatory, anti-oxidative, platelet anti-aggregatory, anticoagulant, and profibrinolytic activities. ApoA-I is the major HDL apoprotein, and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level. ApoA-I synthesis is required for normal production of HDL.

Mutations in the apoA-I gene that cause HDL deficiency often are associated with accelerated atherogenesis. In addition, 2 major subclasses of mature HDL particles in the plasma can be differentiated by their content of the major HDL apoproteins, apoA-I and apoA-II. Epidemiologic evidence in humans suggests
that apoA-II may be atheroprotective.

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL. After free cholesterol is acquired by the pre-β1 HDL, it is esterified by lecithin:cholesterol acyltransferase. The newly esterified and nonpolar cholesterol moves into the core of the particle, which becomes progressively more spherical, larger, and less dense with continued cholesterol acquisition and esterification. As the cholesteryl ester content of the particle (now called HDL₂) increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDL, remnant lipoproteins, and LDL). This exchange, mediated by the cholesteryl ester transfer protein (CETP), accounts for the removal of about two-thirds of the cholesterol associated with HDL in humans. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred.

Treatments that target CETP and the ABC transporters have yielded equivocal results in humans. While CETP inhibitors effectively reduce LDL, they also paradoxically increase the frequency of adverse cardiovascular events (angina, revascularization, myocardial infarction, heart failure, and death).

The triglyceride that is transferred into HDL₂ is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL₃ particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol.

HL activity is regulated and modulates HDL-C levels. Androgens increase HL gene expression/activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

**LIPOPROTEIN (a).** Lipoprotein(a) [Lp(a)] is composed of an LDL particle that has a second apoprotein, apo(a), in addition to apoB-100. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic.
The major conventional risk factors for CVD are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature CHD events (men <55 years; women <65 years) in a first-degree relative (Table 31–3). When total cholesterol levels are below 160 mg/dL, CHD risk is markedly attenuated, even in the presence of additional risk factors. This pivotal role of hypercholesterolemia in atherogenesis gave rise to the almost universally accepted cholesterol-diet-CHD hypothesis: elevated plasma cholesterol levels cause CHD, diets rich in saturated (animal) fat and cholesterol raise cholesterol levels, and lowering cholesterol levels reduces CHD risk.

From The Expert Panel, 2002.

Modest reductions in total cholesterol and LDL-C are associated with reductions in fatal and nonfatal CHD events but not total mortality. Patients benefit regardless of gender, age, baseline lipid values, or whether they have a prior history of vascular disease or type 2 diabetes mellitus. Statin therapy is effective in preventing first and subsequent atherothrombotic strokes. Moderate doses of statins that lower LDL-C levels by about 40% reduce cardiovascular events by about one-third. More intensive regimens that lower LDL-C by 45-50% reduce
CVD events by as much as 50%.

MANAGING PATIENTS WITH DYSLIPIDEMIA: NATIONAL CHOLESTEROL EDUCATION PROGRAM (NCEP) GUIDELINES

Primary prevention involves management of risk factors to prevent a first-ever CHD event. Secondary prevention is aimed at patients who have had a prior CHD event and whose risk factors must be treated aggressively. Recently, the concept of primordial prevention has been applied to CHD. This is a population-based approach to prevention (rather than treatment) that targets smoking, weight management, physical activity, healthy eating habits, cholesterol and glucose levels, and blood pressure.

The patient-based approach to manage dyslipidemia is designed for primary and secondary prevention, requires a risk assessment, and focuses on lowering LDL-C and non-HDL-C (see ranges in Table 31–4). Before drug therapy is initiated, secondary causes of hyperlipidemia (Table 31–5) should be excluded. Treatment of the disorder causing secondary dyslipidemia may preclude the necessity of treatment with hypolipidemic drugs. Table 31–6 summarizes current risk category-treatment guidelines based on LDL-C levels.

Table 31–6

Treatment Based on LDL-C Levels (2004 Revision of NCEP Adult Treatment Panel III Guidelines)
WHOM AND WHEN TO TREAT?

Large-scale trials with statins have provided new insights into which patients with dyslipidemia should be treated and when treatment should be initiated.

**Gender.** Both men and women benefit from lipid-lowering therapy. Statins are the recommended first-line drug therapy for lowering lipids and preventing CHD events in postmenopausal women.

**Age.** Age >45 years in men and >55 years in women is considered to be a CHD
risk factor. The statin trials have shown that patients >65 years of age benefit from therapy as much as do younger patients. Old age per se is not a reason to refrain from initiating drug therapy in an otherwise healthy person.

*Cerebrovascular Disease Patients.* Plasma cholesterol levels correlate positively with the risk of ischemic stroke and statins reduce stroke and transient ischemic attacks in patients with and without CHD.

*Peripheral Vascular Disease Patients.* Statins are beneficial in patients with peripheral vascular disease.

*Hypertensive Patients and Smokers.* The risk reduction for coronary events in statin trials of hypertensive patients and smokers is similar to that in subjects without hypertension.

*Type 2 Diabetes Mellitus.* Patients with type 2 diabetes benefit very significantly from aggressive lipid lowering (see below).

*Post–Myocardial Infarction or Revascularization Patients.* As soon as CHD is diagnosed, it is essential to begin lipid-lowering therapy (NCEP guidelines: LDL-C goal <70 mg/dL for very high-risk patients). Statin therapy also improves the long-term outcome after bypass surgery.

**TREATMENT OF TYPE 2 DIABETES PATIENTS**

Diabetes mellitus is an independent predictor of high risk for CHD. Glucose control is essential but provides only minimal benefit with respect to CHD prevention. Aggressive treatment of diabetic dyslipidemia through diet, weight control, and drugs is critical in reducing risk. Diabetic dyslipidemia usually is characterized by high triglycerides, low HDL-C, and moderate elevations of total cholesterol and LDL-C. Diabetics without diagnosed CHD have the same level of risk as nondiabetics with established CHD. Thus, the dyslipidemia treatment guidelines for diabetic patients are the same as for patients with CHD, irrespective of whether the diabetic patient has had a CHD event.
METABOLIC SYNDROME

There is an increased CHD risk associated with the insulin-resistant, prediabetic state described under the rubric of “metabolic syndrome.” This syndrome consists of a constellation of 5 CHD risk factors: abdominal obesity, hypertension, insulin-resistance, hypertriglyceridemia, and low HDL (Table 31–7). Treatment should focus on weight loss and increased physical activity. Specific treatment of lipid abnormalities should also be undertaken.

The 2001 National Cholesterol Education Program (NCEP) guidelines define the metabolic syndrome as the presence of three or more of these risk factors. From The Expert Panel, 2002.

TREATMENT OF HYPERTRIGLYCERIDEMIA

There is increased CHD risk associated with the presence of triglyceride levels >150 mg/dL. Three categories of hypertriglyceridemia are recognized (see Table 31–4), and treatment is recommended based on the degree of elevation. Weight loss, increased exercise, and alcohol restriction are important for all hypertriglyceridemic patients. If triglycerides remain >200 mg/dL after the LDL-C goal is reached (see Table 31–6), further reduction in triglycerides may be achieved by increasing the dose of a statin or of niacin. Combination therapy (statin plus niacin or statin plus fibrate)
may be required, but caution is necessary with these combinations to avoid myopathy (see below).

**TREATMENT OF LOW HDL-C**

The most frequent risk factor for premature CHD is low HDL-C.

In patients with low HDL-C, the total cholesterol:HDL-C ratio is a particularly useful predictor of CHD risk. Observational studies suggest that a ratio >4.5 is associated with increased risk (Table 31–8). The treatment of low HDL-C patients focuses on lowering LDL-C to the target level based on the patient’s risk factor or CHD status (see Table 31–6) and a reduction of VLDL cholesterol to <30 mg/dL to reach the target for non-HDL-C. Satisfactory treatment results are a ratio of total cholesterol: HDL-C ≤3.5.

**Table 31–8**

**DRUG THERAPY OF DYSLIPIDEMIA**

**STATINS**

The statins are the most effective and best-tolerated agents for treating dyslipidemia. These drugs are competitive inhibitors of HMG-CoA reductase, which catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (e.g.,
atorvastatin, simvastatin, and rosuvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Some statins also are indicated for raising HDL-C levels, although the clinical significance of these effects on HDL-C remains to be proven. Figure 31–2 shows a representative statin structure and the reaction catalyzed by HMG-CoA reductase.

**Figure 31–2 Lovastatin and HMG-CoA reductase reaction.**

**MECHANISM OF ACTION**

Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis. Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. Some studies suggest that statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. The reduction in hepatic VLDL...
production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDL.

**THERAPEUTIC EFFECTS**

*Triglyceride Reduction by Statins.* Triglyceride levels >250 mg/dL are reduced substantially by statins, and the percent reduction achieved is similar to the percent reduction in LDL-C.

*Effect of Statins on HDL-C Levels.* Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (40-50 mg/dL for men; 50-60 mg/dL for women), an increase in HDL-C of 5-10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dL), statins may differ in their effects on HDL-C levels. More studies are needed to ascertain whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

*Effects of Statins on LDL-C Levels.* Dose-response relationships for all statins demonstrate that the efficacy of LDL-C lowering is log-linear; LDL-C is reduced by ~6% (from baseline) with each doubling of the dose. Maximal effects on plasma cholesterol levels are achieved within 7-10 days. The statins are effective in almost all patients with high LDL-C levels. The exception is patients with homozygous familial hypercholesterolemia, who have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene code for dysfunctional LDL receptors. Statin therapy does not reduce Lp(a) levels.

*Potential Cardioprotective Effects Other Than LDL Lowering.* Although the statins clearly exert their major effects on CHD by lowering LDL-C and improving the lipid profile as reflected in plasma cholesterol levels, a multitude of potentially cardioprotective effects are being ascribed to these drugs. However, it is not known whether these potential pleiotropic effects represent a class-action effect, differ among statins, or are biologically or clinically relevant.

**ADME**

After oral administration, intestinal absorption of the statins is variable (30-
85%). All the statins, except simvastatin and lovastatin, are administered in the β-hydroxy acid form, which is the form that inhibits HMG-CoA reductase. Simvastatin and lovastatin are administered as inactive lactones that must be transformed in the liver to their respective β-hydroxy acids, simvastatin acid (SVA) and lovastatin acid (LVA). There is extensive first-pass hepatic uptake of all statins, mediated primarily by the organic anion transporter OATP1B1 (see Chapter 5).

Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. The metabolites of all statins, except fluvastatin and pravastatin, have some HMG-CoA reductase inhibitory activity. Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. In the plasma, >95% of statins and their metabolites are protein bound, with the exception of pravastatin and its metabolites, which are only 50% bound. Peak plasma concentrations of statins are achieved in 1-4 h. The $t_{1/2}$ of the parent compounds are 1-4 h, except in the case of atorvastatin and rosuvastatin, which have half-lives of ~20 h, and simvastatin with a $t_{1/2}$ ~12 h. The longer $t_{1/2}$ of atorvastatin and rosuvastatin may contribute to their greater cholesterol-lowering efficacy. The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver, with subsequent elimination in the feces.

**ADVERSE EFFECTS AND DRUG INTERACTIONS**

*Hepatotoxicity.* Although serious hepatotoxicity is rare, a rate of about 1 case per million person-years of use; it is reasonable to measure alanine aminotransferase (ALT) at baseline and thereafter when clinically indicated.

*Myopathy.* The major adverse effect associated with statin use is myopathy. The risk of myopathy and rhabdomyolysis increases in proportion to statin dose and plasma concentrations. Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially >80 years of age), hepatic or renal dysfunction, perioperative periods, multisystem disease (especially in association with diabetes mellitus), small body size, and untreated hypothyroidism. Concomitant use of drugs that diminish statin catabolism or interfere with hepatic uptake is associated with myopathy and
rhabdomyolysis in 50-60% of all cases. The most common statin interactions occurred with fibrates, especially gemfibrozil (38%), cyclosporine (4%), digoxin (5%), warfarin (4%), macrolide antibiotics (3%), mibefradil (2%), and azole antifungals (1%). Other drugs that increase the risk of statin-induced myopathy include niacin (rare), HIV protease inhibitors, amiodarone, and nefazodone.

Gemfibrozil, the drug most commonly associated with statin-induced myopathy, inhibits both uptake of the active hydroxy acid forms of statins into hepatocytes by OATP1B1 and interferes with the transformation of most statins by glucuronidases. Coadministration of gemfibrozil nearly doubles the plasma concentration of the statin hydroxy acids. When statins are administered with niacin, the myopathy probably is caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction).

Drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4 and include certain macrolide antibiotics (e.g., erythromycin); azole antifungals (e.g., itraconazole); cyclosporine; nefazodone, a phenylpiperazine antidepressant; HIV protease inhibitors; and amiodarone. These pharmacokinetic interactions are associated with increased plasma concentrations of statins and their active metabolites. Atorvastatin, lovastatin, and simvastatin are primarily metabolized by CYPs 3A4 and 3A5. Fluvastatin is mostly (50-80%) metabolized by CYP2C9 to inactive metabolites, but CYP3A4 and CYP2C8 also contribute to its metabolism. Pravastatin, however, is not metabolized to any appreciable extent by the CYP system and is excreted unchanged in the urine. Because pravastatin, fluvastatin, and rosvastatin are not extensively metabolized by CYP3A4, these statins may be less likely to cause myopathy when used with one of the predisposing drugs. However, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy.

**THERAPEUTIC USES.** Hepatic cholesterol synthesis is maximal between midnight and 2:00 A.M. Thus, statins with \( t_{1/2} \leq 4 \) h (all but atorvastatin and rosvastatin) should be taken in the evening. Each statin has a low recommended starting dose that reduces LDL-C by 20-30% (Table 31–9).

The initial recommended dose of **lovastatin** (**MEVACOR**) is 20 mg and is slightly more effective if taken with the evening meal than if it is taken at bedtime. The dose of lovastatin may be increased every 3-6 weeks up to a maximum of 80 mg/day. The 80-mg dose is slightly (2-3%) more effective if given as 40 mg twice daily. Lovastatin, at 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (**ADVICOR**). Few patients are appropriate candidates for this fixed-dose combination (see next section on “Nicotinic Acid”).

The usual starting dose of **simvastatin** (**ZOCOR**) for most patients is 20 mg at bedtime. The maximal dose is 80 mg. In patients taking cyclosporine, fibrates, or niacin, the daily dose should not exceed 20 mg. Simvastatin, 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (**SIMCOR**).

**Pravastatin** (**PRAVACHOL**) therapy is initiated with a 20- or 40-mg dose that may be increased to 80 mg. This drug should be taken at bedtime. Because pravastatin is a hydroxy acid, bile-acid sequestrants will bind it and reduce its absorption. Pravastatin also is marketed in combination with buffered aspirin (**PRAVIGARD**). The small advantage of combining these 2 drugs should be weighed against the disadvantages inherent in fixed-dose combinations.

For **fluvastatin** (**LESCOL**), the starting dose is 20 or 40 mg, and the maximum is 80 mg/day. Like pravastatin, it is administered as a hydroxy acid and should be taken at bedtime, several hours after ingesting a bile-acid sequestrant (if the combination is used).
Atorvastatin (LIPITOR) has a long $t_{1/2}$, which allows administration of this statin at any time of the day. The starting dose is 10 mg, and the maximum is 80 mg/day. Atorvastatin is marketed in combination with the Ca$^{2+}$-channel blocker amlodipine (CADUET) for patients with hypertension or angina as well as hypercholesterolemia.

Rosuvastatin (CRESTOR) is available in doses ranging between 5 and 40 mg. It has a $t_{1/2}$ of 20-30 h and may be taken at any time of day. If the combination of gemfibrozil with rosuvastatin is used, the dose of rosuvastatin should not exceed 10 mg.

Pitavastatin (LIVALO) is available in doses of 1, 2, and 4 mg. Gemfibrozil reduces clearance of pitavastatin and raises blood concentrations; consequently, gemfibrozil should be used cautiously, if at all, in combination with pitavastatin.

The choice of statins should be based on efficacy (reduction of LDL-C) and cost. Three drugs (lovastatin, simvastatin, and pravastatin) have been used safely in clinical trials. Baseline determinations of ALT and repeat testing at 3-6 months are recommended. If ALT is normal after the initial 3-6 months, then it need not be repeated more than once every 6-12 months. Measurements of CK are not routinely necessary unless the patient also is taking a drug that enhances the risk of myopathy.

Statins in Combination with Other Lipid-Lowering Drugs. Statins, in combination with the bile acid–binding resins cholestyramine and colestipol, produce 20-30% greater reductions in LDL-C than can be achieved with statins alone. Preliminary data indicate that colesevelam hydrochloride plus a statin lowers LDL-C by 8-16% more than statins alone. Niacin also can enhance the effect of statins, but the occurrence of myopathy increases when statin doses >25% of maximum (e.g., 20 mg of simvastatin or atorvastatin) are used with niacin. The combination of a fibrate (clofibrate, gemfibrozil, or fenofibrate) with a statin is particularly useful in patients with hypertriglyceridemia and high LDL-C levels. This combination increases the risk of myopathy but usually is safe with a fibrate at its usual maximal dose and a statin at no more than 25% of its maximal dose. Triple therapy with resins, niacin, and statins can reduce LDL-C by up to 70%. VYTORIN, a fixed-dose combination of simvastatin (10, 20, 40, or 80 mg) and ezetimibe (10 mg), decreased LDL-C levels by up to 60% at 24 weeks.
**Statin Use by Children.** Some statins have been approved for use in children with heterozygous familial hypercholesterolemia. Atorvastatin, lovastatin, and simvastatin are indicated for children >11 years. Pravastatin is approved for children ≤8 years.

**Pregnancy.** The safety of statins during pregnancy has not been established.

**BILE-ACID SEQUESTRANTS**

**CHOLESTYRAMINE, COLESTIPOL, COLESEVELAM.** The bile-acid sequestrants cholestyramine and colestipol are among the oldest of the hypolipidemic drugs and are probably the safest, because they are not absorbed from the intestine. These resins also are recommended for patients 11-20 years of age. Because statins are so effective as monotherapy, the resins are most often used as second agents if statin therapy does not lower LDL-C levels sufficiently. When used with a statin, cholestyramine and colestipol usually are prescribed at submaximal doses. Maximal doses can reduce LDL-C by up to 25% but are associated with unacceptable GI side effects (bloating and constipation). Colesevelam, a newer bile-acid sequestrant, lowers LDL-C by 18% at its maximum dose.

**MECHANISM OF ACTION.** The bile-acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the stool. Because more than 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile-acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase. Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins. The resin-induced increase in bile-acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant
hypertriglyceridemia (baseline triglyceride level >250 mg/dL). Use of colesevelam to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1-2 weeks) monitoring of fasting triglyceride levels.

**EFFECTS ON LIPOPROTEIN LEVELS.** The reduction in LDL-C by resins is dose dependent. Doses of 8-12 g of cholestyramine or 10-15 g of colestipol are associated with 12-18% reductions in LDL-C. Maximal doses (24 g of cholestyramine, 30 g of colestipol) may reduce LDL-C by as much as 25% but will cause GI side effects. One to 2 weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. HDL-C levels increase 4-5%. Statins plus resins or niacin plus resins can reduce LDL-C by 40-60%. Colesevelam, in doses of 3-3.75 g, reduces LDL-C levels by 9-19%.

**ADVERSE EFFECTS AND DRUG INTERACTIONS.** The resins are generally safe, as they are not systemically absorbed. Because they are administered as chloride salts, rare instances of hyperchloremic acidosis have been reported. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol because these resins increase triglyceride levels. At present, there are insufficient data on the effect of colesevelam on triglyceride levels.

Cholestyramine and colestipol both are available as a powder that must be mixed with water and drunk as a slurry. The gritty sensation is unpleasant but generally tolerated. Colestipol is available in a tablet form. Colesevelam is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for GI irritation. Patients taking cholestyramine and colestipol complain of bloating and dyspepsia. These symptoms can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion. Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium. Colesevelam may be less likely to cause the dyspepsia, bloating, and constipation.

Cholestyramine and colestipol bind and interfere with the absorption of many drugs, including some thiazides, furosemide, propranolol, \(L\)-thyroxine, digoxin, warfarin, and some of the statins. The effect of cholestyramine and colestipol on the absorption of most drugs has not been studied. For this reason, it is wise to administer all drugs either 1 h before or 3-4 h after a dose of cholestyramine or
colestipol. Colesevelam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin, lovastatin, warfarin, metoprolol, quinidine, and valproic acid. Colesevelam reduces the maximum concentration and the AUC of sustained-release verapamil by 31% and 11%, respectively. In the absence of information to the contrary, prudence suggests that patients take other medications 1 h before or 3-4 h after a dose of colesevelam. The safety and efficacy of colesevelam have not been studied in pediatric patients or pregnant women.

**PREPARATIONS AND USE.** The powdered forms of cholestyramine (QUESTRAN, others, 4 g/dose) and colestipol (COLESTID, others, 5 g/dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with 1 scoop or packet twice daily, and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than 2 doses (scoops or packets) twice daily. Colesevelam hydrochloride (WELCHOL) is available as a solid tablet containing 0.625 g of colesevelam and as a powder in packets of 3.75 g or 1.875 g. The starting dose is either 3 tablets taken twice daily with meals or all 6 tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is 7 tablets (4.375 g).

**NIACIN (NICOTINIC ACID)**

Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide may be given orally as a source of niacin for its functions as a vitamin, but only niacin affects lipid levels. The hypolipidemic effects of niacin require larger doses than are required for its vitamin effects.
MECHANISM OF ACTION. In adipose tissue, niacin inhibits the lipolysis of triglycerides by hormone-sensitive lipase, which reduces transport of free fatty acids to the liver and decreases hepatic triglyceride synthesis. Niacin may exert its effects on lipolysis by stimulating a GPCR (GPR109A) that couples to $G_i$ and inhibits cyclic AMP production in adipocytes. In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and esterification of fatty acids, effects that increase apoB degradation. Reduction of triglyceride synthesis reduces hepatic VLDL production, which accounts for the reduced LDL levels. Niacin also enhances LPL activity, which promotes the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing the fractional clearance of apoA-I in HDL rather than by enhancing HDL synthesis.

EFFECTS ON PLASMA LIPOPROTEIN LEVELS. Regular or crystalline niacin in doses of 2-6 g/day reduces triglycerides by 35-50% (as effectively as fibrates and statins); the maximal effect occurs within 4-7 days. Reductions of 25% in LDL-C levels are possible with doses of 4.5-6 g/day; 3-6 weeks are required for maximal effect. Niacin is the best agent available for increasing HDL-C (30-40%), but the effect is less in patients with HDL-C levels >35 mg/dL. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite salutary effect on lipids, niacin’s side effects limit its use (see “Adverse Effects”).

ADME. The doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations (up to 0.24 mmol) are achieved within 30-60 min. The $t_{1/2}$ is about 60 min, which necessitates dosing 2 to 3 times daily. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid.

ADVERSE EFFECTS. Two of niacin’s side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin mediated. Taking an aspirin each day alleviates the flushing in many patients. Flushing is worse when therapy is initiated or the dosage is increased but ceases in most patients after 1-2 weeks of
a stable dose. Flushing is more likely to occur when niacin is consumed with hot beverages or with alcohol. Flushing is minimized if therapy is initiated with low doses (100-250 mg twice daily) and if the drug is taken after a meal. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions containing *salicylic acid*. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases, and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin, which was developed to reduce flushing and itching, have been reported to cause severe liver toxicity. An extended-release niacin (Niaspan) appears to be less likely to cause severe hepatotoxicity, perhaps simply because it is administered once daily. The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take more than 2 g of sustained-release, over-the-counter preparations. Affected patients experience flu-like fatigue and weakness. Usually, aspartate transaminase and ALT are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially.

In patients with diabetes mellitus, niacin should be used cautiously because niacin-induced insulin resistance can cause severe hyperglycemia. If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for niacin use. Rarer reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. Niacin, at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women.

**THERAPEUTIC USE.** Niacin is indicated for hypertriglyceridemia and elevated LDL-C; it is especially useful in patients with both hypertriglyceridemia and low HDL-C levels. There are 2 commonly available forms of niacin. Crystalline niacin (immediate-release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously
release niacin for 6-8 h after ingestion. Niaspan is the only preparation of niacin that is FDA-approved for treating dyslipidemia and that requires a prescription.

Crystalline niacin tablets are available over the counter in a variety of strengths from 50- to 500-mg tablets. The dose may be increased stepwise every 7 days to a total daily dose of 1.5-2 g. After 2-4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. Lipid levels should be checked and the dose increased further until the desired effect on plasma lipids is achieved. After a stable dose is attained, blood should be drawn every 3-6 months to monitor for the various toxicities. Over-the-counter, sustained-release niacin preparations and Niaspan are effective up to a total daily dose of 2 g. All doses of sustained-release niacin, but particularly doses above 2 g/day, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use. The potential for severe liver damage should preclude use of OTC preparations in most patients. Niaspan may be less likely to cause hepatotoxicity.

Because concurrent use of niacin and a statin can cause myopathy, the statin should be administered at no more than 25% of its maximal dose. Patients also should be instructed to discontinue therapy if flu-like muscle aches occur. Routine measurement of CK in patients taking niacin and statins does not assure that severe myopathy will be detected before onset of symptoms.

**FIBRIC ACID DERIVATIVES: PPAR ACTIVATORS**

Clofibrate is a halogenated fibric acid derivative. Gemfibrozil is a nonhalogenated acid that is distinct from the halogenated fibrates. A number of fibric acid analogs (e.g., fenofibrate, bezafibrate, ciprofibrate) have been developed and are used in Europe and elsewhere.

**MECHANISM OF ACTION.** The mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Many of the effects of these compounds on blood lipids are mediated by their interaction with peroxisome proliferator-activated receptors (PPARs), which regulate gene transcription. Fibrates bind to PPARα and reduce triglycerides through PPARα-mediated stimulation of fatty acid oxidation, increased LPL synthesis, and
reduced expression of apoC-III. Increased LPL synthesis would enhance the clearance of triglyceride-rich lipoproteins. Reduced hepatic production of apoC-III, which serves as an inhibitor of lipolysis and receptor-mediated clearance, would enhance the clearance of VLDL. Fibrate-mediated increases in HDL-C are due to PPARV stimulation of apoA-I and apoA-II expression, which increases HDL levels. Fenofibrate is more effective than gemfibrozil at increasing HDL levels. Most fibrates have potential anti-thrombotic effects, including inhibition of coagulation and enhancement of fibrinolysis.

EFFECTS ON LIPOPROTEIN LEVELS. Effects of fibric acid agents on lipoprotein levels differ widely, depending on the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used. Patients with type III hyperlipoproteinemia (dysbetalipoproteinemia) are among the most sensitive responders to fibrates. Elevated triglyceride and cholesterol levels are dramatically lowered, and tuberoeruptive and palmar xanthomas may regress completely. Angina and intermittent claudication also improve.

In patients with mild hypertriglyceridemia (e.g., triglycerides <400 mg/dL), fibrate treatment decreases triglyceride levels by up to 50% and increases HDL-C concentrations by about 15%; LDL-C levels may be unchanged or increase. Normotriglyceridemic patients with heterozygous familial hypercholesterolemia usually experience little change in LDL levels with gemfibrozil; with the other fibric acid agents, reductions as great as 20% may occur in some patients. Fibrates usually are the drugs of choice for treating severe hypertriglyceridemia and the chylomicronemia syndrome. While the primary therapy is to remove alcohol and lower dietary fat intake as much as possible, fibrates assist by increasing triglyceride clearance and decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dL and thus prevent episodes of pancreatitis.

ADME. Fibrates are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. Peak plasma concentrations are attained within 1-4 h. More than 95% of these drugs in plasma are bound to protein, nearly exclusively to albumin. The $t_{1/2}$ of fibrates range from 1.1 h (gemfibrozil) to 20 h (fenofibrate). The drugs are widely
distributed throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. Gemfibrozil is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates (60-90%) in the urine, with smaller amounts appearing in the feces. Excretion of these drugs is impaired in renal failure.

**ADVERSE EFFECTS AND DRUG INTERACTIONS.** Fibric acid compounds usually are well tolerated. GI side effects occur in up to 5% of patients. Infrequent side effects include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. Clofibrate, bezafibrate, and fenofibrate reportedly potentiate the action of oral anticoagulants, in part by displacing them from binding sites on albumin. Careful monitoring of the prothrombin time and reduction in dosage of the anticoagulant may be appropriate.

A myopathy syndrome occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. Statin doses should be reduced when combination therapy is employed. Gemfibrozil inhibits hepatic uptake of statins by OATP1B1, and competes for the same glucuronosyl transferases that metabolize most statins. Thus, levels of both drugs may be elevated when they are coadministered. Patients taking this combination should be followed at 3-month intervals with careful history and determination of CK values until a stable pattern is established. Patients taking fibrates with rosuvastatin should be followed especially closely even if low doses (5-10 mg) of rosuvastatin are employed. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation; thus, fenofibrate-statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins.

All of the fibrates increase the lithogenicity of bile. Clofibrate use has been associated with increased risk of gallstone formation. Renal failure is a relative contraindication to the use of fibric acid agents, as is hepatic dysfunction. *Fibrates should not be used by children or pregnant women.*

**THERAPEUTIC USE.** Clofibrate is available for oral administration and may be useful in patients who do not tolerate gemfibrozil or fenofibrate. The usual dose is 2 g/day in divided doses. Gemfibrozil (LOPID) usually is administered as a
600-mg dose taken twice daily, 30 min before the morning and evening meals. The Tricor brand of fenofibrate is available in tablets of 48 and 145 mg. The usual daily dose is 145 mg. Generic fenofibrate (Lofibra) is available in capsules containing 67, 134, and 200 mg. The choline salt of fenofibr acid (Trilipix) is available in capsules of 135 and 45 mg. Trilipix, 135 mg, is equivalent to Tricor, 145 mg, and Lofibra, 200 mg. Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia as well as subjects with severe hypertriglyceridemia (triglycerides >1000 mg/dL) who are at risk for pancreatitis. Fibrates appear to have an important role in subjects with high triglycerides and low HDL-C levels associated with the metabolic syndrome or type 2 diabetes mellitus. In these patients, the LDL levels need to be monitored; if LDL levels rise, the addition of a low dose of a statin may be needed. Many experts now treat such patients first with a statin and then add a fibrate, based on the reported benefit of gemfibrozil therapy.

**Ezetimibe and the Inhibition of Dietary Cholesterol Uptake**

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by ~20% and is used primarily as adjunctive therapy with statins.

**Mechanism of Action.** Ezetimibe inhibits luminal cholesterol uptake by jejunal enterocytes, by inhibiting the transport protein NPC1L1. In human subjects, ezetimibe reduces cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis that can be inhibited with a cholesterol synthesis inhibitor (e.g., a statin). The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons; this diminishes the delivery of cholesterol to the liver by chylomicron remnants. The diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. Ezetimibe reduces LDL-C levels by 15-20%.
ADME. Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is glucuronidated in the intestinal epithelium and absorbed and then enters an enterohepatic recirculation. Pharmacokinetic studies indicate that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate). Bile-acid sequestrants inhibit absorption of ezetimibe, and the 2 agents should not be administered together.

ADVERSE EFFECTS AND DRUG INTERACTIONS. Other than rare allergic reactions, specific adverse effects have not been observed in patients taking ezetimibe. Since all statins are contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.

THERAPEUTIC USE. Ezetimibe (ZETIA) is available as a 10-mg tablet that may be taken at any time during the day, with or without food. Ezetimibe may be taken with any medication other than bile-acid sequestrants, which inhibit its absorption.

The role of ezetimibe as monotherapy of patients with elevated LDL-C levels is limited to the small group of statin-intolerant patients. The actions of are complementary to those of statins. Dual therapy with these 2 classes of drugs prevents both the enhanced cholesterol synthesis induced by ezetimibe and the increase in cholesterol absorption induced by statins, providing additive reductions in LDL-C levels. A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) has been approved (VYTORIN). At the highest simvastatin dose (80 mg), plus ezetimibe (10 mg), average LDL-C reduction was 60%.

RECENTLY APPROVED ADJUNCT MEDICATIONS

ICOSAPENT ETHYL. Icosapent ethyl (VASCEPA) is an ethyl ester derivative of the omega-3 fatty acid eicosapentaenoic acid (EPA). EPA reduces VLDL triglycerides and is used as an adjunct to diet for treatment of adult patients with severe hypertriglyceridemia (≥500 mg/dL). Recommended daily oral dose is 4 g/day administered with food. Adverse effects may include arthralgia. Since omega-3-fatty acids may prolong bleeding time, patients taking anticoagulants should be monitored.
LOMITAPIDE. Lomitapide mesylate (JUXTAPID) acts by inhibiting MTP, which is essential for formation of VLDL. Lomitapide is used as an adjunct to diet for lowering LDL-C, total cholesterol, apoB, and non-HDL-C in patients with homozygous familial hypercholesterolemia. The recommended starting oral dose (5 mg/day) is titrated upwards to a maximum dose of 60 mg daily. The drug is metabolized by CYP3A4 and is contraindicated with inhibitors of CYP3A4. Reported adverse effects include diarrhea, vomiting, abdominal pain, and hepatotoxicity. The agent is used under an FDA risk evaluation and mitigation strategy.

MIPOMERSEN SODIUM. Mipomersen (KYNAMRO), an antisense oligonucleotide, inhibits the synthesis of apoB-100. The drug is approved as an addition to lipid-lowering medications and diet for patients with homozygous familial hypercholesterolemia. The recommended dose is 1 mL of 200 mg/mL solution, injected subcutaneously, once a week. Common adverse effects include injection site reactions, flu-like symptoms, headache, and elevation of liver enzymes. The agent is used under an FDA risk evaluation and mitigation strategy.
Section IV
Inflammation, Immunomodulation, and Hematopoiesis
Histamine, Bradykinin, and Their Antagonists

Histamine is a major mediator of inflammation, anaphylaxis, and gastric acid secretion; in addition, histamine plays a role in neurotransmission. Our understanding of the physiological and pathophysiological roles of histamine has been enhanced by the development of subtype-specific receptor antagonists and by the cloning of 4 receptors for histamine. Competitive antagonists of H$_1$ receptors are used therapeutically in treating allergies, urticaria, anaphylactic reactions, nausea, motion sickness, insomnia, and some symptoms of asthma. Antagonists of the H$_2$ receptor are effective in reducing gastric acid secretion. The peptide, bradykinin, has cardiovascular effects similar to those of histamine and plays prominent roles in inflammation and nociception.

**HISTAMINE**

Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by an ethylene group, biosynthesized from histidine by decarboxylation (Figure 32–1). The 4 histamine receptors, all GPCRs, can be differentially activated by analogs of histamine and inhibited by specific antagonists (Table 32–1).

Figure 32–1  *Histamine synthesis and metabolism in humans.* Histamine is synthesized from histidine by decarboxylation. Histamine is metabolized via 2 pathways, predominantly by methylation of the ring followed by oxidative deamination (*left side of figure*), and secondarily by oxidative deamination and then conjugation with ribose. These metabolites have little or no activity and are excreted in the urine. Measurement of urinary *N*-methylhistamine affords a reliable index of histamine production. Artifactually elevated levels of histamine in urine arise from genitourinary tract bacteria that can decarboxylate histidine. MAO, monoamine oxidase.

**DISTRIBUTION AND BIOSYNTHESIS**
**DISTRIBUTION.** Almost all mammalian tissues contain histamine in amounts ranging from $<1$ to $>100$ μg/g. Concentrations in plasma and other body fluids generally are very low, but human cerebrospinal fluid (CSF) contains significant amounts. The concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial mucosa, and intestinal mucosa.

**SYNTHESIS, STORAGE, AND METABOLISM.** Histamine is formed by the decarboxylation of the amino acid histidine by the enzyme L-histidine decarboxylase (see Figure 32–1). Mast cells and basophils synthesize histamine and store it in secretory granules. At the secretory granule pH of $\sim 5.5$, histamine is positively charged and ionically complexed with negatively charged acidic groups on other granule constituents, primarily proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of histamine in secretory granules is slow. Non–mast cell sites of histamine formation include the epidermis, the gastric mucosa, neurons within the CNS, and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non–mast cell sites because the histamine is released continuously rather than stored. Non–mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Because L-histidine decarboxylase is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Histamine that is ingested is rapidly metabolized, and the metabolites are eliminated in the urine.

**RELEASE AND FUNCTIONS OF ENDOGENOUS HISTAMINE**

Histamine is released from storage granules as a result of the interaction of antigen with immunoglobulin E (IgE) antibodies on the mast cell surface. Histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. In addition, some drugs act
directly on mast cells to release histamine, causing untoward effects. Histamine has a major role in regulating gastric acid secretion and also modulates neurotransmitter release.

**ROLE IN ALLERGIC RESPONSES.** The principal target cells of immediate hypersensitivity reactions are mast cells and basophils. As part of the allergic response to an antigen, IgE antibodies are generated and bind to the surfaces of mast cells and basophils via specific high-affinity Fc receptors. This receptor, FceRI, consists of α, β, and 2 γ chains (see Chapter 35). Antigen bridges the IgE molecules and via FceRI activates signaling pathways in mast cells or basophils involving tyrosine kinases and subsequent phosphorylation of multiple protein substrates within 5-15 sec of contact with antigen. These events trigger the exocytosis of the contents of secretory granules.

**RELEASE OF OTHER AUTACOIDS.** Stimulation of IgE receptors also activates phospholipase A2 (PLA2), leading to the production of a host of mediators, including platelet-activating factor (PAF) and metabolites of arachidonic acid such as leukotrienes C4 and D4, which contract the smooth muscles of the bronchial tree.

**HISTAMINE RELEASE BY DRUGS, PEPTIDES, VENOMS, AND OTHER AGENTS.** Many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain categories of substances. Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern, and may account for unexpected anaphylactoid reactions. Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally
increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active. Some venoms, such as that of the wasp, contain potent histamine-releasing peptides. Basic polypeptides released upon tissue injury constitute pathophysiological stimuli to secretion for mast cells and basophils.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion of acid, and moderate bronchospasm also frequently occur. Histamine liberators do not deplete tissues of non–mast cell histamine.

**INCREASED PROLIFERATION OF MAST CELLS AND BASOPHILS AND GASTRIC CARCINOID TUMORS.** In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that sting when stroked. In systemic mastocytosis, overproliferation of mast cells also is found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of GI effects, such as diarrhea or peptic ulceration. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy “geographical” flush.

**GASTRIC ACID SECRETION.** Histamine acting at H₂ receptors is a
powerful gastric secretagogue, evoking a copious secretion of acid from parietal cells (see Figure 45–1); it also increases the output of pepsin and intrinsic factor. The secretion of gastric acid from parietal cells also is caused by stimulation of the vagus nerve and by the enteric hormone gastrin. However, histamine undoubtedly is the dominant physiological mediator of acid secretion; blockade of H₂ receptors not only antagonizes acid secretion in response to histamine but also inhibits responses to gastrin and vagal stimulation (see Chapter 45).

CNS. Histamine-containing neurons control both homeostatic and higher brain functions, including regulation of the sleep-wake cycle, circadian and feeding rhythms, immunity, learning, memory, drinking, and body temperature. However, no human disease has yet been directly linked to dysfunction of the brain histamine system. Histamine, histidine decarboxylase, enzymes that metabolize histamine, and H₁, H₂, and H₃ receptors are distributed widely but non-uniformly in the CNS. H₁ receptors are associated with both neuronal and non-neuronal cells and are concentrated in regions that control neuroendocrine function, behavior, and nutritional state. Distribution of H₂ receptors is more consistent with histaminergic projections than H₁ receptors, suggesting that they mediate many of the postsynaptic actions of histamine. H₃ receptors also are concentrated in areas known to receive histaminergic projections, consistent with their function as presynaptic autoreceptors. Histamine inhibits appetite and increases wakefulness via H₁ receptors.

**PHARMACOLOGICAL EFFECTS**

**RECEPTOR–EFFECTOR COUPLING AND MECHANISMS OF ACTION.** Histamine receptors are GPCRs, coupling to second messenger systems and producing effects as noted in Table 32–1.
H3 and H4 receptors have a much higher affinity for histamine than do H1 and H2 receptors. Activation of H3 receptors also can activate MAP kinase and inhibit the Na+/H+ exchanger; activation of H4 receptors mobilizes stored Ca2+ in some cells. Activation of H1 receptors on vascular endothelium stimulates eNOS to produce nitric oxide (NO), which diffuses to nearby smooth muscle cells to increase cyclic GMP and cause relaxation. Stimulation of H1 receptors on smooth muscle will mobilize Ca2+ and cause contraction, whereas activation of H2 receptors on the same smooth muscle cell will link via Gs to enhanced cyclic AMP accumulation, activation of PKA, and thence to relaxation. Pharmacological definition of H1, H2, and H3 receptors is clear because relatively specific agonists and antagonists are available. However, the H4 receptor exhibits 35-40% homology to isoforms of the H3 receptor, and the 2 were harder to distinguish pharmacologically. Several non-imidazole compounds that are more selective H3 antagonists have been developed, and there are now several selective H4 antagonists. 4-Methylhistamine and dimaprit, previously identified as specific H2 agonists, are actually more potent H4 agonists.

**H1 AND H2 RECEPTORS.** H1 and H2 receptors are distributed widely in the periphery and in the CNS. Histamine causes itching and stimulates secretion from nasal mucosa. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion. Other, less prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H1 receptors. Gastric secretion results from the activation of H2 receptors. Some responses, such as vascular dilation, are mediated by both H1 and H2 receptor stimulation.
**H₃ AND H₄ RECEPTORS.** H₃ receptors are expressed mainly in the CNS, especially in the basal ganglia, hippocampus, and cortex. H₃ receptors function as autoreceptors on histaminergic neurons, inhibiting histamine release and modulating the release of other neurotransmitters. H₃ receptors have high constitutive activity and histamine release is tonically inhibited. Inverse agonists thus reduce receptor activation and increase histamine release from histaminergic neurons. H₃ agonists promote sleep; thus, H₃ antagonists promote wakefulness. H₄ receptors primarily are found in eosinophils, dendritic cells, mast cells, monocytes, basophils, and T cells but have also been detected in the GI tract, dermal fibroblasts, CNS, and primary sensory afferent neurons. Activation of H₄ receptors has been associated with induction of cellular shape change, chemotaxis, secretion of cytokines, and upregulation of adhesion molecules, suggesting that H₄ antagonists may be useful inhibitors of allergic and inflammatory responses.

**FEEDBACK REGULATION OF RELEASE.** H₂ receptor stimulation increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils, whereas activation of H₃ and H₄ receptors has the opposite effect by decreasing cellular cyclic AMP. Activation of presynaptic H₃ receptors also inhibits histamine release from histaminergic neurons.

**CARDIOVASCULAR SYSTEM.** Histamine dilates resistance vessels, increases capillary permeability, and lowers systemic blood pressure. In some vascular beds, histamine constricts veins, contributing to the extravasation of fluid and edema formation upstream in capillaries and postcapillary venules.

**Vasodilation.** This is the most important vascular effect of histamine in humans. H₁ receptors have a higher affinity for histamine and cause
Ca^{2+}\text{-dependent activation of eNOS in endothelial cells; NO diffuses to vascular smooth muscle, increasing cyclic GMP (see Table 32–1) and causing rapid and short-lived vasodilation. By contrast, activation of H}_2\text{ receptors on vascular smooth muscle stimulates the cyclic AMP–PKA pathway, causing dilation that develops more slowly and is more sustained. As a result, H}_1\text{ antagonists effectively counter small dilator responses to low concentrations of histamine but only blunt the initial phase of larger responses to higher concentrations of the amine.}

**Increased “Capillary” Permeability.** Histamine’s effect on small vessels results in efflux of plasma protein and fluid into the extracellular spaces and an increase lymph flow, causing edema. H}_1\text{ receptors on endothelial cells are the major mediators of this response; the role of H}_2\text{ receptors is uncertain.}

**Triple Response of Lewis.** If histamine is injected intradermally, it elicits a characteristic phenomenon known as the *triple response*. This consists of:

- A localized “reddening” around the injection site, appearing within a few seconds, maximal ~1 min
- A “flare” or red flushing extending ~1 cm beyond the original red spot and developing more slowly
- A “wheal” or swelling that is discernible in 1-2 min at the injection site

The initial red spot (a few mm) results from the direct vasodilating effect of histamine (H}_1\text{ receptor–mediated NO production), the flare is due to histamine-induced stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine’s capacity to increase capillary permeability (edema formation).

**Heart.** Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and
ventricular muscle by promoting the influx of Ca\(^{2+}\), and it speeds heart rate by hastening diastolic depolarization in the sinoatrial (SA) node. It also directly slows atrioventricular (AV) conduction to increase automaticity and, in high doses, can elicit arrhythmias. The slowed AV conduction involves mainly H\(_1\) receptors, while the other effects are largely attributable to H\(_2\) receptors and cyclic AMP accumulation. The direct cardiac effects of histamine given intravenously are overshadowed by baroreceptor reflexes due to reduced blood pressure.

**EXTRAVASCULAR SMOOTH MUSCLE.** Histamine directly contracts or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H\(_1\) receptors on smooth muscle to increase intracellular Ca\(^{2+}\), and relaxation is mainly due to activation of H\(_2\) receptors. Although the spasmogenic influence of H\(_1\) receptors is dominant in human bronchial muscle, H\(_2\) receptors with dilator function also are present. Thus, histamine-induced bronchospasm in vitro is potentiated slightly by H\(_2\) blockade.

**PERIPHERAL NERVE ENDINGS.** Histamine stimulates various nerve endings and sensory effects. In the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching.

**HISTAMINE SHOCK.** Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. Resembling surgical or traumatic shock, these effects diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

**HISTAMINE TOXICITY FROM INGESTION.** Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna.
Symptoms include severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity also can follow red wine consumption in persons with a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H₁ antagonists.

**H₁ RECEPTOR ANTAGONISTS**

**PHARMACOLOGICAL PROPERTIES**

All the available H₁ receptor “antagonists” are actually inverse agonists (see Chapter 3) that reduce constitutive activity of the receptor and compete with histamine. At the tissue level, the effect is proportional to receptor occupancy by the antihistamine. Most H₁ antagonists have similar pharmacological actions and therapeutic applications. Their effects are largely predictable from knowledge of the consequences of the activation of H₁ receptors by histamine.

Like histamine, many H₁ antagonists contain a substituted ethylamine moiety.

![Ethylamine structure](image)

Unlike histamine, which has a primary amino group and a single aromatic ring, most H₁ antagonists have a tertiary amino group linked by a 2- or 3-atom chain to 2 aromatic substituents and conform to the general formula

![General formula](image)

where Ar is aryl and X is a nitrogen or carbon atom or a —C—O—ether linkage to the β-aminoethyl side chain. Sometimes the 2 aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure.
EFFECTS ON PHYSIOLOGICAL SYSTEMS

Smooth Muscle. $H_1$ antagonists inhibit both the vasoconstrictor effects of histamine and, to a degree, the more rapid vasodilator effects mediated by activation of $H_1$ receptors on endothelial cells (synthesis/release of NO and other mediators).

Capillary Permeability. $H_1$ antagonists strongly block the increased capillary permeability and formation of edema and wheal caused by histamine.

Flare and Itch. $H_1$ antagonists suppress the action of histamine on nerve endings, including the flare component of the triple response and the itching caused by intradermal injection.

Exocrine Glands. $H_1$ antagonists do not suppress gastric secretion. However, the antimuscarinic properties of many $H_1$ antagonists may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, e.g., the respiratory tree.

Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy. During hypersensitivity reactions, histamine is one of the many potent autacoids released and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by $H_1$ antagonists thus also varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized.

CNS. The first-generation $H_1$ antagonists can both stimulate and depress the CNS. Stimulation occasionally is encountered in patients given conventional doses; they become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies
therapeutic doses of the older H₁ antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., diphenhydramine) are particularly prone to causing sedation. Because of the sedation that occurs with first-generation antihistamines, these drugs cannot be tolerated or used safely by many patients except at bedtime. Even then, patients may experience an antihistamine “hangover” in the morning, resulting in sedation with or without psychomotor impairment. Second-generation “nonsedating” H₁ antagonists do not cross the blood-brain barrier appreciably; their sedative effects are similar to those of placebo.

Many antipsychotic agents are H₁ and H₂ receptor antagonists, but it is unclear whether this property plays a role in the antipsychotic effects of these agents. The atypical antipsychotic agent clozapine is an effective H₁ antagonist and a weak H₃ antagonist but an H₄ receptor agonist in the rat. The H₁ antagonist activity of typical and atypical antipsychotic drugs is responsible for the effect of these agents to cause weight gain.

**Anticholinergic Effects.** Many of the first-generation H₁ antagonists tend to inhibit responses to ACh that are mediated by muscarinic receptors and may be manifest during clinical use. Some H₁ antagonists also can be used to treat motion sickness (see Chapters 9 and 46), probably as a result of their anticholinergic properties. Indeed, promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is the most effective H₁ antagonist in combating motion sickness. The second-generation H₁ antagonists have no effect on muscarinic receptors.

**Local Anesthetic Effect.** Some H₁ antagonists have local anesthetic activity, and a few are more potent than procaine. Promethazine (PHENERGAN) is especially active. However, the concentrations
required for this effect are much higher than those that antagonize histamine’s interactions with its receptors.

**ADME.** The H₁ antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 2-3 h, and effects usually last 4-6 h; however, some of the drugs are much longer acting (Table 32–2). Diphenhydramine, given orally, reaches a maximal concentration in the blood in ~2 h, remains there for another 2 h, then falls exponentially with a plasma elimination $t_{1/2}$ of ~4-8 h. The drug is distributed widely throughout the body, including the CNS. Little, if any, is excreted unchanged in the urine; most appears there as metabolites. Peak concentrations of these drugs in the skin may persist after plasma levels have declined. Thus, inhibition of “wheal and flare” responses to the intradermal injection of histamine or allergen can persist for >36 h after treatment, even when the concentration in plasma is low. Like other extensively metabolized drugs, H₁ antagonists are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. H₁ receptor antagonists also induce hepatic CYPs and thus may facilitate their own metabolism.

</table>
The second-generation H₁ antagonist loratadine is absorbed rapidly from the GI tract and metabolized in the liver to an active metabolite by CYPs. Consequently, metabolism of loratadine can be affected by other drugs that compete CYPs. Two other second-generation H₁ antagonists that were marketed previously, *terfenadine* and *astemizole*, also were converted by CYPs to active metabolites. Both of these drugs were found in rare cases to induce a potentially fatal arrhythmia, *torsade de pointes*, when their metabolism was impaired, such as by liver disease or drugs that inhibit the CYP3A family (see Chapter 29). This led to the withdrawal of terfenadine and astemizole from the market. The active metabolite of terfenadine, fexofenadine, is its replacement. Fexofenadine lacks the toxic side effects of terfenadine, is not sedating, and retains the anti-allergic properties of the parent compound. Another antihistamine developed using this strategy is *desloratadine*, an active metabolite of loratadine. Cetirizine,
loratadine, and fexofenadine are all well absorbed and are excreted mainly in the unmetabolized form. Cetirizine and loratadine are excreted primarily into the urine, whereas fexofenadine is excreted primarily in the feces. Levocetirizine represents the active enantiomer of cetirizine.

**THERAPEUTIC USES**

H₁ antagonists are used for treatment of various immediate hypersensitivity reactions. The central properties of some of the drugs also are of therapeutic value for suppressing motion sickness or for sedation.

**ALLERGIC DISEASES.** H₁ antagonists are useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis. Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (see Chapter 36). In the treatment of systemic anaphylaxis, where autacoids other than histamine are important, the mainstay of therapy is epinephrine; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life.

Certain allergic dermatoses respond favorably to H₁ antagonists. The benefit is most striking in acute urticaria. Angioedema also responds to treatment with H₁ antagonists, but the paramount importance of epinephrine in the severe attack must be reemphasized, especially in life-threatening laryngeal edema (see Chapter 12). H₁ antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients with atopic and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. The urticarial and edematous lesions of serum sickness respond to H₁ antagonists, but fever and arthralgia
often do not.

**COMMON COLD.** H₁ antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.

**MOTION SICKNESS, VERTIGO, AND SEDATION.** Scopolamine, the muscarinic antagonist, given orally, parenterally, or transdermally, is the most effective drug for the prophylaxis and treatment of motion sickness. Some H₁ antagonists are useful for milder cases and have fewer adverse effects. These drugs include dimenhydrinate and the piperazines (e.g., cyclizine, meclizine). Promethazine, a phenothiazine, is more potent and more effective; its additional antiemetic properties may be of value in reducing vomiting, but its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered ~1 h before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial. Some H₁ antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Meniere disease and in other types of true vertigo. Only promethazine is useful in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other, more effective antiemetic drugs (e.g., 5HT₃ antagonists) are available (see Chapter 46). Diphenhydramine can reverse the extrapyramidal side effects caused by phenothiazines (see Chapter 16). The tendency of some H₁ receptor antagonists to produce somnolence has led to their use as hypnotics. H₁ antagonists, principally diphenhydramine, often are present in various proprietary over-the-counter remedies for insomnia. The sedative and mild antianxiety activities of hydroxyzine contribute to its use as a weak anxiolytic.

**ADVERSE EFFECTS.** The most frequent side effect in first-
generation H₁ antagonists is sedation. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors. Other side effects include loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea. Taking the drug with meals may reduce their incidence. H₁ antagonists such as cyproheptadine may increase appetite and cause weight gain. Other side effects, owing to the antimuscarinic actions of some first-generation H₁ antagonists, include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation H₁ antagonists.

Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications, such as leukopenia, agranulocytosis, and hemolytic anemia, are very rare. Because H₁ antihistamines cross the placenta, caution is advised for women who are or may become pregnant. Several antihistamines (e.g., azelastine, hydroxyzine, fexofenadine) had teratogenic effects in animal studies, whereas others (e.g., chlorpheniramine, diphenhydramine, cetirizine, loratadine) did not. Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms such as irritability, drowsiness, or respiratory depression in the nursing infant.

In acute poisoning with H₁ antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, athetosis, and convulsions. Fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever, lend the syndrome a remarkable similarity to that of atropine poisoning. Terminally, there
is deepening coma with cardiorespiratory collapse and death usually within 2-18 h. Treatment is along general symptomatic and supportive lines.

**Pediatric and Geriatric Indications and Problems.** Although little clinical testing has been done, second-generation antihistamines are recommended for elderly patients (>65 years of age), especially those with impaired cognitive function, because of the sedative and anticholinergic effects of first-generation drugs. First-generation antihistamines are not recommended for use in children because their sedative effects can impair learning and school performance. The second-generation drugs have been approved by the FDA for use in children and are available in appropriate lower-dose formulations (e.g., chewable or rapidly dissolving tablets, syrup). Use of over-the-counter cough and cold medicines (containing mixtures of antihistamines, decongestants, antitussives, expectorants) in young children has been associated with serious side effects and deaths. In 2008, the FDA recommended that they not be used in children <2 years of age, and drug manufacturers affiliated with the Consumer Healthcare Products Association voluntarily relabeled products “do not use” for children <4 years of age.

**AVAILABLE H₁ ANTAGONISTS.** Summarized below are the therapeutic side effects of a number of H₁ antagonists, grouped by their chemical structures. Representative preparations are listed in Table 32–2.

**Dibenzoxepin Tricyclics (Doxepin).** Doxepin, the only drug in this class, is marketed as a tricyclic antidepressant (see Chapter 16). It also is one of the most potent H₁ antagonists and has significant H₂ antagonist activity, but this does not translate into greater clinical effectiveness. It can cause drowsiness and is associated with anticholinergic effects. Doxepin is better tolerated by patients with
depression than those who are not depressed, where even small doses (e.g., 20 mg) may cause disorientation and confusion.

**Ethanolamines (Prototype: Diphenhydramine).** These drugs possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated acutely with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.

**Ethylenediamines (Prototype: Pyrilamine).** These include some of the most specific H₁ antagonists. Although their central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are quite common.

**Alkylamines (Prototype: Chlorpheniramine).** These are among the most potent H₁ antagonists. The drugs are less prone to produce drowsiness and are more suitable for daytime use, but a significant proportion of patients do experience sedation. Side effects involving CNS stimulation are more common than with other groups.

**First-Generation Piperazines.** The oldest member of this group, chlorcyclizine, has a more prolonged action and produces a comparatively low incidence of drowsiness. Hydroxyzine is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent anti-pruritic action. Cyclizine and meclizine have been used primarily to counter motion sickness, although promethazine and diphenhydramine are more effective (as is the antimuscarinic scopolamine).

**Second-Generation Piperazines (Cetirizine).** Cetirizine is the only drug in this class. It has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat
higher incidence of drowsiness than the other second-generation H\textsubscript{1} antagonists. The active enantiomer levocetirizine has slightly greater potency and may be used at half the dose with less resultant sedation.

*Phenothiazines (Prototype: Promethazine).* Most drugs of this class are H\textsubscript{1} antagonists and also possess considerable anticholinergic activity. Promethazine, which has prominent sedative effects, and its many congeners are used primarily for their antiemetic effects (*see Chapter 46*).

*First-Generation Piperidines (Cyproheptadine, Phenindamine).* Cyproheptadine uniquely has both antihistamine and anti-serotonin activity. Cyproheptadine and phenindamine cause drowsiness and also have significant anticholinergic effects and can increase appetite.

*Second-Generation Piperidines (Prototype: Terfenadine).* Terfenadine and astemizole were withdrawn from the market. Current drugs in this class include loratadine, desloratadine, and fexofenadine. These agents are highly selective for H\textsubscript{1} receptors, lack significant anticholinergic actions, and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines.

**H\textsubscript{2} RECEPTOR ANTAGONISTS**

The pharmacology and clinical utility of H\textsubscript{2} antagonists to inhibit gastric acid secretion are described in *Chapter 45*.

**H\textsubscript{3} RECEPTOR AND LIGANDS**

H\textsubscript{3} receptors are presynaptic autoreceptors on histaminergic neurons that originate in the tuberomammillary nucleus in the hypothalamus and project throughout the CNS, most prominently to the hippocampus, amygdala, nucleus accumbens, globus pallidus,
striatum, hypothalamus, and cortex. The activated H₃ receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H₃ agonists decrease histaminergic transmission, and antagonists increase it.

H₃ receptors also are presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, and their activation inhibits release from noradrenergic, serotonergic, GABA-ergic, cholinergic, and glutamatergic neurons, as well as pain-sensitive C fibers. H₃ receptors in the brain have significant constitutive activity in the absence of agonist; consequently, inverse agonists will activate these neurons.

H₃ antagonists/inverse agonists have a wide range of central effects; for example, they promote wakefulness, improve cognitive function (e.g., enhance memory, learning, and attention), and reduce food intake. As a result, there is considerable interest in developing H₃ antagonists for possible treatment of sleeping disorders, attention deficit hyperactivity disorder (ADHD), epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer disease. Thioperamide was the first “specific” H₃ antagonist/inverse agonist available experimentally, but was equally effective at the H₄ receptor. A number of other imidazole derivatives have been developed as H₃ antagonists, including clobenpropit, ciproxifan, and proxyfan. More selective non-imidazole H₃ antagonists/inverse agonists are in phase II clinical trials.

**H₄ RECEPTOR AND LIGANDS**

H₄ receptors are expressed on cells with inflammatory or immune functions and can mediate histamine-induced chemotaxis, induction of cell shape change, secretion of cytokines, and upregulation of
adhesion molecules. The H₄ receptors also have a role in pruritus and neuropathic pain. Because of the unique localization and function of H₄ receptors, H₄ antagonists are promising candidates to treat these conditions. No H₄ antagonists have yet been tested in clinical trials.

The H₄ receptor has the highest homology with the H₃ receptor and binds many H₃ ligands, especially those with imidazole rings, although sometimes with different effects. For example, thioperamide is an effective inverse agonist at both H₃ and H₄ receptors, whereas H₃ inverse agonist clobenpropit is a partial agonist of the H₄ receptor; impentamine (an H₃ agonist) and iodophenpropit (an H₃ inverse agonist) are both neutral H₄ antagonists.

**BRADYKININ, KALLIDIN, AND THEIR ANTAGONISTS**

Tissue damage, allergic reactions, viral infections, and other inflammatory events activate a series of proteolytic reactions that generate bradykinin and kallidin in tissues. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability but can also have beneficial effects, for example in the heart, kidney, and circulation. Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or endothelium-derived hyperpolarizing factor (EDHF).

**THE ENDOGENOUS KALLIKREIN–KININOGEN–KININ SYSTEM**

Bradykinin is a nonapeptide. Kallidin is a decapeptide containing an additional N-terminal lysine, is sometimes referred to as lysyl-bradykinin (Table 32–3). The 2 peptides are cleaved from 3₂ globulins termed kininogens (Figure 32–2). There are 2 kininogens: high-molecular-weight (HMW) kininogen and low-molecular-weight (LMW) kininogen. A number of serine proteases will generate kinins, but the highly specific proteases that release bradykinin and kallidin
from the kininogens are termed **kallikreins**.

**Figure 32–2** Synthesis and signaling in the kallikrein-kinin and renin-angiotensin systems. Bradykinin is generated by the action of plasma kallikrein
on high-molecular-weight (HMW) kininogen and kallidin is released by the hydrolysis of low-molecular-weight (LMW) kininogen by tissue kallikrein. Kallidin and bradykinin are the natural ligands of the B<sub>2</sub> receptor but can be converted to corresponding agonists of the B<sub>1</sub> receptor by removal of the C-terminal Arg by kininase I–type enzymes: the plasma membrane–bound carboxypeptidase M (CPM) or soluble plasma carboxypeptidase N (CPN). Kallidin or [des-Arg<sup>10</sup>]-kallidin can be converted to the active peptides bradykinin or to [des-Arg<sup>9</sup>]-bradykinin by aminopeptidase cleavage of the N-terminal Lys residue. In a parallel fashion, angiotensin I is generated by the action of renin on angiotensinogen. Angiotensin I is then converted by angiotensin-converting enzyme (ACE) to the active peptide angiotensin II (AngII). These 2 systems have opposing effects. Bradykinin is a vasodilator that stimulates Na<sup>+</sup> excretion by activating the B<sub>2</sub> receptor. AngII is a potent vasoconstrictor that also causes aldosterone release and Na<sup>+</sup> retention via activation of the AT<sub>1</sub> receptor. ACE simultaneously generates active AngII and inactivates bradykinin and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents.

**KALLIKREINS.** Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma and tissue kallikrein, respectively (see Figure 32–2). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms. Plasma prekallikrein is an inactive protein of ~88,000 Da that complexes with its substrate, HMW kininogen. The ensuing proteolytic cascade is restrained by the protease inhibitors present in plasma. Among the most important of these are the inhibitor of the activated first component of complement (C1-INH) and r<sub>2</sub> macroglobulin. Under experimental conditions, the kallikrein–kinin system is activated by the binding of factor XII, also known as Hageman factor, to negatively charged surfaces. Factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (see Chapter 30), undergoes autoactivation and, in turn, activates prekallikrein. Importantly, kallikrein further activates factor XII, thereby exerting a positive feedback on the system. Tissue kallikrein (29,000 Da) is synthesized as a preproprotein in the epithelial cells or secretory cells
in several tissues, including salivary glands, pancreas, prostate, and distal nephron. Tissue kallikrein also is expressed in human neutrophils. It acts locally near its sites of origin. The synthesis of tissue prokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. The activation of tissue prokallikrein to kallikrein requires proteolytic cleavage to remove a 7–amino acid propeptide.

**KININOGENS.** The 2 substrates for the kallikreins, HMW kininogen and LMW kininogen, are derived from a single gene by alternative splicing. HMW kininogen is cleaved by plasma and tissue kallikrein to yield bradykinin and kallidin, respectively. LMW kininogen is a substrate only of tissue kallikrein, and the product is kallidin.

**METABOLISM OF KININS.** The decapeptide kallidin is about as active as the nonapeptide bradykinin, even without conversion to bradykinin, which occurs when the N-terminal lysine residue is removed by an aminopeptidase (see Figure 32–2). The \( t_{1/2} \) of kinins in plasma is only \( \sim 15 \) sec; 80-90% of the kinins may be destroyed in a single passage through the pulmonary vascular bed. Plasma concentrations of bradykinin are difficult to measure because inadequate inhibition of kininogenases or kininases in the blood can lead to artifactual formation or degradation of bradykinin during blood collection. When care is taken to inhibit these processes, the reported physiological concentrations of bradykinin in blood are in the picomolar range.

The principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE (see Chapter 26). Removal of the C-terminal dipeptide by ACE or neutral endopeptidase 24.11 (neprilysin) inactivates kinins (Figure 32–3). A slower-acting enzyme, carboxypeptidase N (lysine carboxypeptidase, kininase I), releases the C-terminal arginine residue, producing \([\text{desArg}^9]\)-bradykinin or \([\text{des-Arg}^{10}]\)-kallidin (see Table 32–3 and Figures 32–2 and 32–3), which are potent \( \text{B}_1 \) receptor agonists. Carboxypeptidase N is expressed
constitutively in blood plasma. A familial carboxypeptidase N deficiency is associated with angioedema or urticaria. Carboxypeptidase M, which also cleaves basic C-terminal amino acids, is a widely distributed plasma membrane–bound enzyme. Finally, aminopeptidase P can cleave the N-terminal arginine, rendering bradykinin inactive and susceptible to cleavage by dipeptidyl peptidase IV.

Figure 32–3 Degradation of bradykinin.

KININ RECEPTORS. The B₁ and B₂ kinin receptors are GPCRs.

The bradykinin B₂ receptor is expressed in most normal tissues, where it selectively binds intact bradykinin and kallidin (see Table 32–3 and see Figure 32–2). The B₂ receptor mediates most of bradykinin’s effects under normal circumstances, whereas synthesis of the B₁ receptor is induced by inflammatory mediators in inflammatory conditions. Both B₁ and B₂ receptors couple through G₉ to activate PLC and increase intracellular Ca²⁺; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For example, on endothelial cells, activation of B₂ receptors results in Ca²⁺–calmodulin–dependent activation of eNOS and generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, B₁ receptor stimulation results in prolonged NO production via G₁ and
MAP kinase-dependent activation of iNOS expression. On smooth muscle cells, activation of kinin receptors coupling through G\textsubscript{q} results in an increased [Ca\textsuperscript{2+}]\textsubscript{i} and contraction. Bradykinin activates the pro-inflammatory transcription factor NF- B through GB\textsubscript{q} and subunits and also activates the MAP kinase pathway. B\textsubscript{1} and B\textsubscript{2} receptors also can couple through G\textsubscript{i} to activate PLA\textsubscript{2}, causing the release of arachidonic acid and the local generation of a variety of metabolites, including inflammatory mediators and vasodilator epoxyeicosatrienoic acids (EETs) and prostacyclin such as EDHF. Kallikrein also plays a role in the intrinsic blood coagulation pathway.

The B\textsubscript{1} receptor is activated by the des-Arg metabolites of bradykinin and kallidin produced by the actions of carboxypeptidases N and M (see Table 32–3). Interestingly, carboxypeptidase M and the B\textsubscript{1} receptor interact on the cell surface to form an efficient signaling complex. B\textsubscript{1} receptors are normally absent or expressed at low levels in most tissues. B\textsubscript{1} receptor expression is upregulated by tissue injury and inflammation and by cytokines, endotoxins, and growth factors. Carboxypeptidase M expression also is increased by cytokines, to such a degree that B\textsubscript{1} receptor effects may predominate over B\textsubscript{2} effects. The B\textsubscript{1} and B\textsubscript{2} receptors differ in their time courses of downregulation; the B\textsubscript{2} receptor response is rapidly desensitized, whereas the B\textsubscript{1} response is not. This likely is due to modification at a Ser/Thr-rich cluster present in the C-terminal tail of the B\textsubscript{2} receptor that is not conserved in the B\textsubscript{1} receptor sequence.

FUNCTIONS AND PHARMACOLOGY OF KALLIKREINS AND KININS

The utility of specific kinin-receptor antagonists currently is being investigated in diverse areas such as pain, inflammation, chronic inflammatory diseases, and the cardiovascular system. That the beneficial effects of ACE inhibitor therapy rests in part on enhancing
bradykinin activity (e.g., on the heart, kidney, blood pressure; see Chapter 26) demonstrates the complexities in interpreting bradykinin’s actions.

**Pain.** The kinins are powerful algesic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide. Although there is overlap, B₂ receptors generally mediate acute bradykinin algesia, whereas the pain of chronic inflammation appears to involve increased numbers and activation of B₁ receptors.

**Inflammation.** Kinins participate in a variety of inflammatory conditions. Plasma kinins increase permeability in the microcirculation, acting on the small venules to cause disruption of the inter-endothelial junctions. This, together with an increased hydrostatic pressure gradient, causes edema. Edema, coupled with stimulation of nerve endings, results in a “wheal and flare” response to intradermal injection. In hereditary angioedema, bradykinin is formed, and there is depletion of the upstream components of the kinin cascade during episodes of swelling, laryngeal edema, and abdominal pain. B₁ receptors on inflammatory cells (e.g., macrophages) can elicit production of the inflammatory mediators IL-1 and TNF-α. Kinin levels are increased in a number of chronic inflammatory diseases and may be significant in gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, or asthma. Kinins also may contribute to the skeletal changes seen in chronic inflammatory states. Kinins stimulate bone resorption through B₁ and possibly B₂ receptors, perhaps by osteoblast-mediated osteoclast activation (see Chapter 44).

**Respiratory Disease.** The kinins have been implicated in allergic
airway disorders such as asthma and rhinitis. Inhalation or intravenous injection of kinins causes bronchospasm in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and glandular secretions in patients with allergic rhinitis.

**Cardiovascular System.** Infusion of bradykinin causes vasodilation and lowers blood pressure. Bradykinin causes vasodilation by activating its B₂ receptor on endothelial cells, resulting in the generation of NO, prostacyclin, and a hyperpolarizing EET that is a CYP-derived metabolite of arachidonic acid. The endogenous kallikrein–kinin system plays a minor role in the regulation of normal blood pressure, but it may be important in hypertensive states. Urinary kallikrein concentrations are decreased in individuals with high blood pressure.

The kallikrein–kinin system is cardioprotective. Many of the beneficial effects of ACE inhibitors on heart function are attributable to enhancement of bradykinin effects, such as their antiproliferative activity or ability to increase glucose uptake in tissue. Bradykinin contributes to the beneficial effect of preconditioning to protect the heart against ischemia and reperfusion injury. Bradykinin also stimulates tissue plasminogen activator (tPA) release from the vascular endothelium and may contribute to the endogenous defense against some cardiovascular events, such as myocardial infarction and stroke.

**Kidney.** Renal kinins act in a paracrine manner to regulate urine volume and composition. Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kininogen and kinin receptors are present in the cells of the collecting duct. Like other
vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting sodium reabsorption at the cortical collecting duct. Treatment with mineralocorticoids, ACE inhibitors, and neutral endopeptidase (neprilysin) inhibitors increases renal kallikrein.

**Other Effects.** Kinins promote dilation of the fetal pulmonary artery, closure of the ductus arteriosus, and constriction of the umbilical vessels, all of which occur in the transition from fetal to neonatal circulation. Kinins also affect the CNS, disrupting the blood-brain barrier and allowing increased CNS penetration.

**Potential Therapeutic Uses.** Bradykinin contributes to many of the effects of the ACE inhibitors. Aprotinin, a kallikrein and plasmin inhibitor, has been administered to patients undergoing coronary bypass to minimize bleeding and blood requirements. Based on the pro-inflammatory and algesic effects of kinins, B<sub>1</sub> and B<sub>2</sub> receptor antagonists are being tested for the treatment of inflammatory conditions and certain types of pain.

**KALLIKREIN INHIBITORS**

Aprotinin (TRASYLOL) is a natural proteinase inhibitor that inhibits mediators of the inflammatory response, fibrinolysis, and thrombin generation following cardiopulmonary bypass surgery, including kallikrein and plasmin. Aprotinin has been employed clinically to reduce blood loss in patients undergoing coronary artery bypass surgery, but unfavorable survival statistics in retrospective and prospective studies have resulted in its discontinuation. Ecallantide (DX-88), a synthetic plasma kallikrein inhibitor, inhibits acute episodes of angioedema in patients with hereditary angioedema.

**BRADYKININ AND THE EFFECTS OF ACE INHIBITORS.** ACE inhibitors, widely used in the treatment of hypertension, congestive heart failure, and diabetic nephropathy, block the conversion of AngI
to AngII and also block the degradation of bradykinin by ACE (see Figure 32–2 and Chapter 26). Numerous studies demonstrate that bradykinin contributes to many of the protective effects of ACE inhibitors. The search is on to find a suitable stable B₂ agonist for clinical evaluation that provides cardiovascular benefit without pro-inflammatory effects.

A rare side effect of ACE inhibitors is angioedema, which may be connected to the inhibition of kinin metabolism by ACE. A common side effect of ACE inhibitors is a chronic, nonproductive cough that dissipates when the drug is stopped. Bradykinin may contribute to the effects of the AT₁-receptor antagonists. During AT₁ receptor blockade, AngII concentrations increase, which enhances signaling through the unopposed AT₂ subtype receptor, causing an increase in renal bradykinin concentrations.

**KININ RECEPTOR ANTAGONISTS.** The selective B₂ receptor antagonist HOE-140 (*icatibant*; FIRAZYR) has been approved in the E.U. and recently in the U.S. for treatment of acute episodes of swelling in patients with hereditary angioedema. It is administered by subcutaneous injection.
chapter 33
Lipid-Derived Autacoids: Eicosanoids and Platelet-Activating Factor

Membrane lipids supply the substrate for the synthesis of eicosanoids and platelet-activating factor (PAF). Eicosanoids—arachidonate metabolites, including prostaglandins (PGs), prostacyclin (PGI₂), thromboxane A₂ (TxA₂), leukotrienes (LTs), lipoxins, and hepoxilins—are not stored but are produced by most cells when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. Membrane glycerophosphocholine derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids contribute to inflammation, smooth muscle tone, hemostasis, thrombosis, parturition, and gastrointestinal secretion. Several classes of drugs, most notably aspirin, the traditional nonsteroidal anti-inflammatory agents (tNSAIDs), and the specific inhibitors of cyclooxygenase-2 (COX-2), such as the coxibs, owe their principal therapeutic effects to blockade of eicosanoid formation.

EICOSANOIDS
PGs, LTs, and related compounds are called eicosanoids, from the Greek eikosi (“twenty”). Precursor essential fatty acids contain 20 carbons and 3, 4, or 5 double bonds. Arachidonic acid (AA; 5,8,11,14-eicosatetraenoic acid) is the most abundant precursor, derived from dietary linoleic acid (9,12-octadecadienoic acid) or ingested directly as a dietary constituent.

BIOSYNTHESIS. Biosynthesis of eicosanoids is limited by the availability of AA and depends primarily on the removal of esterified
AA from membrane phospholipids or other complex lipids by acyl hydrolases, notably phospholipase A2 (PLA2). Once liberated, AA is metabolized rapidly to oxygenated products by cyclooxygenases (COXs), lipoxygenases (LOXs), and CYPs (Figure 33–1).

Figure 33–1 Metabolism of arachidonic acid (AA). The cyclooxygenase (COX) pathway is highlighted in gray. The lipoxygenase (LOX) pathways are expanded in Figure 33–2. Major degradation pathways are shown in Figure 33–3. Cyclic endoperoxides (PGG2 and PGH2) arise from the sequential cyclooxygenase and hydroperoxidase actions of COX-1 or COX-2 on AA released from membrane...
phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects via membrane-bound receptors (blue boxes). Dashed lines indicate putative ligand-receptor interactions. Epoxycosatrienoic acids (EETs; shaded in blue) and isoprostanes are generated via CYP activity and non-enzymatic free radical attack, respectively. COX-2 can use modified arachidonoylglycerol, an endocannabinoid, to generate the glyceryl prostaglandins. Aspirin and tNSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. Epilipoxins are generated by COX-2 following its acetylation by aspirin (see Figure 33–2). Dual 5-LOX-COX inhibitors interfere with both pathways. See the text for other abbreviations.

Chemical and physical stimuli activate the Ca\(^{2+}\)-dependent translocation of group IV\(_A\) cytosolic PLA\(_2\) (cPLA\(_2\)) to the membrane, where it hydrolyzes the sn-2 ester bond of membrane phosphatidylcholine and phosphatidylethanolamine, releasing AA. Multiple additional PLA\(_2\) isoforms (secretory [s] and Ca\(^{2+}\)-independent [i] forms) have been characterized. Under basal conditions, AA liberated by iPLA\(_2\) is reincorporated into cell membranes. The inducible sPLA\(_2\) contributes to AA release under conditions of sustained or intense stimulation of AA production.

**PRODUCTS OF PROSTAGLANDIN G/H SYNTHASES (CYCLOOXYGENASES).** PG endoperoxide G/H synthase also is called cyclooxygenase or COX. Products of this pathway are PGs, prostacyclin (PGI\(_2\)), and thromboxanes (TX\(_2\)), collectively termed prostanoids. The pathway is well described by Figure 33–1 and its legend.

Prostanoids are distinguished by substitutions on their cyclopentane rings the number of double bonds in their side chains, as indicated by numerical subscripts (dihomo-\(\gamma\)-linolenic acid is the precursor of series\(_1\), AA for series\(_2\), and EPA for series\(_3\)). Prostanoids derived from AA carry the subscript 2 and are the major series in mammals.
There are 2 distinct COX isoforms, COX-1 and COX-2. COX-1, expressed constitutively in most cells, is the dominant source of prostanoids for housekeeping functions. COX-2, in contrast, is upregulated by cytokines, shear stress, and growth factors and is the principal source of prostanoid formation in inflammation and cancer. However, this distinction is not absolute; both enzymes may contribute to the generation of prostanoids of some physiologic and pathophysiologic processes. These enzymes are expressed in a relatively cell-specific fashion. For example, COX-1-derived TxA2 is the dominant product in platelets, whereas COX-2-derived PGE2 and TxA2 dominate in activated macrophages. Prostanoids are released from cells predominantly by facilitated transport through the PG transporter and possibly other transporters.

**LIPOXYGENASE (LOX) PRODUCTS.** Products of the LOX pathways are hydroxy fatty acid derivatives (HETEs), LTs, and lipoxins (LXs) (Figure 33–2). LTs play a major role in the development and persistence of the inflammatory response.
LOXs are a family of non-heme iron–containing enzymes that catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides. The enzymes require a fatty acid substrate with 2 cis double bonds separated by a methylene group. AA is metabolized to
hydroperoxy eicosatetraenoic acids (HPETEs). HPETEs are converted to HETEs and leukotrienes.

The 5-LOX pathway leads to the synthesis of the LTs. When eosinophils, mast cells, polymorphonuclear leukocytes, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with 5-LOX-activating protein (FLAP), an integral membrane protein that facilitates AA to 5-LOX interaction. Drugs that inhibit FLAP block LT production. A 2-step reaction is catalyzed by 5-LOX: oxygenation of AA to form 5-HPETE, followed by dehydration of 5-HPETE to an unstable epoxide, LTA₄. LTA₄ is transformed by LTA₄ hydrolase to LTB₄; or is conjugated with GSH by LTC₄ synthase to form LTC₄. Extracellular metabolism of the peptide moiety of LTC₄ and the removal of glutamic acid and subsequent cleavage of glycine generates LTD₄ and LTE₄, respectively. LTC₄, LTD₄, and LTE₄ are the cysteinyl leukotrienes (CysLTs). LTB₄ and LTC₄ are actively transported out of the cell. LTA₄, the primary product of the 5-LOX pathway, is metabolized by 12-LOX to form the lipoxins LXA₄ and LXB₄. These mediators also can arise through 5-LOX metabolism of 15-HETE.

**PRODUCTS OF CYPs.** AA is metabolized to epoxyeicosatrienoic acids (EETs) by CYP epoxygenases, primarily CYP2C and CYP2J. EETs are synthesized in endothelial cells, where they function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation. EETs biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression.

**Other Pathways.** The isoeicosanoids, a family of eicosanoid isomers, are generated by nonenzymatic free radical catalyzed oxidation of AA. Unlike PGs, these compounds are initially formed esterified in phospholipids and released by phospholipases; the isoeicosanoids then
circulate and are metabolized and excreted into urine. Their production is not inhibited in vivo by inhibitors of COX-1 or COX-2, but their formation is suppressed by antioxidants. Isoprostanes correlate with cardiovascular risk factors and increased levels are found in a large number of clinical conditions.

**INHIBITORS OF EICOSANOID BIOSYNTHESIS.** Inhibition of PLA$_2$ decreases the release of the precursor fatty acid and the synthesis of all its metabolites. PLA$_2$ may be inhibited by drugs that reduce the availability of Ca$^{2+}$. *Glucocorticoids* inhibit PLA$_2$ indirectly by inducing the synthesis of a group of proteins termed *annexins* that modulate PLA$_2$ activity. Glucocorticoids also downregulate induced expression of COX-2 but not of COX-1 (see Chapter 42). Aspirin and tNSAIDs inhibit the COX, but not the hydroperoxidase (HOX), moieties of both PG G/H syntheses, and thus the formation of their downstream prostanoid products. In addition, these drugs do not inhibit LOXs and may cause increased formation of LTs by shunting of substrate to the LOX pathway. LTs may contribute to the GI side effects associated with NSAIDs.

COX-1 and COX-2 differ in their sensitivity to inhibition by certain anti-inflammatory drugs. This led to the development of selective inhibitors of COX-2, including the coxibs (see Chapter 34). These drugs were hypothesized to offer therapeutic advantages over tNSAIDs (many of which are nonselective COX inhibitors) because COX-2 is the predominant COX at sites of inflammation, whereas COX-1 is the major source of cytoprotective PGs in the GI tract. There now is compelling evidence that COX-2 inhibitors confer a spectrum of cardiovascular hazards (myocardial infarction, stroke, systemic and pulmonary hypertension, congestive heart failure, and sudden cardiac death). The hazards can be explained by suppression of cardioprotective COX-2-derived PGs, especially PGI$_2$, and the unrestrained effects of endogenous stimuli, such as platelet COX-1-
derived TxA₂, for platelet activation, vascular proliferation and remodeling, hypertension, and atherogenesis.

Because LTs mediate inflammation, efforts have focused on development of LT-receptor antagonists and selective inhibitors of the LOXs. Zileuton, an inhibitor of 5-LOX, and selective CysLT-receptor antagonists (zafirlukast, pranlukast, and montelukast) have established efficacy in the treatment of mild to moderate asthma (see Chapter 36). A common polymorphism in the gene for LTC₄ synthase that correlates with increased LTC₄ generation is associated with aspirin-intolerant asthma and with the efficacy of anti-LT therapy. Interestingly, although polymorphisms in the genes encoding 5-LOX or FLAP do not appear to be linked to asthma, studies have demonstrated an association of these genes with myocardial infarction, stroke, and atherosclerosis; thus, inhibition of LT biosynthesis may be useful in the prevention of cardiovascular disease.

**EICOSANOID DEGRADATION** (FIGURE 33–3). Most eicosanoids are efficiently and rapidly inactivated. The enzymatic catabolic reactions are of 2 types: a rapid initial step, catalyzed by widely distributed PG-specific enzymes, wherein PGs lose most of their biological activity; and a second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β and ω oxidation of fatty acids. The lung, kidney, and liver play prominent roles in the enzymatically catalyzed reactions. PGI₂ and TxA₂ undergo spontaneous hydrolysis as a first degradative step.
Figure 33–3 Major pathways of prostanoid degradation. Active metabolites are shaded in gray. Major urinary metabolites are shaded in orange. The red dashed lines indicate reactions that use common enzymatic processes. M, metabolite. See the text for other abbreviations.

PHARMACOLOGICAL PROPERTIES

The eicosanoids function through activation of specific GPCRs that couple to intracellular second-messenger systems to modulate cellular activity (Table 33–1 and Figure 33–4).

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants for EP₂, TP, and FP are indicated. IsoPs, isoprostanes; 15d-PGJ₂, 15-deoxy-Δ¹₂,14-PGJ₂; DP, is a member of the FMLP-receptor superfamily; fMLP, formyl-methionyl-leucyl-phenylalanine.
Prostanoid receptors and their primary signaling pathways.
Prostanoid receptors are heptaspanning GPCRs. The terms “relaxant,” “contractile,” and “inhibitory” refer to the phylogenetic characterization of their primary effects. **All EP\textsubscript{3} isoforms couple through G\textsubscript{i}; some can also activate G\textsubscript{s} or G\textsubscript{12/13} pathways. See the text for additional details.

Prostaglandin Receptors. PGs activate membrane receptors locally near their sites of formation. Eicosanoid receptors interact with G\textsubscript{s}, G\textsubscript{i}, and G\textsubscript{q} to modulate the activities of adenylyl cyclase and phospholipase C (see Chapter 3). Single gene products have been identified for the receptors for PGI\textsubscript{2} (the IP), PGF\textsubscript{2\alpha} (the FP), and TxA\textsubscript{2} (the TP). Four distinct PGE\textsubscript{2} receptors (EP\textsubscript{1-4}) and 2 PGD\textsubscript{2} receptors (DP\textsubscript{1} and DP\textsubscript{2}—also known as CRTH\textsubscript{2}) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP\textsubscript{3} (I-VI, e, f) receptors can arise through differential mRNA splicing.
The prostanoid receptors appear to derive from an ancestral EP receptor and share high homology. Phylogenetic comparison of this receptor family reveals 3 subclusters:

- The relaxant receptors EP$_2$, EP$_4$, IP, and DP$_1$, which increase cellular cyclic AMP generation
- The contractile receptors EP$_1$, FP, and TP, which increase cytosolic levels of Ca$^{2+}$
- EP$_3$, which can couple to both elevation of cytosolic [Ca$^{2+}$] and inhibition of adenylyl cyclase

The DP$_2$ receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the formyl-methionyl-leucyl-phenylalanine (fMLP)-receptor superfamily.

**Leukotriene and Lipoxin Receptors.** Two receptors exist for both LTB$_4$ (BLT$_1$ and BLT$_2$) and the cysteiny1 leukotrienes (CysLT$_1$ and CysLT$_2$). A receptor that binds lipoxin, ALX, is identical to the fMLP-1 receptor; the nomenclature now reflects LXA$_4$ as a natural and potent ligand. All are GPCRs and couple with G$_q$ and other G proteins, depending on the cellular context. BLT$_1$ is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT$_2$, the low-affinity receptor for LTB$_4$, is found in spleen, leukocytes, ovary, liver, and intestine. CysLT$_1$ binds LTD$_4$ with higher affinity than LTC$_4$, while CysLT$_2$ shows equal affinity for both LTs. Both receptors bind LTE$_4$ with low affinity. CysLT$_1$ is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas CysLT$_2$ is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain. Responses to ALX-receptor activation vary with cell type. The ALX receptor is expressed in lung, peripheral blood leukocytes, and spleen.

**Other Agents.** Other AA metabolites (e.g., isoprostanes,
epoxyeicosatrienoic acids, hepoxilins) have potent biological activities, and there is evidence for distinct receptors for some of these substances. Specific receptors for the HETEs and EETs have been proposed but not yet isolated.

**PHARMACOLOGICAL EFFECTS**

**CARDIOVASCULAR SYSTEM.** In most vascular beds, PGE$_2$, PGI$_2$, and PGD$_2$ elicit vasodilation and a drop in blood pressure; physiologically, these responses are quite local, since endogenous prostanoids are paracrine mediators that do not circulate. Responses to PGF$_{2\alpha}$ vary with vascular bed; it is a potent constrictor of both pulmonary arteries and veins; however, it does not alter blood pressure in humans. TxA$_2$ is a potent vasoconstrictor and a mitogen in smooth muscle cells.

PGE$_2$ can cause vasoconstriction through activation of the EP$_1$ and EP$_3$ receptors. Infusion of PGD$_2$ in humans results in flushing, nasal stuffiness, and hypotension. Local subcutaneous release of PGD$_2$ contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans. Subsequent formation of F-ring metabolites from PGD$_2$ may result in hypertension. PGI$_2$ relaxes vascular smooth muscle, causing hypotension and reflex tachycardia on intravenous administration. LTC$_4$ and LTD$_4$ can constrict or relax isolated vascular smooth muscle preparations, depending on the concentrations used and the vascular bed. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not. LTC$_4$ and LTD$_4$ act in the microvasculature to increase permeability of postcapillary venules; they are ~1,000-fold more potent than histamine in this regard. At higher concentrations, LTC$_4$ and LTD$_4$ can constrict arterioles and reduce exudation of plasma. EETs cause vasodilation in a number of vascular beds by activating the large conductance Ca$^{2+}$-
activated K+ channels of smooth muscle cells, thereby hyperpolarizing the smooth muscle and causing relaxation. EETs likely also function as EDHFs. Isoprostanes usually are vasoconstrictors, although there are examples of vasodilation in preconstricted vessels.

**PLATELETS.** Mature platelets express only COX-1. TxA2, the major product of COX-1 in platelets, induces platelet aggregation and amplifies the signal for other, more potent platelet agonists, such as thrombin and ADP. Low concentrations of PGE2, via the EP3, enhance platelet aggregation. In contrast, higher concentrations of PGE2, acting via the IP or possibly EP2 or EP4 receptors, inhibit platelet aggregation. Both PGI2 and PGD2 inhibit the aggregation of platelets. PGI2 limits platelet activation by TxA2, and disaggregates preformed clumps.

TxA2 induces platelet shape change, through G12/G13-mediated Rho/Rho-kinase-dependent regulation of myosin light-chain phosphorylation, and aggregation through Gq-dependent activation of PKC. The actions of TxA2 on platelets are restrained by its short t1/2 (~30 sec), by rapid TP desensitization, and by endogenous inhibitors of platelet function, including NO and PGI2.

**INFLAMMATION AND IMMUNITY.** Eicosanoids play a major role in the inflammatory and immune responses. LTs generally are pro-inflammatory and lipoxins anti-inflammatory. Prostanoids can exert both kinds of activity. COX-2 is the major source of prostanoids formed during and after an inflammatory response.

PGE2 and PGI2 are the predominant pro-inflammatory prostanoids, as a result of increased vascular permeability and blood flow in the inflamed region. TxA2 can increase platelet–leukocyte interaction. Prostanoids, especially PGD2, also contribute to resolution of inflammation. PGs generally inhibit lymphocyte function and
proliferation, suppressing the immune response. PGE\textsubscript{2} depresses the humoral antibody response by inhibiting the differentiation of B lymphocytes into antibody-secreting plasma cells. PGE\textsubscript{2} acts on T lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE\textsubscript{2} and TxA\textsubscript{2} also may play a role in T lymphocyte development by regulating apoptosis of immature thymocytes. PGD\textsubscript{2} is a potent leukocyte chemoattractant primarily through the DP\textsubscript{2}.

LTB\textsubscript{4} is a potent chemotactic agent for neutrophils, T lymphocytes, eosinophils, monocytes, dendritic cells, and possibly also mast cells. LTB\textsubscript{4} stimulates the aggregation of eosinophils and promotes degranulation and the generation of superoxide. LTB\textsubscript{4} promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of pro-inflammatory cytokines from macrophages and lymphocytes. The CysLTs are chemotaxins for eosinophils and monocytes. They also induce cytokine generation in eosinophils, mast cells, and dendritic cells. At higher concentrations, these LTs also promote eosinophil adherence, degranulation, cytokine or chemokine release, and oxygen radical formation. In addition, CysLTs contribute to inflammation by increasing endothelial permeability, thus promoting migration of inflammatory cells to the site of inflammation. Lipoxins A and B inhibit natural killer cell cytotoxicity.

**BRONCHIAL AND TRACHEAL MUSCLE.** In general, TxA\textsubscript{2}, PGF\textsubscript{2α}, and PGD\textsubscript{2} contract, and PGE\textsubscript{2} and PGI\textsubscript{2} relax, bronchial and tracheal muscle. PGD\textsubscript{2} appear to be the primary bronchoconstrictor prostanoid of relevance in humans.

Roughly 10% of people given aspirin or tNSAIDs develop bronchospasm. This appears attributable to a shift in AA metabolism to LT formation. This substrate diversion appears to involve COX-1,
not COX-2. CysLTs are bronchoconstrictors that act principally on smooth muscle in the airways and are a thousand times more potent than histamine. They also stimulate bronchial mucus secretion and cause mucosal edema. PGI₂ causes bronchodilation in most species; human bronchial tissue is particularly sensitive, and PGI₂ antagonizes bronchoconstriction induced by other agents.

**UTERUS.** Strips of nonpregnant human uterus are contracted by PGF₂α and TxA₂ but are relaxed by PGEs. PGE₂, together with oxytocin, is essential for the onset of parturition. PGI₂ and high concentrations of PGE₂ produce relaxation. The intravenous infusion of low concentrations of PGE₂ or PGF₂α to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. PGEs and PGFs are used to terminate pregnancy.

**GI SMOOTH MUSCLE.** PGEs and PGFs stimulate contraction of the main longitudinal muscle from stomach to colon. Circular muscle generally relaxes in response to PGE₂ and contracts in response to PGF₂α. The LTs have potent contractile effects. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE. PGEs and PGFs stimulate the movement of water and electrolytes into the intestinal lumen. PGE₂ appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with tNSAIDs.

**GASTRIC AND INTESTINAL SECRETIONS.** In the stomach, PGE₂ and PGI₂ contribute to increased mucus secretion (*cytoprotection*), reduced acid secretion, and reduced pepsin content. PGE₂ and its analogs also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (*see Chapter 45*). CysLTs, by constricting gastric blood vessels and
enhancing production of pro-inflammatory cytokines, may contribute to the gastric damage.

**KIDNEY.** COX-2-derived PGE$_2$ and PGI$_2$ increase medullary blood flow and inhibit tubular sodium reabsorption. Expression of medullary COX-2 is increased during high salt intake. COX-1-derived products promote salt excretion in the collecting ducts. Cortical COX-2-derived PGE$_2$ and PGI$_2$ increase renal blood flow and glomerular filtration through their local vasodilating effects. There is an added layer of complexity: low dietary salt intake increases expression of cortical COX-2 expression. Through the action of PGE$_2$, and also possibly PGI$_2$, this results in increased renin release, leading to sodium retention and elevated blood pressure.

TxA$_2$, generated at low levels in the normal kidney, has potent vasoconstrictor effects that reduce renal blood flow and glomerular filtration rate. Infusion of PGF$_{2\alpha}$ causes both natriuresis and diuresis. Conversely, PGF$_{2\alpha}$ may activate the renin–angiotensin system, contributing to elevated blood pressure. There is substantial evidence for a role of the CYP epoxyxygenase products in regulating renal function, although their exact role in the human kidney remains unclear. Both 20-HETE and the EETs are generated in renal tissue. 20-HETE constricts the renal arteries, while EETs mediate vasodilation and natriuresis.

**EYE.** PGF$_{2\alpha}$ induces constriction of the iris sphincter muscle, but its overall effect in the eye is to decrease intraocular pressure (IOP) by increasing the aqueous humor outflow. A variety of FP receptor agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (see Chapter 64).

**CNS.** PGE$_2$ induces fever.
The hypothalamus regulates the body temperature set point, which is elevated by endogenous pyrogens. The response is mediated by coordinate induction of COX-2 and mPGE synthase-1 in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE2. PGE2 acts on EP3, and perhaps EP1, on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature. Exogenous PGF2α and PGI2 induce fever but do not contribute to the pyretic response. PGD2 and TxA2 do not induce fever. PGD2 also appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep. COX-2-derived prostanoids also have been implicated in several CNS degenerative disorders (e.g., Alzheimer disease, Parkinson disease; see Chapter 22).

**PAIN.** Inflammatory mediators, including LTs and PGs, increase the sensitivity of nociceptors and potentiate pain perception.

Centrally, both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli. PGE2, and perhaps PGD2, PGI2, and PGF2α, can increase excitability in pain transmission neuronal pathways in the spinal cord, causing hyperalgesia and allodynia. Hyperalgesia also is produced by LTB4. The role of PGE2 and PGI2 in inflammatory pain is discussed in more detail in Chapter 34.

**ENDOCRINE SYSTEM.** The systemic administration of PGE2 increases circulating concentrations of adrenocorticotropic hormone (ACTH), growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. The critical role of PGF2α in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. PGE2 works as part of a positive-feedback loop to induce oocyte maturation required
for fertilization during and after ovulation. LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by AngII, but not that which occurs in response to ACTH.

**BONE.** PGs are strong modulators of bone metabolism. COX-1 is expressed in normal bone, while COX-2 is upregulated in settings such as inflammation and during mechanical stress. PGE$_2$ stimulates bone formation by increasing osteoblastogenesis and bone resorption via activation of osteoclasts.

**THERAPEUTIC USES**

**INHIBITORS AND ANTAGONISTS.** The nonselective tNSAIDs, and those with selective COX-2 inhibition, are used widely as anti-inflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection. LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glaucoma (see Chapter 64). EP agonists are used to induce labor and to ameliorate gastric irritation owing to tNSAIDs. DP$_1$ antagonists may be useful in offsetting the facial flushing associated with niacin. Orally active antagonists of LTC$_4$ and D$_4$, which block the CysLT$_1$ receptor, are used in the treatment of mild to moderately severe asthma (see Chapter 36). Their effectiveness in patients with aspirin-induced asthma also has been shown. Prostanoids have a short $t_{1/2}$ in the circulation and their systemic administration produces significant adverse effects. Nonetheless, several prostanoids are of clinical utility in the following situations.

*Therapeutic Abortion.* PGEs, PGFs, and their analogs, are used to induce labor and terminate pregnancy at any stage by promoting uterine contractions. Dinoprostone, a synthetic preparation of PGE$_2$, is approved for inducing abortion in the second trimester of
pregnancy, for missed abortion, for cervical ripening prior to induction of labor, and for managing benign hydatidiform moles. Systemic or intravaginal administration of the PGE_{1} analog misoprostol in combination with mifepristone (RU486) or methotrexate is highly effective in the termination of early pregnancy. An analog of PGF_{2α}, carboprost tromethamine, is used to induce second-trimester abortions and to control postpartum hemorrhage that is not responding to conventional methods.

**Gastric Cytoprotection.** Several PG analogs are used to suppress gastric ulceration. Misoprostol (CYTOTEC), a PGE_{1} analog, is approved for prevention of NSAID-induced gastric ulcers.

**Impotence.** PGE_{1} (alprostadil), given as an intracavernous injection (CAVERJECT, EDEX) or urethral suppository (MUSE) is a second-line treatment of erectile dysfunction, PDE5 inhibitors being preferred (see Chapters 27 and 28).

**Maintenance of Patent Ductus Arteriosus.** The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE_{1}. PGE_{1} (alprostadil, PROSTIN VR PEDIATRIC) is highly effective for palliative therapy to maintain temporary patency until surgery can be performed.

**Pulmonary Hypertension.** Long-term therapy with PGI_{2} (prostacyclin; epoprostenol, FLOLAN), via continuous intravenous infusion, improves symptoms and can delay or preclude the need for lung or heart-lung transplantation in a number of patients. Several PGI_{2} analogs with longer \( t_{1/2} \) have been used clinically. Iloprost can be inhaled (VENTAVIS) or delivered by intravenous administration (not available in the U.S.). Treprostinil (REMODULIN) \( (t_{1/2} \sim 4\ h) \) may be delivered by continuous subcutaneous or intravenous infusion.
**Glaucoma.** Latanoprost, a PGF$_{2\alpha}$ derivative, was the first prostanoid used for glaucoma. Similar prostanoids with ocular hypotensive effects include bimatoprost and travoprost. These drugs act as agonists at the FP receptor and are administered as ophthalmic drops (see Chapter 64).

**PLATELET-ACTIVATING FACTOR**

PAF is 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine. PAF represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12-18 carbon atoms. In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated. PAF is not stored in cells but is synthesized from an acyl precursor in response to stimulation by a 2-step process (Figure 33–5).
PAF synthesis occurs in 2 steps. In the first step, activated PLA₂ cleaves membrane 1-O-alkyl-2-acyl-glycerophosphocholine to form lyso-PAF and a free fatty acid (usually AA that may be metabolized to eicosanoids). In the rate-limiting second step, PAF is formed from lyso-PAF by an acetyl CoA-lyso-PAF acetyltransferase. The synthesis of PAF may be stimulated during antigen–antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. PAF synthesis is regulated by the availability of Ca²⁺. PAF is degraded by the reversal of the synthetic steps, de-acetylation by acetylhydrolases (AHs) followed by acylation at the 2 position to regenerate a 1-O-alkyl-2-acyl-glycerophosphocholine. PAF synthesis also can occur de novo: a phosphocholine substituent is transferred to alkyl acetyl glycerol by a distinct lyso-glycerophosphate acetyl-CoA transferase. CoA, coenzyme A.

PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. Depending on cell type, PAF can either remain cell-associated or be secreted. For example, PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells, PAF is displayed on the surface for juxtacrine signaling and stimulates adherent leukocytes. PAF-like molecules can be formed from the oxidative fragmentation of membrane phospholipids (oxPLs). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the sn-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the sn-2 position. oxPLs mimic the structure of PAF closely enough to bind to its receptor and elicit the same responses. Increased levels of plasma PAF acyl hydrolase (PAF-AH) have been associated with colon cancer, cardiovascular disease, and stroke.

**MECHANISM OF ACTION OF PAF.** Extracellular PAF exerts its actions by stimulating a specific GPCR. The PAF receptor couples to Gq (to activate the PLC-IP₃–Ca²⁺ pathway) and to Gi (to inhibit
adenylyl cyclase). Consequent activation of phospholipases A₂, C, and D gives rise to myriad messengers, including AA-derived PGs, TxA₂, or LTs, which may function as mediators of the effects of PAF.

In addition, p38 MAP kinase is activated downstream of the PAF-receptor- \( G_q \) interaction, while ERK activation can occur via interaction of activated PAF receptor with \( G_q, G_o, \) or \( G_{\beta\gamma} \), or via transactivation of the EGF receptor, leading to NF-\( \kappa \)B activation. PAF exerts many of its important pro-inflammatory actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, polymorphonuclear leukocytes, and monocytes, and acts cooperatively with P selectin to promote adhesion. This function of PAF is important for orchestrating the interaction of platelets and circulating inflammatory cells with the inflamed endothelium.

**PHYSIOLOGICAL AND PATHOLOGICAL FUNCTIONS OF PAF**

**Inflammatory and Allergic Responses.** The administration of PAF reproduces many of the signs and symptoms in anaphylactic shock. However, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. In patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air.

**Cardiovascular System.** PAF is a potent vasodilator in most vascular beds; when administered intravenously, it causes hypotension. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin–angiotensin system, or AA metabolism and likely results from a combination of direct and indirect actions. PAF may, alternatively, induce vasoconstriction depending on the concentration, vascular bed, and involvement of platelets or leukocytes. Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and
bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by 3 orders of magnitude.

Platelets. The PAF receptor is constitutively expressed on the surface of platelets. PAF potently stimulates platelet aggregation in vitro and in vivo. Although this is accompanied by the release of TxA$_2$ and the granular contents of the platelet, PAF does not require the presence of TxA$_2$ or other aggregating agents to produce this effect. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia.

Leukocytes. PAF is a potent and common activator of inflammatory cells. PAF stimulates a variety of responses in polymorphonuclear leukocytes (eosinophils, neutrophils, and basophils). PAF stimulates PMNs to aggregate, degranulate, and generate free radicals and LTs. PAF is a potent chemotactic for eosinophils, neutrophils, and monocytes and promotes PMN-endothelial adhesion contributing, along with other adhesion molecular systems, to leukocyte rolling, tight adhesion, and migration through the endothelial monolayer. PAF also stimulates basophils to release histamine, activates mast cells, and induces cytokine release from monocytes. In addition, PAF promotes aggregation of monocytes and degranulation of eosinophils.

Smooth Muscle. PAF contracts GI, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; these contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels.
**Stomach.** PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

**Kidney.** PAF decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na⁺ without changes in systemic hemodynamics. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

**Other.** PAF, a potent mediator of angiogenesis, has been implicated in breast and prostate cancer. PAF-AH deficiency has been associated with small increases in a range of cardiovascular and thrombotic diseases in some human populations.

**PAF Receptor Antagonists.** Several experimental PAF-receptor antagonists exist that selectively inhibit the actions of PAF in vivo and in vitro. None has proven clinically useful.
Chapter 34
Pharmacotherapy of Inflammation, Fever, Pain, and Gout

The chapter describes the nonsteroidal anti-inflammatory drugs (NSAIDs) used to treat inflammation, pain, and fever and the drugs used for hyperuricemia and gout. The NSAIDS are first considered by class, then by groups of chemically similar agents described in more detail. Many of the basic properties of these drugs are summarized in Tables 34–2, 34–3, and 34–4. Most currently available traditional NSAIDs (tNSAIDs) act by inhibiting the prostaglandin (PG) G/H synthase enzymes, colloquially known as the cyclooxygenases (COXs; see Chapter 33). The inhibition of cyclooxygenase-2 (COX-2) is thought to mediate, in large part, the antipyretic, analgesic, and anti-inflammatory actions of tNSAIDs, while the simultaneous inhibition of cyclooxygenase-1 (COX-1) largely but not exclusively accounts for unwanted adverse effects in the GI tract. Selective inhibitors of COX-2 (celecoxib, etoricoxib, lumiracoxib) are a subclass of NSAIDs. Aspirin irreversibly acetylates COX; several structural subclasses of tNSAIDs, including propionic acid derivatives (ibuprofen, naproxen), acetic acid derivatives (indomethacin), and enolic acids (piroxicam) compete in a reversible manner with arachidonic acid (AA) at the active site of COX-1 and COX-2. Acetaminophen (paracetamol) is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs, has only weak anti-inflammatory activity, and exhibits fewer GI side effects than the tNSAIDs.

INFLAMMATION, PAIN, AND FEVER

INFLAMMATION. The inflammatory process is the response to an injurious stimulus. It can be evoked by noxious agents, infections, antibodies, physical injuries. The ability to mount an inflammatory response is essential for survival in the face of environmental
pathogens and injury; in some situations and diseases, the inflammatory response may be exaggerated and sustained without apparent benefit and even with severe adverse consequences. The inflammatory response is characterized mechanistically by:

- Transient local vasodilation and increased capillary permeability
- Infiltration of leukocytes and phagocytic cells
- Tissue degeneration and fibrosis

Many molecules are involved in the promotion and resolution of the inflammatory process. Histamine, bradykinin, 5-HT, prostanoids, leukotrienes (LTs), and platelet-activating factor are important mediators of inflammation (see Chapter 33).

Prostanoid biosynthesis is significantly increased in inflamed tissue. Inhibitors of the COXs, which depress prostanoid formation, are effective and widely used anti-inflammatory agents. Prostaglandin E2 (PGE2) and prostacyclin (PGI2) are the primary prostanoids that mediate inflammation. They increase local blood flow, vascular permeability, and leukocyte infiltration through activation of their respective receptors, EP2 and IP. PGD2, a major product of mast cells, contributes to inflammation in allergic responses, particularly in the lung.

Activation of endothelial cells plays a key role in “targeting” circulating cells to inflammatory sites. Endothelial activation results in leukocyte adhesion as the leukocytes recognize newly expressed L- and P-selectin and E-selectin with sialylated Lewis X and other glycoproteins on the leukocyte surface and endothelial intercellular adhesion molecule-1 (ICAM-1) with leukocyte integrins.

The recruitment of inflammatory cells to sites of injury also involves the concerted interactions of several types of soluble mediators. These include the complement factor C5a, PAF, and the eicosanoid LTB4 (see Chapter 33). All can act as chemotactic agonists. Several cytokines also play essential roles in
orchestrating the inflammatory process, especially tumor necrosis factor (TNF) and interleukin-1 (IL-1). Other cytokines and growth factors (e.g., IL-2, IL-6, IL-8, GM-CSF) contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF-α (see Chapter 35). Although some of the actions of these cytokines are accompanied by the release of PGs and thromboxane A₂ (TxA₂), cyclooxygenase (COX) inhibitors appear to block only their pyrogenic effects.

**PAIN.** Inflammatory mediators released from nonneuronal cells during tissue injury increase the sensitivity of nociceptors and potentiate pain perception. Among these mediators are bradykinin, H⁺, 5-HT, ATP, neurotrophins (nerve growth factor), LTs, and PGs. PGE₂ and PGI₂ reduce the threshold to stimulation of nociceptors, causing *peripheral sensitization*. Centrally active PGE₂ and perhaps also PGD₂, PGI₂, and PGF₂α contribute to *central sensitization*, an increase in excitability of spinal dorsal horn neurons that causes hyperalgesia and allodynia in part by disinhibition of glycinergic pathways.

**FEVER.** The hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, reflecting an infection, or resulting from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL-1 β, IL-6, TNF-α, and interferons, which act as endogenous pyrogens. The initial phase of the thermoregulatory response to such pyrogens may be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus. A late response is mediated by coordinate induction of COX-2 and formation of PGE₂. PGE₂ can cross the blood-brain barrier and acts on EP₃ and perhaps EP₁ receptors on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. NSAIDs suppress this
response by inhibiting PGE$_2$ synthesis.

**NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**

NSAIDs are classified as tNSAIDs, which inhibit both COX-1 and COX-2, and COX-2–selective NSAIDs. Most NSAIDs are competitive, reversible, active site inhibitors of the COX enzymes. However, aspirin (acetyl salicylic acid, ASA) acetylates the isozymes and inhibits them irreversibly; thus, aspirin often is distinguished from the tNSAIDs. Similarly, acetaminophen, which is antipyretic and analgesic but largely devoid of anti-inflammatory activity, also is conventionally segregated from the group.

The vast majority of tNSAID compounds are organic acids with relatively low pK$_a$ values (Figure 34–1). Even the nonacidic parent drug nabumetone is converted to an active acetic acid derivative in vivo. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, where the pH is lower, potentially confounding the relationship between plasma concentrations and duration of drug effect. Most COX-2–selective NSAIDs are diaryl heterocyclic compounds with a relatively bulky side group, which aligns with a large side pocket in the AA binding channel of COX-2 but hinders its optimal orientation in the smaller binding channel of COX-1. Both tNSAIDs and the COX-2–selective NSAIDs generally are hydrophobic drugs, a feature that allows them to access the hydrophobic arachidonate binding channel and results in shared pharmacokinetic characteristics. Again, aspirin and acetaminophen are exceptions to this rule.
MECHANISM OF ACTION

CYCLOOXYGENASE INHIBITION. The principal therapeutic effects of NSAIDs derive from their ability to inhibit PG production. The first enzyme in the PG synthetic pathway is COX, also known as PG G/H synthase. This enzyme converts AA to the unstable intermediates PGG<sub>2</sub> and PGH<sub>2</sub> and leads to the production of the prostanoids, TxA<sub>2</sub>, and a variety of PGs (see Chapter 33). There are 2 forms of COX, COX-1 and COX-2. COX-1, expressed constitutively in most cells, is the dominant source of prostanoids for housekeeping functions. Conversely, COX-2, induced by cytokines, shear stress, and tumor promoters, is the more important source of prostanoid
formation in inflammation and perhaps in cancer (see Chapter 33). COX-1 is the dominant isoform in gastric epithelial cells and is thought to be the major source of cytoprotective PG formation. Inhibition of COX-1 accounts for the gastric adverse events that complicate therapy with tNSAIDs.

Aspirin and NSAIDs inhibit the COX enzymes and PG production; they do not inhibit the lipoxygenase (LOX) pathways of AA metabolism and hence do not suppress LT formation (see Chapter 33).

**IRREVERSIBLE CYCLOOXYGENASE INHIBITION BY ASPIRIN.** Aspirin covalently modifies COX-1 and COX-2, irreversibly inhibiting COX activity. This is an important distinction from all the NSAIDs because the duration of aspirin’s effects is related to the turnover rate of COXs in different target tissues.

The importance of enzyme turnover in recovery from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 last for the lifetime of the platelet. Inhibition of platelet COX-1–dependent TxA₂ formation therefore is cumulative with repeated doses of aspirin (at least as low as 30 mg/day) and takes ~8-12 days (the platelet turnover time) to recover fully once therapy has been stopped. The unique sensitivity of platelets to inhibition by such low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver. In contrast to aspirin, salicylic acid has no acetylating capacity. It is a weak, reversible, competitive inhibitor of COX.

**SELECTIVE INHIBITION OF CYCLOOXYGENASE-2.** The therapeutic use of the tNSAIDs is limited by their poor GI tolerability. Since COX-1 was the predominant source of cytoprotective PGs formed by the GI epithelium, selective inhibitors of COX-2 were developed to afford efficacy similar to tNSAIDs with better GI tolerability. Six COX-2 inhibitors, the coxibs, were initially approved for use: celecoxib, rofecoxib, valdecoxib and its prodrug parecoxib,
etoricoxib, and lumiracoxib. Most coxibs have been either restricted in their use or withdrawn from the market in view of their adverse event profile. Celecoxib (CELEBREX) currently is the only COX-2 inhibitor licensed for use in the U.S.

**ADME**

NSAIDs are rapidly absorbed following oral ingestion, and peak plasma concentrations are reached within 2-3 h. Food intake may delay absorption and systemic availability (i.e., fenoprofen, sulindac). Antacids, commonly prescribed to patients on NSAID therapy, variably delay, absorption. Some compounds (e.g., diclofenac, nabumetone) undergo first-pass or presystemic elimination. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation.

Most NSAIDs are extensively bound to plasma proteins (95-99%), usually albumin. Highly protein bound NSAIDs have the potential to displace other drugs, if they compete for the same binding sites. Most NSAIDs are distributed widely throughout the body and readily penetrate arthritic joints, yielding synovial fluid concentrations in the range of half the plasma concentration (i.e., ibuprofen, naproxen, piroxicam). Most NSAIDs achieve sufficient concentrations in the CNS to have a central analgesic effect. Celecoxib is particularly lipophilic and moves readily into the CNS. Lumiracoxib is more acidic than other COX-2–selective NSAIDs, which may favor its accumulation at sites of inflammation.

Plasma $t_{1/2}$ varies considerably among NSAIDs. Ibuprofen, diclofenac, and acetaminophen have $t_{1/2}$ of 1-4 h, while piroxicam has a $t_{1/2}$ of 50 h at steady state. The $t_{1/2}$ of COX-2–selective NSAIDs vary (2-6 h for lumiracoxib, 6-12 h for celecoxib, and 20-26 h for etoricoxib). Hepatic biotransformation and renal excretion are the principal routes of metabolism and elimination of the majority of NSAIDs. Acetaminophen, at therapeutic doses, is oxidized only to a small degree to form traces of the highly reactive metabolite, $N$-acetyl-$p$-benzoquinone imine (NAPQI). Following overdose (usually $>10$ g of acetaminophen), however, the principal metabolic pathways are saturated, and hepatotoxic NAPQI concentrations can be formed (see Figure 4–5). Rarely, other NSAIDs also may be complicated by hepatotoxicity (e.g., diclofenac, lumiracoxib).
NSAIDs usually are not removed by hemodialysis due to their extensive plasma protein binding; salicylic acid is an exemption to this rule. NSAIDs are not recommended in advanced hepatic or renal disease.

**THERAPEUTIC USES**

All NSAIDs are antipyretic, analgesic, and anti-inflammatory, with the exception of acetaminophen, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity.

**INFLAMMATION.** NSAIDs provide mostly symptomatic relief from pain and inflammation associated with musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. Some NSAIDs are approved for the treatment of ankylosing spondylitis and gout.

**PAIN.** NSAIDs are effective only against pain of low to moderate intensity. Although their maximal efficacy is much less than the opioids, NSAIDs lack the unwanted adverse effects of opiates. Coadministration of NSAIDs can reduce the opioid dose needed for sufficient pain control and reduce the likelihood of adverse opioid effects. NSAIDs are particularly effective when inflammation has caused peripheral and/or central sensitization of pain perception. An exception to this is menstrual pain. The release of PGs by the endometrium during menstruation may cause severe cramps and other symptoms of primary dysmenorrhea; treatment of this condition with NSAIDs has met with considerable success. NSAIDs are commonly used to treat migraine attacks and can be combined with drugs such as the triptans (e.g., TREXIMET, a fixed-dose combination of naproxen and sumatriptan) or with antiemetics to aid relief of the associated nausea. NSAIDs lack efficacy in neuropathic pain.

**FEVER.** Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. NSAIDs reduce fever in most situations,
but not the circadian variation in temperature or the rise in response to exercise or increased ambient temperature. COX-2 is the dominant source of PGs that mediate the rise in temperature evoked by bacterial lipopolysaccharide (LPS) administration.

**FETAL CIRCULATORY SYSTEM.** PGs are implicated in the maintenance of patency of the ductus arteriosus, and indomethacin, ibuprofen, and other tNSAIDs have been used in neonates to close the inappropriately patent ductus.

**CARDIOPROTECTION.** Ingestion of aspirin prolongs bleeding time. This effect is due to irreversible acetylation of platelet COX and the consequent inhibition of platelet function. It is the permanent suppression of platelet TxA<sub>2</sub> formation that is thought to underlie the cardioprotective effect of aspirin.

Aspirin reduces the risk of serious vascular events in high-risk patients (e.g., those with previous myocardial infarction) by 20-25%. Low-dose (<100 mg/day) aspirin is relatively selective for COX-1 and is associated with a lower risk for GI adverse events. However, low-dose aspirin increases the incidence of serious GI bleeds. It also increases the incidence of intracranial bleeds. The benefit from aspirin outweighs these risks in the case of secondary prevention of cardiovascular disease. Given their relatively short t<sub>1/2</sub> and reversible COX inhibition, most other tNSAIDs are not thought to afford cardioprotection. Data suggest that cardioprotection is lost when combining low-dose aspirin with ibuprofen. COX-2–selective NSAIDs are devoid of antiplatelet activity, as mature platelets do not express COX-2.

**OTHER CLINICAL USES**

**Systemic Mastocytosis.** Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin. In patients with systemic mastocytosis, PGD<sub>2</sub>, released from mast cells is the major mediator of severe episodes of flushing, vasodilation, and hypotension. The addition of aspirin or ketoprofen has provided relief. However,
aspirin and tNSAIDs can cause degranulation of mast cells, so blockade with H₁ and H₂ histamine receptor antagonists should be established before NSAIDs are initiated.

**Niacin Tolerability.** Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce low-density lipoprotein, and raise high-density lipoprotein (see Chapter 31). However, niacin induces intense facial flushing mediated largely by release of PGD₂ from the skin, which can be inhibited by treatment with aspirin.

**Cancer Chemoprevention.** Epidemiological studies suggested that frequent use of aspirin is associated with as much as a 50% decrease in the risk of colon cancer. Similar observations have been made with NSAID use in this and other cancers.

**ADVERSE EFFECTS OF NSAID THERAPY**

Common adverse events of aspirin and NSAIDs are outlined in Table 34–1.

<sup>a</sup>Side effects decreased with COX-2-selective NSAIDs.
<sup>b</sup>With the exception of low-dose aspirin.

**GASTROINTESTINAL.** The most common symptoms associated with these
drugs are GI, including anorexia, nausea, dyspepsia, abdominal pain, and diarrhea. These symptoms may be related to the induction of gastric or intestinal ulcers, which is estimated to occur in 15-30% of regular users. Ulceration may be complicated by bleeding, perforation, or obstruction. The risk is further increased in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. All selective COX-2 inhibitors are less prone to induce gastric ulcers than equally efficacious doses of tNSAIDs.

**CARDIOVASCULAR.** COX-2–selective NSAIDs were developed to improve the GI safety. However, clinical trials—with celecoxib, valdecoxib (withdrawn), and rofecoxib (withdrawn)—revealed an increase in the incidence of myocardial infarction, stroke, and thrombosis. COX-2-inhibitors depress formation of PGI$_2$ but do not inhibit COX-1 catalyzed formation of platelet thromboxane TxA$_2$. PGI$_2$ inhibits platelet aggregation and constrains the effect of prothrombotic and atherogenic stimuli by TxA$_2$.

**BLOOD PRESSURE, RENAL, AND RENOVASCULAR ADVERSE EVENTS.** NSAIDs and COX-2 inhibitors have been associated with renal and renovascular adverse events. In patients with congestive heart failure, hepatic cirrhosis, chronic kidney disease, hypovolemia, and other states of activation of the sympathoadrenal or renin–angiotensin systems, PG formation becomes crucial. NSAIDs are associated with loss of the PG-induced inhibition of both the reabsorption of Cl$^-$ and the action of antidiuretic hormone, leading to the retention of salt and water. Epidemiological studies suggest hypertensive complications occur more commonly in patients treated with coxibs than with tNSAIDs.

**ANALGESIC NEPHROPATHY.** Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections.

**PREGNANCY AND LACTATION.** Myometrial COX-2 expression and levels of PGE$_2$ and PGF$_{2\alpha}$ increase markedly in the myometrium during labor. Prolongation of gestation by NSAIDs has been demonstrated in humans. Some NSAIDs, particularly indomethacin, have been used off-label to terminate
preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation in utero, particularly in fetuses older than 32 weeks’ gestation. COX-2–selective inhibitors have been used off-label as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios. Finally, the use of NSAIDs and aspirin late in pregnancy may increase the risk of postpartum hemorrhage. Therefore, pregnancy, especially close to term, is a relative contraindication to the use of all NSAIDs. In addition, their use must be weighed against potential fetal risk, even in cases of premature labor, and especially in cases of pregnancy-induced hypertension.

**HYPERSENSITIVITY.** Hypersensitivity symptoms to aspirin and NSAIDs range from vasomotor rhinitis, generalized urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance is a contraindication to therapy with any other NSAID because cross-sensitivity. Treatment of aspirin hypersensitivity is similar to that of other severe hypersensitivity reactions, with support of vital organ function and administration of epinephrine.

**ASPIRIN RESISTANCE.** All forms of treatment failure with aspirin have been collectively called *aspirin resistance*. Genetic variants of COX-1 that cosegregate with resistance have been described, but the relation to clinical outcome is not clear.

**REYE SYNDROME.** Due to the possible association with Reye syndrome, aspirin and other salicylates are contraindicated in children and young adults < 20 years of age with viral illness–associated fever. Reye syndrome, a severe and often fatal disease, is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera. Although a mechanistic understanding is lacking, the epidemiologic association between aspirin use and Reye syndrome is sufficiently strong that aspirin and bismuth subsalicylate labels now must indicate the risk. As the use of aspirin in children has declined dramatically, so has the incidence of Reye syndrome. Acetaminophen has not been implicated in Reye syndrome and is the drug of choice for antipyresis in children and young adults.

**CONCOMITANT NSAIDS AND LOW-DOSE ASPIRIN.** Many patients combine either tNSAIDs or COX-2 inhibitors with low-dose aspirin for
“cardioprotection.” Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone.

**DRUG INTERACTIONS**

Angiotensin-converting enzyme (ACE) inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate PG production (see Figure 32–2). Thus, it is logical that NSAIDs might attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic PGs. Due to hyperkalemia, the combination of NSAIDs and ACE inhibitors also can produce marked bradycardia leading to syncope, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. Corticosteroids and SSRIs may increase the frequency or severity of GI complications when combined with NSAIDs. NSAIDs may augment the risk of bleeding in patients receiving warfarin both because almost all tNSAIDs suppress normal platelet function temporarily during the dosing interval and because some NSAIDs also increase warfarin levels by interfering with its metabolism. Many NSAIDs are highly bound to plasma proteins and thus may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with warfarin, sulfonylurea hypoglycemic agents, or methotrexate; the dosage of such agents may require adjustment to prevent toxicity. Patients taking lithium should be monitored because certain NSAIDs (e.g., piroxicam) can reduce the renal excretion of this drug and lead to toxicity, while others can decrease lithium levels (e.g., sulindac).

**PEDIATRIC AND GERIATRIC USE**

**THERAPEUTIC USES IN CHILDREN.** Therapeutic indications for NSAID use in children include fever, mild pain, postoperative pain, and inflammatory disorders, such as juvenile arthritis and Kawasaki disease. Only drugs that have been extensively tested in children should be used (acetaminophen, ibuprofen, and naproxen).

**PHARMACOKINETICS IN CHILDREN.** NSAID dosing recommendations frequently are based on extrapolation of pharmacokinetic data from adults or children >2 years, and there is often insufficient data for dose selection in
younger infants. For example, the pharmacokinetics of the most commonly used NSAID in children, acetaminophen, differ substantially between the neonatal period and older children or adults. The systemic bioavailability of rectal acetaminophen formulations in neonates and preterm babies is higher than in older patients. Acetaminophen clearance is reduced in preterm neonates probably due to their immature glucuronide conjugation system (sulfation is the principal route of biotransformation at this age). Therefore, acetaminophen dosing intervals need to be extended (8-12 h) or daily doses reduced to avoid accumulation and liver toxicity. Aspirin elimination also is delayed in neonates and young infants compared to adults bearing the risk of accumulation. Disease also may affect NSAID disposition in children. For example, ibuprofen plasma concentrations are reduced and clearance increased (~80%) in children with cystic fibrosis. This probably is related to the GI and hepatic pathologies associated with this disease. Aspirin’s kinetics are markedly altered during the febrile phase of rheumatic fever or Kawasaki vasculitis. The reduction in serum albumin associated with these conditions causes an elevation of the free salicylate concentration, which may saturate renal excretion and result in salicylate accumulation to toxic levels. In addition to dose reduction, monitoring of the free drug may be warranted in these situations.

PHARMACOKINETICS IN THE ELDERLY. The clearance of many NSAIDs is reduced in the elderly due to changes in hepatic metabolism. NSAIDs with a long $t_{1/2}$ and primarily oxidative metabolism (i.e., piroxicam, tenoxicam, celecoxib) have elevated plasma concentrations in elderly patients. For example, plasma concentrations after the same dose of celecoxib may rise up to 2-fold higher in patients >65 years than in patients <50 years of age, warranting dose adjustment. The capacity of plasma albumin to bind drugs is diminished in older patients and may result in higher concentrations of unbound NSAIDs. The higher susceptibility of older patients to GI complications may be due to a reduction in gastric mucosal defense and to elevated total and/or free NSAID concentrations. Generally, it is advisable to start most NSAIDs at a low dosage in the elderly and increase the dosage only if the therapeutic efficacy is insufficient.

SPECIFIC PROPERTIES OF INDIVIDUAL NSAIDS

General properties shared by NSAIDs were considered in the
preceding section, “Nonsteroidal Anti-Inflammatory Drugs.” In this section, important characteristics of individual substances are discussed. NSAIDs are grouped by their chemical similarity, as in Figure 34–1.

**ASPIRIN AND OTHER SALICYLATES**

The salicylates include, aspirin, salicylic acid, methyl salicylate, diflunisal, salsalate, olsalazine, and sulfasalazine. Aspirin is the most widely consumed analgesic, antipyretic, and anti-inflammatory agent. Because aspirin is so available, the possibility of misuse and serious toxicity is underappreciated.

Salicylic acid is so irritating that it can only be used externally; therefore various derivatives of this acid have been synthesized for systemic use. For example, aspirin is the acetate ester of salicylic acid. Table 34–2 summarizes the clinical pharmacokinetic properties of 2 salicylates, aspirin and diflunisal.

**Table 34–2**

**Comparison of NSAIDS: Salicylates, Acetaminophen, and Acetic Acid Derivatives**
MECHANISM OF ACTION

Salicylates generally act by virtue of their content of salicylic acid. The effects of aspirin are largely caused by its capacity to acetylate proteins, as described in “Irreversible Cyclooxygenase Inhibition by Aspirin,” above.

ADME

ABSORPTION. Orally ingested salicylates are absorbed rapidly, partly from the stomach but mostly from the upper small intestine. Appreciable concentrations are found in plasma in <30 min; after a single dose, the peak plasma level is
reached in ~1 h and then declines gradually. The rate of absorption is determined by disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its GI absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

**DISTRIBUTION.** After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent passive processes. Salicylates are transported actively out of the CSF across the choroid plexus. The drugs readily cross the placental barrier. Ingested aspirin mainly is absorbed as such, but some enters the systemic circulation as salicylic acid after hydrolysis by esterases in the GI mucosa and liver. Roughly 80-90% of the salicylate in plasma is bound to proteins, especially albumin; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein binding sites; these include thyroxine, triiodothyronine, penicillin, phenytoin, sulfinpyrazone, bilirubin, uric acid, and other NSAIDs such as naproxen. Aspirin is bound to a more limited extent; however, it acetylates human plasma albumin in vivo by reaction with the ε-amino group of lysine and may change the binding of other drugs to albumin. Aspirin also acetylates hormones, DNA, and hemoglobin and other proteins.

**METABOLISM AND ELIMINATION.** The 3 chief metabolic products are salicyluric acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. Salicylates and their metabolites are excreted in the urine. The excretion of free salicylates is variable and depends on the dose and the urinary pH. For example, the clearance of salicylate is about 4 times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is
true in oliguria. The plasma $t_{1/2}$ for aspirin is $\sim$20 min, and for salicylate is 2-3 h at antiplatelet doses, rising to 12 h at usual anti-inflammatory doses. The $t_{1/2}$ of salicylate may rise to 15-30 h at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicyluric acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses. Salicylate clearance is reduced and salicylate exposure is significantly increased in the elderly. The plasma concentration of salicylate is increased by conditions that decrease glomerular filtration rate or reduce proximal tubule secretion, such as renal disease or the presence of inhibitors that compete for the transport system (e.g., probenecid).

**THERAPEUTIC USES**

**SYSTEMIC USES.** The *analgesic–antipyretic* dose of aspirin for adults is 324-1000 mg orally every 4-6 h. The anti-inflammatory doses of aspirin recommended for *arthritis, spondyloarthropathies, and systemic lupus erythematosus* (SLE) range from 3-4 g/day in divided doses. The maximum recommended daily dose of aspirin for adults and children (>12 years or older) is 4 g. The rectal administration of aspirin suppositories may be preferred in infants or when the oral route is unavailable. Salicylates suppress clinical signs and improve tissue inflammation in acute rheumatic fever. Other salicylates available for systemic use include salsalate (salicylsalicylic acid), magnesium salicylate, and a combination of choline salicylate and magnesium salicylate (choline magnesium–trisalicylate).

Diflunisal is a difluorophenyl derivative of salicylic acid that is not converted to salicylic acid in vivo. Diflunisal is a competitive inhibitor of COX, it is a potent anti-inflammatory but is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used as an analgesic in the treatment of *osteoarthritis* and musculoskeletal strains or sprains; in these circumstances, it is 3-4 times more potent than aspirin. The usual initial dose is 1000 mg, followed by 500 mg every 8-12 h. Diflunisal produces fewer auditory side effects (see “Ototoxic Effects”) and appears to cause fewer GI and antiplatelet effects than does aspirin.

**LOCAL USES.** Mesalamine (5-aminosalicylic acid) is a salicylate that is used for its local effects in the treatment of *inflammatory bowel disease* (see Figure
Oral formulations that deliver drug to the lower intestine are efficacious in the treatment of inflammatory bowel disease (in particular, ulcerative colitis). These preparations rely on pH-sensitive coatings and other delayed release mechanisms, such as linkage to another moiety to create a poorly absorbed parent compound that must be cleaved by bacteria in the colon to form the active drug. Some over-the-counter medications to relieve indigestion and diarrhea agents contain bismuth subsalicylate (Pepto-Bismol, others) and have the potential to cause salicylate intoxication, particularly in children.

The keratolytic action of free salicylic acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. Methyl salicylate (oil of wintergreen) is a common ingredient of ointments and deep-heating liniments used in the management of musculoskeletal pain. The cutaneous application of methyl salicylate can result in pharmacologically active, and even toxic, systemic salicylate concentrations and has been reported to increase prothrombin time in patients receiving warfarin.

**ADVERSE EFFECTS**

**RESPIRATION.** Salicylates increase O₂ consumption and CO₂ production (especially in skeletal muscle) at anti-inflammatory doses, a result of uncoupling oxidative phosphorylation. The increased production of CO₂ stimulates respiration. Salicylates also stimulate the respiratory center directly in the medulla. Respiratory rate and depth increases, the Pco₂ falls, and primary respiratory alkalosis ensues.

**ACID–BASE AND ELECTROLYTE BALANCE AND RENAL EFFECTS.** Therapeutic doses of salicylate produce definite changes in the acid–base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis, is achieved by increased renal excretion of bicarbonate, which is accompanied by increased Na⁺ and K⁺ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This is the stage of compensatory renal acidosis. This stage is most often seen in adults given intensive salicylate therapy and seldom proceeds further unless toxicity ensues (see “Salicylate Intoxication”). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is
associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other NSAIDs can produce papillary necrosis and interstitial nephritis (see “Analgesic Nephropathy”).

**CARDIOVASCULAR EFFECTS.** Low doses of aspirin (<100 mg daily) are used widely for their cardioprotective effects. At high therapeutic doses (>3 g daily), as might be given for acute rheumatic fever, salt and water retention can lead to an increase (<20%) in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce noncardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

**GI EFFECTS.** Ingestion of salicylates may result in epigastric distress, nausea, and vomiting. Salicylates also may cause gastric ulceration, exacerbation of peptic ulcer symptoms (heartburn, dyspepsia), GI hemorrhage, and erosive gastritis. These effects occur primarily with acetylated salicylates (i.e., aspirin). Because nonacetylated salicylates lack the capacity to acetylate COX and irreversibly inhibit its activity, they are weaker inhibitors than aspirin.

**HEPATIC EFFECTS.** Salicylates can cause hepatic injury, usually after high doses of salicylates that result in plasma concentrations of >150 μg/mL. The injury is not an acute effect; rather, the onset characteristically occurs after several months of treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible upon discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Considerable evidence implicates the use of salicylates as an important factor in the severe hepatic injury and encephalopathy observed in Reye syndrome. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen.
URICOSURIC EFFECTS. The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g/day) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/day) usually do not alter urate excretion. Large doses (>5 g/day) induce uricosuria and lower plasma urate levels; however, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of probenecid and other uricosuric agents that decrease tubular reabsorption of uric acid.

HEMATOLOGIC EFFECTS. Irreversible inhibition of platelet function underlies the cardioprotective effect of aspirin. If possible, aspirin therapy should be stopped at least 1 week before surgery; however, preoperative aspirin often is recommended prior to carotid artery stenting, carotid endarterectomy, infrainguinal arterial bypass, and PCI (percutaneous coronary intervention) procedures. Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because the inhibition of platelet hemostasis can result in hemorrhage. Aspirin is used widely for the prophylaxis of thromboembolic disease.

OTOTOXIC EFFECTS. Hearing impairment, alterations of perceived sounds, and tinnitus commonly occur during high-dose salicylate therapy. Ototoxic symptoms sometimes are observed at low doses. Symptoms usually resolve within 2 or 3 days after withdrawal of the drug. As most competitive COX inhibitors are not associated with hearing loss or tinnitus, a direct effect of salicylic acid rather than suppression of PG synthesis is likely.

SALICYLATES AND PREGNANCY. Infants born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester, there also is an increase in perinatal mortality, anemia, and complicated deliveries; thus, its use during this period should be avoided. NSAIDs during the third trimester of pregnancy also can cause premature closure of the ductus arteriosus.

DRUG INTERACTIONS. The plasma concentration of salicylates generally is little affected by other drugs, but concurrent administration of aspirin lowers the concentrations of indomethacin, naproxen, ketoprofen, and fenoprofen, at least in part by displacement from plasma proteins. Important adverse interactions of aspirin with warfarin, sulfonylureas, and methotrexate are mentioned above (in “Drug Interactions”). Other interactions of aspirin include the antagonism of
spironolactone-induced natriuresis and the blockade of the active transport of penicillin from CSF to blood. Magnesium-aluminum hydroxide antacids can alkalize the urine enough to increase salicylic acid clearance significantly and reduce steady-state concentrations. Conversely, discontinuation of antacid therapy can increase plasma concentrations to toxic levels.

**SALICYLATE INTOXICATION**

Salicylate poisoning or serious intoxication often occurs in children and sometimes is fatal. CNS effects, intense hyperpnea, and hyperpyrexia are prominent symptoms. Death has followed use of 10-30 g of sodium salicylate or aspirin in adults, but much larger amounts (130 g of aspirin in 1 case) have been ingested without a fatal outcome. The lethal dose of methyl salicylate (also known as oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as a 4 mL (4.7 g) of methyl salicylate may cause severe systemic toxicity in children. Mild chronic salicylate intoxication is called *salicylism*. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

**NEUROLOGICAL EFFECTS.** In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone.

**RESPIRATION.** The respiratory effects of salicylates contribute to the serious acid–base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration indirectly by uncoupling of oxidative phosphorylation and directly by stimulation of the respiratory center in the medulla (described above). Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children. Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO₂ production continues, respiratory acidosis ensues. Respiratory failure is the
usual cause of death in fatal cases of salicylate poisoning.

ACID–BASE BALANCE AND ELECTROLYTES. High therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory renal acidosis. The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and renal acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma Pco₂. Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO₂. Consequently, plasma Pco₂ increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid–base status at this stage essentially is an uncompensated respiratory acidosis. Superimposed, however, is a true metabolic acidosis caused by accumulation of acids as a result of 3 processes. First, toxic concentrations of salicylates displace ~2-3 mEq/L of plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids; renal failure can ensue. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The low plasma Pco₂ leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na⁺, K⁺, and water. Dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia.

MANAGEMENT OF SALICYLATE OVERDOSE. Salicylate poisoning represents an acute medical emergency, and death may result despite heroic efforts. Monitoring of salicylate levels is a useful guide to therapy but must be used in conjunction with an assessment of the patient’s overall clinical condition, acid–base balance, formulation of salicylate ingested, timing, and dose. There is no specific antidote for salicylate poisoning. Management begins with a rapid assessment followed by the ABCD approach to medical emergencies: A (airway), B (breathing), C (circulation), D (decontamination).
PARA-AMINOPHENOL DERIVATIVES

ACETAMINOPHEN

Acetaminophen (paracetamol; TYLENOL, others) is the active metabolite of phenacetin.

Acetaminophen is available without a prescription and is used as a common household analgesic. It also is available in fixed-dose combinations containing narcotic and nonnarcotic analgesics (including aspirin and other salicylates), barbiturates, caffeine, vascular headache remedies, sleep aids, toothache remedies, antihistamines, antitussives, decongestants, expectorants, cold and flu preparations, and sore throat treatments. Acetaminophen is well tolerated and has a low incidence of GI side effects. However, acute overdosage can cause severe hepatic damage (see Figure 4–4), and the number of poisonings with acetaminophen continues to grow.

MECHANISM OF ACTION

Acetaminophen has analgesic and antipyretic effects similar to those of aspirin, but only weak anti-inflammatory effects. Acetaminophen is postulated to have a poor ability to inhibit COX isoforms in the presence of high concentrations of peroxides, as occur at sites of inflammation. COX inhibition might be disproportionately pronounced in the brain, explaining its antipyretic efficacy.

ADME

Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30-60 min, and the $t_{1/2}$ in plasma is ~2 h. Binding of the drug to plasma proteins is variable but less than with other NSAIDs; only 20-50% is
bound at the concentrations encountered during acute intoxication. Some 90-
100% of drug may be recovered in the urine within the first day at therapeutic
dosing, primarily after hepatic conjugation with glucuronic acid (see Table 34–
2). Children have less capacity for glucuronidation of the drug than do adults. A
small proportion of acetaminophen undergoes CYP-mediated N-hydroxylation to
form NAPQI, a highly reactive intermediate.

THERAPEUTIC USES

Acetaminophen is suitable for analgesic or antipyretic uses; it is particularly
valuable for patients in whom aspirin is contraindicated (e.g., those with peptic
ulcer, aspirin hypersensitivity, children with a febrile illness). The conventional
oral dose of acetaminophen is 325-650 mg every 4-6 h; total daily doses should
not exceed 4000 mg (2000 mg/day for chronic alcoholics). Single doses for
children 2-11 years old range from 160-480 mg, depending on age and weight;
no more than 5 doses should be administered in 24 h. A dose of 10 mg/kg also
may be used. An injectable preparation is now available (see recent review on
the Goodman & Gilman website at AccessMedicine.com).

ADVERSE EFFECTS AND TOXICITY

Acetaminophen usually is well tolerated. Rash and other allergic reactions occur
occasionally, but sometimes it is more serious and may be accompanied by drug
fever and mucosal lesions. Patients who show hypersensitivity reactions to the
salicylates only rarely exhibit sensitivity to acetaminophen. The most serious
acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic
necrosis. Hepatic injury with acetaminophen involves its conversion to the toxic
metabolite, NAPQI. The glucuronide and sulfate conjugation pathways become
saturated, and increasing amounts undergo CYP-mediated N-hydroxylation to
form NAPQI. This is eliminated rapidly by conjugation with GSH and then
further metabolized to a mercapturic acid and excreted into the urine. In the
setting of acetaminophen overdose, hepatocellular levels of GSH become
depleted. The highly reactive NAPQI metabolite binds covalently to cell
macromolecules, leading to dysfunction of enzymatic systems and structural and
metabolic disarray. Furthermore, depletion of intracellular GSH renders the
hepatocytes highly susceptible to oxidative stress and apoptosis (see Figure 4–4).
Renal tubular necrosis and hypoglycemic coma also may occur.
MANAGEMENT OF ACETAMINOPHEN OVERDOSE. Severe liver damage occurs in 90% of patients with plasma concentrations of acetaminophen >300 μg/mL at 4 h or 45 μg/mL at 15 h after the ingestion of the drug. Activated charcoal, if given within 4 h of ingestion, decreases acetaminophen absorption by 50-90% and is the preferred method of gastric decontamination. Gastric lavage generally is not recommended.

*N*-acetylcysteine (NAC) (*MUCOMYST*, *ACETADOTE*) is indicated for those at risk of hepatic injury. NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. In addition to NAC therapy, aggressive supportive care is warranted. This includes management of hepatic and renal failure if they occur and intubation if the patient becomes obtunded. Hypoglycemia can result from liver failure, and plasma glucose should be monitored closely. Fulminant hepatic failure is an indication for liver transplantation, and a liver transplant center should be contacted early in the course of treatment of patients who develop severe liver injury despite NAC therapy.

ACETIC ACID DERIVATIVES

INDOMETHACIN

Indomethacin (*INDOCIN*, others) is indicated for the treatment of moderate to severe rheumatoid arthritis, osteoarthritis, and acute gouty arthritis; ankylosing spondylitis; and acute painful shoulder. Indomethacin is a more potent nonselective inhibitor of the COXs than is aspirin; it also inhibits the motility of polymorphonuclear leukocytes, depresses the biosynthesis of mucopolysaccharides, and may have a direct, COX-independent vasoconstrictor effect. Indomethacin has prominent anti-inflammatory and analgesic—antipyretic properties similar to those of the salicylates. The ADME data for indomethacin are summarized in Table 34–2.

THERAPEUTIC USES. Indomethacin is estimated to be ~20 times more potent than aspirin. A high rate of intolerance limits the long-term analgesic use of indomethacin. Indomethacin is approved for closure of persistent patent ductus
arteriosus in premature infants who weigh between 500 and 1750 g, who have a hemodynamically significant patent ductus arteriosus, and in whom other supportive maneuvers have been attempted. Successful closure can be expected in >70% of neonates treated. The principal limitation of treating neonates is renal toxicity, and therapy is interrupted if the output of urine falls to <0.6 mL/kg/h.

ADVERSE EFFECTS AND DRUG INTERACTIONS. A very high percentage (35%-50%) of patients receiving indomethacin experience untoward symptoms. GI adverse events are common and can be fatal; elderly patients are at significantly greater risk. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect is severe frontal headache. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson’s disease, because they are at greater risk for the development of serious CNS adverse effects. Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia.

SULINDAC

Sulindac (CLINORIL, others) is a congener of indomethacin. Sulindac, which is less than half as potent as indomethacin, is a prodrug whose anti-inflammatory activity resides in its sulfide metabolite (which is >500 times more potent than sulindac as an inhibitor of COX but less than half as potent as indomethacin). ADME data are summarized in Table 34–2. The same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity, cardiovascular risk, and renal impairment also apply to sulindac.

THERAPEUTIC USES. Sulindac is used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, tendonitis, bursitis, and the pain of acute gout. Its analgesic and anti-inflammatory effects are comparable to those achieved with aspirin. The most common dosage for adults is 150-200 mg twice a day.
ADVERSE EFFECTS. Although the incidence of toxicity is lower than with indomethacin, untoward reactions to sulindac are common. The typical NSAID GI side effects are seen in nearly 20% of patients. CNS side effects as described above for indomethacin are seen in <10% of patients. Rash and pruritus occur in 5% of patients. Transient elevations of hepatic transaminases in plasma are less common.

ETODOLAC

Etodolac is an acetic acid derivative with some degree of COX-2 selectivity (see Table 34–2). At anti-inflammatory doses, the frequency of gastric irritation may be less than with other tNSAIDs. A single oral dose (200-400 mg) of etodolac provides postoperative analgesia that lasts for 6-8 h. Etodolac also is effective in the treatment of osteoarthritis, rheumatoid arthritis, and mild to moderate pain, and the drug appears to be uricosuric. Sustained-release preparations are available. Etodolac is relatively well tolerated. About 5% of patients who have taken the drug for <1 year discontinue treatment because of GI side effects, rashes, and CNS effects.

TOLMETIN

Tolmetin (TOLECTIN, others) is approved for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis; and has been used in the treatment of ankylosing spondylitis. ADME and comparison to aspirin are in Table 34–2. Tolmetin recommended doses (200-600 mg 3 times/day) typically given with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food. Side effects occur in 25-40% of patients who take tolmetin. GI side effects are the most common (15%), and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

KETOROLAC

Ketorolac is a potent analgesic but only a moderately effective anti-inflammatory drug. The use of ketorolac is limited to <5 days for acute pain requiring opioid-level analgesia and can be administered intramuscularly,
intravenously, or orally. Typical doses are 30-60 mg (intramuscular), 15-30 mg (intravenous), and 10-20 mg (oral). Ketorolac has a rapid onset of action and a short duration of action (see Table 34–2). It is widely used in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac (ACULAR, others) is approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation. Side effects include somnolence, dizziness, headache, GI pain, dyspepsia, nausea, and pain at the site of injection. The black box warning for ketorolac stresses the possibility of serious adverse GI, renal, bleeding, and hypersensitivity reactions. Patients receiving greater than recommended doses or concomitant NSAID therapy and the elderly appear to be particularly at risk.

**NABUMETONE**

Nabumetone is the prodrug of 6-methoxy-2-naphthylacetic acid. Nabumetone is an anti-inflammatory agent with substantial efficacy in the treatment of rheumatoid arthritis and osteoarthritis. Its comparative pharmacokinetic properties are summarized in Table 34–2. Nabumetone is associated with crampy lower abdominal pain and diarrhea, but the incidence of GI ulceration appears to be lower than with other tNSAIDs. Other side effects include rash, headache, dizziness, heartburn, tinnitus, and pruritus.

**DICLOFENAC**

Diclofenac, a phenylacetic acid derivative, is among the most commonly used NSAID in the E.U. Diclofenac has analgesic, antipyretic, and anti-inflammatory activities. Its potency is substantially greater than that of indomethacin, naproxen, or several other tNSAIDs. The selectivity of diclofenac for COX-2 resembles that of celecoxib. Diclofenac displays rapid absorption, extensive protein binding, and a $t_{1/2}$ of 1-2 h (see Table 34–2). The short $t_{1/2}$ makes it necessary to dose diclofenac considerably higher than would be required to inhibit COX-2 fully at peak plasma concentrations to afford inhibition throughout the dosing interval. There is a substantial first-pass effect, such that only ~50% of diclofenac is available systemically. The drug accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than its plasma $t_{1/2}$. 
**THERAPEUTIC USES.** Diclofenac is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, and acute migraine. Myriad oral formulations are available to provide a range of release times; the usual daily oral dosage is 100-200 mg, given in several divided doses. For migraine, a powdered form is available for dissolution in water; a gel and a transdermal patch are also available. Diclofenac also is available in combination with misoprostol, a PGE$_1$ analog (ARTHROTEC); this combination retains the efficacy of diclofenac while reducing the frequency of GI ulcers and erosions. In addition, an ophthalmic solution of diclofenac (VOLTAREN, others) is available for treatment of postoperative inflammation following cataract extraction.

**ADVERSE EFFECTS.** Diclofenac produces side effects (particularly GI) in ~20% of patients. The incidence of GI adverse effects are similar to the COX-2–selective inhibitors celecoxib and etoricoxib. Hypersensitivity reactions have occurred following topical application. Modest reversible elevation of hepatic transaminases in plasma occurs in 5-15% of patients. Transaminases should be monitored during the first 8 weeks of therapy with diclofenac. Other untoward responses to diclofenac include CNS effects, rashes, allergic reactions, fluid retention, edema, and renal function impairment. The drug is not recommended for children, nursing mothers, or pregnant women. Unlike ibuprofen, diclofenac does not interfere with the antiplatelet effect of aspirin.

**PROPIONIC ACID DERIVATIVES**

The propionic acid derivatives **ibuprofen, naproxen, flurbiprofen, fenoprofen, ketoprofen, and oxaprozin**, are available in the U.S. ([Table 34–3](#)). Ibuprofen is the most commonly used tNSAID in the U.S. and is available without a prescription. Naproxen, also available without prescription, has a longer but variable $t_{1/2}$. Oxaprozin also has a long $t_{1/2}$ and may be given once daily.

| **Table 34–3** |
| **Comparison of NSAIDS: Fenamates and Propionic Acid Derivatives** |
**MECHANISM OF ACTION**

Propionic acid derivatives are nonselective COX inhibitors with the effects and side effects common to other tNSAIDs. Some of the propionic acid derivatives, particularly naproxen, have prominent inhibitory effects on leukocyte function, and some data suggest that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness. This suggestion of benefit accords with the clinical pharmacology of naproxen that suggests that some but not all individuals dosed with 500 mg twice daily sustain platelet inhibition throughout the dosing interval.

**THERAPEUTIC USES**
Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis and osteoarthritis. Some also are approved for pain, ankylosing spondylitis, acute gouty arthritis, tendinitis, bursitis, and migraine and for primary dysmenorrhea. These agents may be comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis.

**DRUG INTERACTIONS**

Ibuprofen has been shown to interfere with the antiplatelet effects of aspirin. There also is evidence for a similar interaction between aspirin and naproxen. Propionic acid derivatives have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or warfarin.

**IBUPROFEN**

Table 34–3 summarizes the comparative pharmacokinetics of ibuprofen.

**THERAPEUTIC USES.** Ibuprofen [Advil, Motrin IB, Brufen, others] is supplied as tablets, capsules, caplets, and gelcaps containing 50-800 mg; as oral drops; and as an oral suspension. Dosage forms containing <200 mg are available without a prescription. Ibuprofen is licensed for marketing in fixed-dose combinations with antihistamines, decongestants, oxycodone (Combunox, others), and hydrocodone (Reprexain, Ibudone, Vicoprofen, others). The usual dose for mild to moderate pain is 400 mg every 4-6 h as needed.

**ADVERSE EFFECTS.** Ibuprofen is thought to be better tolerated than aspirin, and indomethacin and has been used in patients with a history of GI intolerance to other NSAIDs. Nevertheless, 5-15% of patients experience GI side effects. Less frequent adverse effects of ibuprofen include rashes, thrombocytopenia, rashes, headache, dizziness, blurred vision, and in a few cases, toxic amblyopia, fluid retention, and edema. Patients who develop ocular disturbances should discontinue the use of ibuprofen. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.
NAPROXEN

Naproxen (ALEVE, NAPROSYN, others) is supplied as tablets, delayed-release tablets, controlled-release tablets, gelcaps, and caplets containing 200 - 750 mg of naproxen or naproxen sodium and as an oral suspension. Dosage forms containing <200 mg are available without a prescription. Naproxen is licensed for marketing in fixed-dose combinations with pseudoephedrine (ALEVE-D SINUS & COLD, others) and sumatriptan (TREXIMET) and is copackaged with lansoprazole (PREVACID NAPRAPAC). Naproxen is indicated for juvenile and rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, tendonitis, bursitis, and acute gout.

Naproxen is absorbed fully after oral administration. The $t_{1/2}$ of naproxen in plasma is variable; from 14 h in the young, it may increase ~2-fold in the elderly because of age-related decline in renal function (see Table 34–3). Naproxen crosses the placenta and appears in the milk of lactating women at ~1% of the maternal plasma concentration.

ADVERSE EFFECTS. The relative risk of myocardial infarction may be reduced by ~10% by naproxen, compared to a reduction of 20-25% by aspirin. However, increased rates of cardiovascular events also have been reported. GI adverse effects with naproxen occur at approximately the same frequency as with indomethacin and other tNSAIDs but perhaps with less severity. CNS side effects range from drowsiness, headache, dizziness, and sweating to fatigue, depression, and ototoxicity. Less common reactions include pruritus and a variety of dermatological problems. A few instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

THE FENAMATES

The fenamates include mefenamic, meclofenamic, and flufenamic acids. The pharmacological properties of the fenamates are those of typical tNSAIDs, and therapeutically, they have no clear advantages over others in the class. See Table 34–3. Mefenamic acid [PONSTEL, PONSTAN (U.K.), DYSMAN (U.K.)] and meclofenamate sodium are used in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and rheumatoid and osteoarthritis. These drugs are not
recommended for use in children or pregnant women. Approximately 25% of users develop GI side effects at therapeutic doses. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

**ENOLIC ACIDS (OXICAMS)**

The oxicam derivatives are enolic acids that inhibit COX-1 and COX-2 and have anti-inflammatory, analgesic, and antipyretic activity. These agents are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid arthritis or osteoarthritis. The main advantage suggested for these compounds is their long $t_{1/2}$, which permits once-a-day dosing (see comparative pharmacokinetic and dosing data in Table 34–4).

**PIROXICAM**

Piroxicam can inhibit activation of neutrophils, apparently independently of its
ability to inhibit COX; hence, additional modes of anti-inflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage. Piroxicam is approved for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used to treat acute gout. The usual daily dose is 20 mg, steady-state blood levels are reached in 7-12 days. Approximately 20% of patients experience side effects with piroxicam, and ~5% of patients discontinue use because of these effects. Piroxicam may be with more GI and serious skin reactions than other nonselective NSAIDs. The European Medicines Agency no longer considers piroxicam a first-line agent.

MELOXICAM

Meloxicam (MOBIC, others) is approved for use in osteoarthritis. The recommended dose for meloxicam is 7.5-15 mg once daily. Meloxicam demonstrates some COX-2 selectivity, however, a clinical advantage or hazard has yet to be established. There is significantly less gastric injury compared to piroxicam (20 mg/day) in subjects treated with 7.5 mg/day of meloxicam, but the advantage is lost with a dosage of 15 mg/day.

COX-2–SELECTIVE NSAIDS

Celecoxib, a diaryl heterocyclic coxib, is the only such compound still approved in the U.S. (see its clinical pharmacokinetic properties and precautions in Table 34–4).

Etoricoxib is approved in several countries; rofecoxib (VIOXX) and valdecoxib were withdrawn worldwide. Lumiracoxib, a derivative diclofenac, has been discussed earlier. Selective inhibitors of COX-2 are used for relief of dental pain and relief from inflammation in osteoarthritis and rheumatoid arthritis.

CELECOXIB

ADME. The bioavailability of oral celecoxib (CELEBREX) is not known, peak plasma levels occur at 2-4 h after administration. The elderly (>65 years of age) may have up to 2-fold higher peak concentrations and AUC values than younger patients (<55 years of age). Celecoxib is bound extensively to plasma proteins.
Most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination $t_{1/2}$ is $\sim 11$ h. The drug commonly is given once or twice daily during chronic treatment. Celecoxib has not been studied in patients with severe renal insufficiency. Plasma concentrations are increased in patients with mild and moderate hepatic impairment, requiring reduction in dose. Celecoxib is metabolized predominantly by CYP2C9 and inhibits CYP2D6. Clinical vigilance is necessary during coadministration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6.

**THERAPEUTIC USES.** Celecoxib is used for the management of acute pain for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/day as a single dose or divided as 2 doses. In the treatment of rheumatoid arthritis, the recommended dose is 100-200 mg twice daily. Due to cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible time. Celecoxib also is approved for the chemoprevention of polyposis coli.

**ADVERSE EFFECTS.** Celecoxib confers a risk of myocardial infarction and stroke and this appears to relate to dose and the underlying risk of cardiovascular disease. Effects attributed to inhibition of PG production in the kidney—hypothesis and edema—occur with nonselective COX inhibitors and also with celecoxib. None of the coxibs has established superior efficacy over tNSAIDs. Selective COX-2 inhibitors lose their GI advantage over a tNSAID alone when used in conjunction with aspirin.

**PARECOXIB**

Parecoxib is the only COX-2–selective NSAID administered by injection and has been shown to be an effective analgesic for the perioperative period when patients are unable to take oral medication. It is not widely available, and clinical experience is limited.

**ETORICOXIB**

Etoricoxib (ARCOXIA) is a COX-2–selective inhibitor with selectivity second only to that of lumiracoxib. Etoricoxib is incompletely (m80%) absorbed and has a long $t_{1/2}$ of 20-26 h. It is extensively metabolized before excretion. Patients
with hepatic impairment are prone to drug accumulation. Renal insufficiency does not affect drug clearance. Etoricoxib is approved for symptomatic relief in the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea. The drug is associated with increased the risk of heart attack and stroke.

OTHER NSAIDS

APAZONE (AZAPROPAZONE). Apazone is a tNSAID that has anti-inflammatory, analgesic, and antipyretic activity and is a potent uricosuric agent. Some of its efficacy may arise from its capacity to inhibit neutrophil migration, degranulation, and superoxide production.

Apazone has been used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and gout but usually is restricted to cases where other tNSAIDs have failed. Typical doses are 600 mg 3 times per day for acute gout. Once symptoms have abated, or for non-gout indications, typical dosage is 300 mg 3 to 4 times per day. Clinical experience to date suggests that apazone is well tolerated. Mild GI side effects (nausea, epigastric pain, dyspepsia) and rashes occur in ~3% of patients, while CNS effects (headache, vertigo) are reported less frequently. Precautions appropriate to other nonselective COX inhibitors also apply to apazone.

NIMESULIDE. Nimesulide is a sulfonanilide compound available in Europe that demonstrates COX-2 selectivity similar to celecoxib in whole-blood assays. Additional effects include inhibition of neutrophil activation, decrease in cytokine production, decrease in degradative enzyme production, and possibly activation of glucocorticoid receptors. Nimesulide is administered orally in doses <100 mg twice daily as an anti-inflammatory, analgesic, and antipyretic. Its use in the E.U. is limited to <15 days due to the risk of hepatotoxicity.

DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Rheumatoid arthritis is an autoimmune disease that affects ~1% of the population. The pharmacological management of rheumatoid arthritis includes symptomatic relief through the use of NSAIDs. However,
although they have anti-inflammatory effects, NSAIDs have minimal, if any effect on progression of joint deformity. Disease-modifying antirheumatic drugs (DMARDs), on the other hand, reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. DMARDs include a diverse group of small molecule nonbiological and biological agents (mainly antibodies or binding proteins), as summarized in Table 34–5.

IL, interleukin; TNF, tumor necrosis factor.

Biological DMARDs remain reserved for patients with persistent moderate or high disease activity and indicators of poor prognosis. Therapy is tailored to the individual patient, and the use of these agents must be weighed against their potentially serious adverse effects. The combination of NSAIDs with these agents is common.
PHARMACOTHERAPY OF GOUT

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes painful distal monoarthritis and also can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects ~0.5-1% of the population of Western countries.

The pathophysiology of gout is incompletely understood. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal urate transporters, URAT-1, are associated with hypouricemia. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the toll-like receptor pathway mounting an innate immune response. This results in the secretion of cytokines, including IL-1β and TNF-α; endothelial activation; and attraction of neutrophils to the site of inflammation. Neutrophils secrete inflammatory mediators that lower the local pH and lead to further urate precipitation.

The aims of treatment are to:

- Decrease the symptoms of an acute attack.
- Decrease the risk of recurrent attacks.
- Lower serum urate levels.

The substances available for these purposes are:

- Drugs that relieve inflammation and pain (NSAIDs, colchicine, glucocorticoids)
- Drugs that prevent inflammatory responses to crystals (colchicine and NSAIDs)
- Drugs that act by inhibition of urate formation (allopurinol, febuxostat) or to augment urate excretion (probenecid)
NSAIDs have been discussed earlier. Glucocorticoids are discussed in Chapter 42. This section focuses on colchicine, allopurinol, febuxostat, and the uricosuric agents probenecid and benzbromarone.

**COLCHICINE**

Colchicine is one of the oldest available therapies for acute gout. Colchicine is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses.

**MECHANISM OF ACTION.** Colchicine exerts a variety of pharmacological effects, but how these relate to its activity in gout is not well understood. It has antimitotic effects, arresting cell division in G₁ by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Colchicine may alter neutrophil motility and decreases the secretion of chemotactic factors and superoxide anions by activated neutrophils. Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores. Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation but depresses it by a direct effect, and alters neuromuscular function.

**ADME.** Absorption of oral colchicine is rapid but variable. Peak plasma concentrations occur 0.5-2 h after dosing. In plasma, 50% of colchicine is protein bound. There is significant enterohepatic circulation. The exact metabolism of colchicine in humans is unknown, but in vitro studies indicate that it may undergo oxidative demethylation by CYP3A4. Only 10-20% is excreted in the urine, although this increases in patients with liver disease. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. The plasma $t_{1/2}$ of colchicine is 9 h.
**THERAPEUTIC USES.** A minimum of 3 days, but preferably 7-14 days, should elapse between courses of gout treatment with colchicine to avoid cumulative toxicity. Patients with hepatic or renal disease and dialysis patients should receive reduced doses and/or less frequent therapy. For elderly patients, adjust the dose for renal function.

**Acute Gout.** Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 h of attack onset. Pain, swelling, and redness abate within 12 h and are completely gone within 48-72 h. The regimen approved for adults recommends a total of 2 doses taken 1 h apart: 1.2 mg (2 tablets) at the first sign of a gout flare followed by 0.6 mg (1 tablet) 1 h later.

**Prevention of Acute Gout.** The main off-label indication for colchicine is in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose for prophylaxis is 0.6 mg taken orally 3 or 4 days/wk for patients who have <1 attack per year, 0.6 mg daily for patients who have >1 attack per year, and 0.6 mg 2-3 times daily for patients who have severe attacks. The dose must be decreased for patients with impaired renal function.

**ADVERSE EFFECTS.** Exposure of the GI tract to large amounts of colchicine and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects and the earliest signs of impending colchicine toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose or route of administration, of several hours or more between the administration of the drug and the onset of symptoms. A dosing study demonstrated that 1 dose initially and a single additional dose after 1 h was much less toxic than traditional hourly dosing for acute gout flares. Acute intoxication causes hemorrhagic gastropathy. Other serious side effects of colchicine therapy include myelosuppression, leukopenia, granulocytopenia, thrombopenia, aplastic anemia, and rhabdomyolysis. Life-threatening toxicities are associated with administration of concomitant therapy with P-glycoprotein or CYP3A4 inhibitors. The FDA suspended the U.S. marketing of all injectable dosage forms of colchicine in 2008.
ALLOPURINOL

Allopurinol inhibits xanthine oxidase (XO) and prevents the synthesis of urate from hypoxanthine and xanthine. Allopurinol is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

Allopurinol is an analog of hypoxanthine. Its active metabolite, oxypurinol, is an analog of xanthine.

MECHANISM OF ACTION. Both allopurinol and its primary metabolite, oxypurinol (alloxanthine), reduce urate production by inhibiting XO, which converts xanthine to uric acid. Allopurinol competitively inhibits XO at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for XO; the product of this reaction, oxypurinol, also is a noncompetitive inhibitor of the enzyme. The formation of oxypurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Because each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy, which can be minimized by liberal fluid intake and alkalization.
Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal function but may delay disease progression. The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid. Coadministration of colchicine helps suppress such acute attacks. In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of reutilization of oxypurines and feedback inhibition of de novo purine biosynthesis.

**ADME.** Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60-90 min. About 20% is excreted in the feces in 48-72 h, presumably as unabsorbed drug, and 10-30% is excreted unchanged in the urine. The remainder undergoes metabolism, mostly to oxypurinol. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma $t_{1/2}$ of allopurinol and oxypurinol is ~1-2 h and 118-30 h (longer in those with renal impairment), respectively. This allows for once-daily dosing and makes allopurinol the most commonly used antihyperuricemic agent. Allopurinol and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the 2 compounds do not correlate well with therapeutic or toxic effects.

**DRUG INTERACTIONS.** Allopurinol increases the $t_{1/2}$ of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol. Allopurinol inhibits the enzymatic inactivation of mercaptopurine and its derivative azathioprine by XO. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced to 25-33% of the usual dose (see Chapters 35 and 61). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with
cytotoxic agents that are not metabolized by XO, particularly cyclophosphamide. Allopurinol also may interfere with the hepatic inactivation of other drugs, including warfarin. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 36).

**THERAPEUTIC USES.** Allopurinol (Zyloprim, Alopurinol, others) is available for oral and intravenous use. Oral therapy provides effective therapy for primary and secondary gout, hyperuricemia secondary to malignancies, and calcium oxalate calculi. The goal of therapy is to reduce the plasma uric acid concentration to \(<6 \text{ mg/dL}\ (<360 \mu\text{mol/L}). In the management of gout, it is customary to antecedes allopurinol therapy with colchicine and to avoid starting allopurinol during an acute attack. Fluid intake should be sufficient to maintain daily urinary volume \(>2 \text{ L}; \) slightly alkaline urine is preferred. An initial daily dose of 100 mg in patients with estimated glomerular filtration rates \(>40 \text{ mg/min}\) is increased by 100-mg increments at weekly intervals. Most patients can be maintained on 300 mg/day. Those with hematological malignancies may need up to 800 mg/day beginning 2-3 days before the start of chemotherapy. Daily doses \(>300 \text{ mg}\) should be divided. Dosage must be reduced in patients in proportion to the reduction in glomerular filtration.

The usual daily dose in children with secondary hyperuricemia associated with malignancies is 150-300 mg, depending on age. Allopurinol also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome and thereby prevents the complications resulting from hyperuricemia; there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease.

**ADVERSE EFFECTS.** Allopurinol generally is well tolerated. The most common adverse effects are hypersensitivity reactions that may manifest after
months or years of therapy. Serious hypersensitivity reactions preclude further use of the drug. The cutaneous reaction caused by allopurinol is predominantly a pruritic, erythematous, or maculopapular eruption, but occasionally the lesion is urticarial or purpuric. Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment. Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue allopurinol. If indicated, desensitization to allopurinol can be carried out starting at 10-25 ug/day, with the drug diluted in oral suspension and doubled every 3-14 days until the desired dose is reached. This is successful in approximately half of patients. Oxypurinol has orphan drug status and is available for compassionate use in the U.S. for patients intolerant of allopurinol. Fever, malaise, and myalgias also may occur in ~3% of patients, more frequently in those with renal impairment. Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in patients with hyperuricemia post-transplantation. It can be used in conjunction with a uricosuric agent.

**FEBUXOSTAT**

Febuxostat is an XO inhibitor approved for treatment of hyperuricemia in patients with gout.

**MECHANISM OF ACTION.** Febuxostat is a nonpurine inhibitor of XO. Unlike oxypurinol, the active metabolite of allopurinol, which inhibits the reduced form of XO, febuxostat forms a stable complex with both the reduced and oxidized enzymes and inhibits catalytic function in both states.

**ADME.** Febuxostat is rapidly absorbed with maximum plasma concentrations at 1-1.5 h postdose. The absolute bioavailability is unknown. Magnesium
hydroxide and aluminum hydroxide delay absorption by ~1 h. Food reduces absorption slightly. Febuxostat, $t_{1/2}$ of 5-8 h, is extensively metabolized by oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes and is eliminated by both hepatic and renal pathways. Mild to moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.

**THERAPEUTIC USE.** Febuxostat (ULORIC; ADENURIC) is approved for hyperuric patients with gout attacks, but not recommended for treatment of asymptomatic hyperuricemia. It is available in 40- and 80-mg oral tablets. A dose of 40 mg/day febuxostat lowered serum uric acid to similar levels as 300 mg/day allopurinol. More patients reached the target concentration of 6.0 mg/dL (360 μmol/L) on 80 mg/day febuxostat than on 300 mg/day allopurinol. Thus, therapy should be initiated with 40 mg/day and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

**ADVERSE EVENTS.** The most common adverse reactions in clinical studies were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting in mobilization of urate from tissue deposits. Concurrent prophylactic treatment with an NSAID or colchicine is usually required. There was a higher rate of myocardial infarction and stroke in patients on febuxostat than on allopurinol. Whether there is a causal relationship between the cardiovascular events and febuxostat therapy or whether these were due to chance is not clear. Meanwhile patients should be monitored for cardiovascular complications.

**DRUG INTERACTIONS.** Plasma levels of drugs metabolized by XO (e.g., theophylline, mercaptopurine, azathioprine) will increase when administered concurrently with febuxostat. Thus, febuxostat is contraindicated in patients on azathioprine, mercaptopurine, or theophylline.

**RASBURICASE**

Rasburicase (ELITEK) is a recombinant urate oxidase that catalyzes the enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It has been shown to lower urate levels more effectively than allopurinol. It is indicated for the initial management
of elevated plasma uric acid levels in pediatric patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia.

Rasburicase is produced by a genetically modified *Saccharomyces cerevisiae* strain. The drug’s efficacy may be hampered by the production of antibodies against the drug. Hemolysis G6PD-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug. The recommended dose of rasburicase is 0.15 mg/kg or 0.2 mg/kg as a single daily dose for 5 days, with chemotherapy initiated 4-24 h after infusion of the first rasburicase dose.

**URICOSURIC AGENTS**

Uricosuric agents increase the rate of excretion of uric acid. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption is robust, such that the net the amount excreted usually is ~10% of that filtered. Reabsorption is mediated by an organic anion transporter family member, URAT-1, which can be inhibited.

URAT-1 exchanges urate for either an organic anion such as lactate or nicotinate or less potently for an inorganic anion such as chloride. Uricosuric drugs such as probenecid, sulfinpyrazone, benzbromarone, and losartan compete with urate for the transporter, thereby inhibiting its reabsorption via the urate–anion exchanger system. However, transport is bidirectional, and depending on dosage, a drug may either decrease or increase the excretion of uric acid. There are 2 mechanisms by which 1 drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by 1 drug may counterbalance the inhibition of urate reabsorption by the other.
PROBENECID. Probenecid is a highly lipid-soluble benzoic acid derivative ($pK_a$ 3.4).

![PROBENECID](image)

**MECHANISM OF ACTION**

Inhibition of Organic Acid Transport. The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. Probenecid inhibits the reabsorption of uric acid by organic anion transporters, principally URAT-1. Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. The uricosuric action of probenecid is blunted by the coadministration of salicylates.

Inhibition of Transport of Miscellaneous Substances. Probenecid inhibits the tubular secretion of a number of drugs, such as methotrexate and the active metabolite of clofibrate. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as naproxen, ketoprofen, and indomethacin, and thereby can increase their plasma concentrations. Probenecid inhibits the transport of 5-hydroxyindoleacetic acid (5-HIAA) and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as penicillin G also may be affected. Probenecid depresses the biliary secretion of certain compounds, including the diagnostic agents indocyanine green and bromosulphophthalein (BSP). It also decreases the biliary secretion of rifampin, leading to higher plasma concentrations.

**ADME.** Probenecid is absorbed completely after oral administration. Peak plasma concentrations are reached in 2-4 h. The $t_{1/2}$ of the drug in plasma is dose-dependent and varies from <5 h to >8 h. Between 85% and 95% of the drug is bound to plasma albumin; the 5% to 15% of unbound drug is cleared by glomerular filtration and active secretion by the proximal tubule. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

**THERAPEUTIC USES (GOUT).** Probenecid [PROBALAN, BENURYL] is marketed for oral administration. The starting dose is 250 mg twice daily, increasing over
1-2 weeks to 500-1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in <20% of gouty patients treated with probenecid alone.

**Combination with Penicillin.** Higher doses of probenecid are used as an adjuvant to prolong the dwell-time of penicillin in the body. This dosing method usually is confined to those being treated for gonorrhea or neurosyphilis infections or penicillin resistance (see Chapter 53).

**ADVERSE EFFECTS.** Probencid is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of <50 mL/min. Hypersensitivity reactions usually are mild and occur in 2-4% of patients. Substantial overdosage with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

**BENZBROMARONE**

Benzbromarone is a potent uricosuric agent that is used in Europe. It is a reversible inhibitor of the urate–anion exchanger in the proximal tubule. Hepatotoxicity has been reported in conjunction with its use. The drug is absorbed readily after oral ingestion; peak plasma levels are achieved in ~4 h. It is metabolized to monobrominated and dehalogenated derivatives, both of which have uricosuric activity, and is excreted primarily in the bile.

As the micronized powder, it is effective in a single daily dose of 40-80 mg. It is effective in patients with renal insufficiency and may be prescribed to patients who are either allergic or refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone are more effective than either drug alone in lowering serum uric acid levels, in spite of the fact that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol. The uricosuric action is blunted by aspirin or sulfinpyrazone.
chapter 35
Immunosuppressants, Tolerogens, and Immunostimulants

This chapter reviews the components of the immune response and drugs that modulate immunity in 3 ways: immunosuppression, tolerance, and immunostimulation. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (see Chapter 42), calcineurin inhibitors, antiproliferative and antimetabolic agents (see Chapter 61), and antibodies. The chapter ends with a brief case study of immunotherapy for MS.

THE IMMUNE RESPONSE

The immune system evolved to discriminate self from nonself. Innate immunity (natural immunity) is primitive, does not require priming, and is of relatively low affinity, but is broadly reactive. Adaptive immunity (learned immunity) is antigen specific, depends on antigen exposure or priming, and can be of very high affinity. The 2 arms of immunity work closely together, with the innate immune system being most active early in an immune response and adaptive immunity becoming progressively dominant over time.

The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, natural killer cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells are important in the normal immune response to infection and tumors but also mediate transplant rejection and autoimmunity.

Immunoglobulins (antibodies) on the B-lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the
context of self major histocompatibility complex (MHC) antigens (called human leukocyte antigens [HLAs] in humans) on the surface of antigen-presenting cells, such as dendritic cells, macrophages, and other cell types expressing MHC class I and class II antigens. Once activated by specific antigen recognition, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response.

**IMMUNOSUPPRESSION**

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are:

- Glucocorticoids
- Calcineurin inhibitors
- Antiproliferative/antimetabolic agents
- Biologicals (antibodies)

Table 35–1 summarizes the sites of action of representative immunosuppressants on T-cell activation.

*IL, interleukin; mTOR, mammalian target of rapamycin.*

These drugs are used in treating conditions such as acute immune rejection of organ transplants and severe auto-immune diseases. However, such therapies
require lifelong use and nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. The calcineurin inhibitors and glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings. Monoclonal and polyclonal antibody preparations directed at reactive T cells are important adjunct therapies and provide a unique opportunity to target specifically immune-reactive cells. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mammalian target of rapamycin (mTOR) inhibitors (sirolimus, everolimus) and anti-CD25 (interleukin-2 receptor [IL-2R]) antibodies (basiliximab, daclizumab) target growth-factor pathways, substantially limiting clonal expansion and thus potentially promoting tolerance.

GENERAL APPROACH TO ORGAN TRANSPLANTATION THERAPY. Organ transplantation therapy is organized around 5 general principles.

• Carefully prepare patient and select the best available ABO blood type–compatible HLA match for organ donation.
• Employ multitiered immunosuppressive therapy; simultaneously use several agents, each of which is directed at a different molecular target within the allograft response. Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect.
• Employ intensive induction and lower-dose maintenance drug protocols; greater immunosuppression is required to gain early engraftment and/or to treat established rejection than to maintain long-term immunosuppression.
• Investigation of each episode of transplant dysfunction is required, including evaluation for rejection, drug toxicity, and infection.
• Reduce dosage or withdraw a drug if its toxicity exceeds its benefit.

BIOLOGICAL INDUCTION THERAPY. Induction therapy with polyclonal and monoclonal antibodies (mAbs) has been an important component of immunosuppression since the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection. Two preparations are
FDA-approved for use in transplantation: lymphocyte immune globulin (ATGAM) and antithymocyte globulin (ATG; THYMoglobulin). ATG is the most frequently used depleting agent. Alemtuzumab, a humanized anti-CD52 monoclonal antibody that produces prolonged lymphocyte depletion, is approved for use in chronic lymphocytic leukemia but is increasingly used off label as induction therapy in transplantation.

In many transplant centers, induction therapy with biological agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensitized patients, African American patients, or pediatric patients). Most of the limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have a prolonged serum t½. Antibodies derived from transgenic mice carrying human antibody genes are labeled “humanized” (90-95% human) or “fully human” (100% human); antibodies derived from human cells are labeled “human.” However, all 3 types of antibodies probably are of equal efficacy and safety. Chimeric antibodies generally contain ~33% mouse protein and 67% human protein and can still produce an antibody response, resulting in reduced efficacy and shorter t½ compared to humanized antibodies.

Biological agents for induction therapy in the prophylaxis of rejection currently are used in ~70% of de novo transplant patients. Biological agents for induction can be divided into 2 groups: the depleting agents and the immune modulators. The depleting agents consist of lymphocyte immune globulin, ATG, and muromonab-CD3 mAb; their efficacy derives from their ability to deplete the recipient’s CD3-positive cells at the time of transplantation and antigen presentation. The second group of biological agents, the anti–IL-2R mAbs, do not deplete T lymphocytes, with the possible exception of T regulatory cells, but rather block IL-2–mediated T-cell activation by binding to the α chain of IL-2R. For patients with high levels of anti-HLA antibodies and humoral rejection, more aggressive therapies include plasmapheresis, intravenous immunoglobulin, and rituximab, a chimeric anti-CD20 monoclonal antibody.

MAINTENANCE IMMUNOTHERAPY. Basic immunosuppressive
therapy uses multiple drugs simultaneously, typically a calcineurin inhibitor, glucocorticoids, and mycophenolate (a purine metabolism inhibitor), each directed at a discrete site in T-cell activation. Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate, sirolimus, and various monoclonal and polyclonal antibodies all are approved for use in transplantation.

THERAPY FOR ESTABLISHED REJECTION. Low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, or sirolimus are effective in preventing acute cellular rejection; they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection. Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3.

GLUCOCORTICOIDS

The glucocorticoids are described in Chapter 42. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders.

Mechanism of Action. Glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity, but relatively little effect on humoral immunity. Glucocorticoids bind to receptors inside cells and regulate the transcription of numerous other genes (see Chapter 42). Glucocorticoids also curtail activation of NF-κB, suppress formation of pro-inflammatory cytokines such as IL-1 and IL-6, inhibit T cells from making IL-2 and proliferating, and inhibit the activation of cytotoxic T lymphocytes. In addition, neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release.
Therapeutic Uses. Glucocorticoids commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. Glucocorticoids also are efficacious for treatment of graft-versus-host disease in bone-marrow transplantation. Glucocorticoids are routinely used to treat autoimmune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, auto-immune hematological disorders, and acute exacerbations of MS (see “Multiple Sclerosis,” below). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonab-CD3 and to a lesser extent ATG (see “Antithymocyte Globulin”).

Toxicity. Extensive steroid use often results in disabling and life-threatening adverse effects described in Chapter 42. The advent of combined glucocorticoid/calcineurin inhibitor regimens has allowed reduced doses or rapid withdrawal of steroids, resulting in lower steroid-induced morbidities.

CALCINEURIN INHIBITORS

The most effective immunosuppressive drugs in routine use are the calcineurin inhibitors, cyclosporine and tacrolimus, which target intracellular signaling pathways induced as a consequence of T-cell–receptor activation (Figure 35–1). Cyclosporine and tacrolimus bind to an immunophilin (cyclophilin for cyclosporine, or FKBP-12 for tacrolimus), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the nuclear factor of activated T lymphocytes (NFAT) into the nucleus. NFAT, in turn, is required to induce a number of cytokine genes, including that for IL-2, a prototypic T-cell growth and differentiation
factor.

Figure 35–1 Mechanisms of action of cyclosporine, tacrolimus, and sirolimus on T cells. Cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FK506-binding protein [FKBP], respectively), forming a complex that inhibits the phosphatase calcineurin and the calcineurin-catalyzed dephosphorylation that permits translocation of nuclear factor of activated T cells (NFAT) into the nucleus. NFAT is required for transcription of interleukin-2 (IL-2) and other growth and differentiation–associated cytokines (lymphokines). Sirolimus (rapamycin) works downstream of the IL-2 receptor, binding to FKBP; the FKBP-sirolimus complex binds to and inhibits the mammalian target of rapamycin (mTOR), a kinase involved in cell-cycle progression (proliferation). TCR, the T-cell receptor that recognizes antigens bound to the major histocompatibility complex. (Reproduced with permission from Clayberger C, Krensky AM. Mechanisms of allograft rejection. In Neilson EG, Couser WG, eds, Immunologic Renal Diseases, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, pp 321–346. http://lww.com.)

TACROLIMUS. Tacrolimus (PROGRAF, FK506) is a macrolide
antibiotic produced by *Streptomyces tsukubaensis*. Because of perceived slightly greater efficacy and ease of blood level monitoring, tacrolimus has become the preferred calcineurin inhibitor in most transplant centers.

**Mechanism of Action.** Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin. Tacrolimus binds to an intracellular protein, FK506-binding protein–12 (FKBP-12), an immunophilin structurally related to cyclophilin. A complex of tacrolimus-FKBP-12, Ca\(^{2+}\), calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited (see Figure 35–1). Inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression.

**ADME.** Tacrolimus is available for oral administration as capsules (0.5, 1, and 5 mg) and as a solution for injection (5 mg/mL). Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. For tacrolimus, whole blood seems to be the best sampling compartment; the trough drug level in whole blood seems to correlate better with clinical events for tacrolimus than for cyclosporine. Target concentrations are 10-15 ng/mL in the early preoperative period and 100-200 ng/mL 3 months after transplantation. GI absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75-99%, involving primarily albumin and α1-acid glycoprotein. The *t\(_{1/2}\)* of tacrolimus is ~12 h. Tacrolimus is extensively metabolized in the liver by CYP3A; some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces.

**Therapeutic Uses.** Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine (see “Cyclosporine”) and is used off label as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine. Recommended initial oral doses are 0.2 mg/kg/day for adult kidney transplant patients, 0.1-0.15 mg/kg/day for adult liver transplant patients, 0.075 mg/kg/day for adult heart transplant patients, and 0.15-0.2 mg/kg/day for pediatric liver transplant patients in 2 divided doses 12 h apart. These dosages are intended to achieve typical blood trough levels in the 5-
to 20-ng/mL range.

**Toxicity.** Nephrotoxicity, neurotoxicity (e.g., tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes all are associated with tacrolimus use. Tacrolimus has a negative effect on pancreatic islet β cells, and glucose intolerance and diabetes mellitus are well-recognized complications of tacrolimus-based immunosuppression. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol. Diarrhea and alopecia are common in patients on concomitant mycophenolate therapy.

**Drug Interactions.** Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely. Coadministration with cyclosporine results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 h is required when switching a patient from cyclosporine to tacrolimus. Because tacrolimus is metabolized mainly by CYP3A, the potential interactions described in the following section for cyclosporine also apply for tacrolimus.

**CYCLOSPORINE.** Cyclosporine (cyclosporin A), a cyclic polypeptide of 11 amino acids, is produced by the fungus *Beauveria nivea*. Figure 35–1 depicts the molecular action of cyclosporine to inhibit calcineurin activity. At the level of immune system function, cyclosporine suppresses some humoral immunity but is more effective against T cell–dependent immune mechanisms such as those underlying transplant rejection and some forms of autoimmunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of anti-apoptotic proteins. Cyclosporine also increases expression of transforming growth factor β (TGF-β), a potent inhibitor of IL-2–stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (CTLs).

**ADME.** Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to
ensure solubilization. Cyclosporine can be administered intravenously or orally. The intravenous preparation (SANDIMMUNE, others) is provided as a solution in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule is absorbed slowly, with 20-50% bioavailability. A modified microemulsion formulation (NEORAL) has become the most widely used preparation. It has more uniform and slightly increased bioavailability compared to the original formulation. It is provided as 25-mg and 100-mg soft gelatin capsules and a 100-mg/mL oral solution. The original and microemulsion formulations are not bioequivalent and cannot be used interchangeably without supervision by a physician and monitoring of drug concentrations in plasma. Generic preparations of both NEORAL and SANDIMMUNE are bioequivalent by FDA criteria. Transplant units need to educate patients that SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity.

Blood levels taken 2 h after a dose administration (so-called C2 levels) may correlate better with the AUC than other single points, but no single time point can simulate the exposure better than more frequent drug sampling. In practice, if a patient has clinical signs or symptoms of toxicity, or if there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person’s exposure to the drug.

Cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. The elimination of cyclosporine from the blood generally is biphasic, with a terminal t1/2 of 5-18 h. After intravenous infusion, clearance is ~5-7 mL/min/kg in adult recipients of renal transplants, but results differ by age and patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required. After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5-2 h. Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 min of administration decrease the AUC by ~13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients.
Cyclosporine is extensively metabolized by hepatic CYP3A and to a lesser degree by the GI tract and kidneys. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with ~6% excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for dialysis or renal failure patients.

**Therapeutic Uses.** Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; and psoriasis. Its use in dermatology is discussed in *Chapter 65*. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate and, most recently, sirolimus. The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. Dosing is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the reason for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient can take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to methotrexate. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely. In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies have failed. Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T cell–mediated diseases. Cyclosporine reportedly is effective in Behçet’s acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

**Toxicity.** The principal adverse reactions to cyclosporine therapy are renal dysfunction and hypertension; tremor, hirsutism, hyperlipidemia, and gum hyperplasia also are frequently encountered. Hypertension occurs in ~50% of renal transplant and almost all cardiac transplant patients. Hyperuricemia may
lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia. Nephrotoxicity occurs in the majority of patients and is the major reason for cessation or modification of therapy. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic. Especially at risk are obese patients, African American or Hispanic transplant recipients, or those with a family history of type II diabetes or obesity. Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol.

Drug Interactions. Any drug that affects CYPs, especially CYP3A, may impact cyclosporine blood concentrations. Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca\(^{2+}\) channel blockers (e.g., verapamil, nicardipine), antifungal agents (e.g., fluconazole, ketoconazole), antibiotics (e.g., erythromycin), glucocorticoids (e.g., methylprednisolone), HIV-protease inhibitors (e.g., indinavir), and other drugs (e.g., allopurinol, metoclopramide). Grapefruit juice inhibits CYP3A and the P-glycoprotein multidrug efflux pump and thereby can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., nafcillin, rifampin), anticonvulsants (e.g., phenobarbital, phenytoin), and others (e.g., octreotide, ticlopidine).

Interactions between cyclosporine and sirolimus require that administration of the 2 drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Additive nephrotoxicity may occur when cyclosporine is coadministered with NSAIDs and other drugs that cause renal dysfunction; elevation of methotrexate levels when the 2 drugs are coadministered; and reduced clearance of other drugs, including prednisolone, digoxin, and statins.

ANTIPROLIFERATIVE AND ANTIMETABOLIC DRUGS

SIROLIMUS

Sirolimus (rapamycin; RAPAMUNE) is a macrocyclic lactone produced by *Streptomyces hygroscopicus*. Sirolimus inhibits T-
lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (see Figure 35–1). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKB-12. The sirolimus–FKBP-12 complex does not affect calcineurin activity; rather, it binds to and inhibits the protein kinase mTOR, which is a key enzyme in cell-cycle progression. Inhibition of mTOR blocks cell-cycle progression at the G1 → S phase transition.

**ADME.** After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within ~1 h after a single dose in healthy subjects and within ~2 h after multiple oral doses in renal transplant patients. Systemic availability is ~15%, and blood concentrations are proportional to dose between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood (blood-to-plasma ratio = 38 in renal transplant patients). Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. Although some of its metabolites are active, sirolimus itself is the major active component in whole blood and contributes > 90% of the immunosuppressive effect. The blood t₁/₂ after multiple doses in stable renal transplant patients is 62 h. A loading dose of 3 times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

**Therapeutic Uses.** Sirolimus is indicated for prophylaxis of organ transplant rejection usually in combination with a reduced dose of calcineurin inhibitor and glucocorticoids. Sirolimus has been used with glucocorticoids and mycophenolate to avoid permanent renal damage. Sirolimus dosing regimens are relatively complex with blood levels generally targeted between 5 and 15 ng/mL. It is recommended that the daily maintenance dose be reduced by approximately one-third in patients with hepatic impairment. Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion.

**Toxicity.** The use of sirolimus in renal transplant patients is associated with a
dose-dependent increase in serum cholesterol and triglycerides that may require treatment. Although immunotherapy with sirolimus per se is not nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine alone. Sirolimus also may prolong delayed graft function in deceased-donor kidney transplants, presumably because of its antiproliferative action. Renal function therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up. Other adverse effects include anemia, leukopenia, thrombocytopenia, mouth ulcer, hypokalemia, proteinuria, and GI effects. Delayed wound healing may occur with sirolimus use. As with other immunosuppressive agents, there is an increased risk of neoplasms, especially lymphomas, and infections.

**Drug Interactions.** Because sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required. Dose adjustment may be required when sirolimus is coadministered with diltiazem or rifampin.

**EVEROLIMUS**

Everolimus [40-O-(2-hydroxyethyl)-rapamycin] is closely related to sirolimus but has distinct pharmacokinetics. The main difference is a shorter $t_{1/2}$ and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to that of sirolimus. As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone. The toxicity of everolimus and the drug interactions seem to be the same as with sirolimus.

**AZATHIOPRINE**

Azathioprine (IMURAN, others) is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine, metabolites of which can inhibit purine synthesis.

**Mechanism of Action.** Following exposure to nucleophiles such as glutathione,
azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Chapter 61). A fraudulent nucleotide, 6-thio-IMP, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation thereby is inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-mercaptopurine.

**Disposition and Pharmacokinetics.** Azathioprine is well absorbed orally and reaches maximum blood levels within 1-2 h after administration. The $t_{1/2}$ of azathioprine is $\sim$10 min, and $t_{1/2}$ of 6-mercaptopurine is $\sim$1 h. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and mercaptopurine are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver and/or erythrocytes.

**Therapeutic Uses.** Azathioprine is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. The usual starting dose of azathioprine is 3-5 mg/kg/day. Lower initial doses (1 mg/kg/day) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

**Toxicity.** The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), and/or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

**Drug Interactions.** Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. Adverse effects resulting from coadministration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

**MYCOPHENOLATE MOFETIL**

Mycophenolate mofetil (MMF; CELLCEPT) is the 2-morpholinoethyl ester of mycophenolic acid (MPA). MMF is a prodrug that is rapidly
hydrolyzed to the active drug, MPA, a selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), an important enzyme in the de novo pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation; MPA thus selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

Disposition and Pharmacokinetics. MMF undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA is then metabolized to the inactive glucuronide MPAG. The $t_{1/2}$ of MPA is ~16 h. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency.

Therapeutic Uses. MMF is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor but not with azathioprine. Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels. For renal transplants, 1 g is administered orally or intravenously (over 2 h) twice daily (2 g/day). A higher dose, 1.5 g twice daily (3 g/day), may be recommended for African American renal transplant patients and all liver and cardiac transplant patients. MMF is increasingly used off label in systemic lupus. A delayed-release formulation of MPA (MYFORTIC) is available. It does not release MPA under acidic conditions ($pH < 5$), as in the stomach, but is soluble in neutral pH, as in the intestine. The enteric coating results in a delay in the time to reach maximum MPA concentrations.

Toxicity. The principal toxicities of MMF are GI and hematologic: leukopenia, pure red cell aplasia, diarrhea, and vomiting. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus. Tacrolimus in combination with MMF has been associated with activation of polyoma viruses such as BK virus, which can cause interstitial nephritis. The use of mycophenolate in pregnancy is associated with congenital anomalies and increased risk of pregnancy loss.

Drug Interactions. Tacrolimus delays elimination of MMF by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Coadministration
with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of MMF; thus, these drugs should not be administered simultaneously. MMF should not be administered with cholestyramine or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Acyclovir and ganciclovir may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency.

**OTHER ANTIPROLIFERATIVE AND CYTOTOXIC AGENTS**

Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (see Chapter 61) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used off label as immunosuppressive agents include methotrexate, cyclophosphamide, thalidomide (Thalomid), and chlorambucil (Leukeran). Methotrexate is used for treatment of graft-versus-host disease, rheumatoid arthritis, psoriasis, and some cancers. Cyclophosphamide and chlorambucil are used in leukemia and lymphomas and a variety of other malignancies. Cyclophosphamide also is FDA-approved for childhood nephrotic syndrome and is used widely for treatment of severe systemic lupus erythematosus and other vasculitides such as Wegener granulomatosis. Leflunomide (Arava, others) is a pyrimidine-synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis. This drug has found increasing empirical use in the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients. There are no controlled studies showing efficacy compared with control patients treated with only withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the de novo pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

**FINGOLIMOD (FTY720).** This is the first agent in a new class of small molecules, sphingosine-1-phosphate receptor (S1P-R) agonists. This S1P receptor prodrug reduces recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, thereby shunting lymphocytes away from inflammatory lesions and organ grafts.
Mechanism of Action. FTY720 specifically and reversibly causes sequestration of host lymphocytes into the lymph nodes and Peyer patches and thus away from the circulation, thereby protecting lesions and grafts from T cell–mediated attack. FTY720 does not impair T- and B-cell functions. Sphingosine kinase-2 phosphorylates FTY720; the FTY720-phosphate product is a potent agonist of S1P receptors. Altered lymphocyte traffic induced by FTY720 clearly results from its effect on S1P receptors.

Therapeutic Uses. The drug has not been as effective as standard regimens in phase III trials, and further drug development has been limited.

Toxicity. Lymphopenia, the predictable and most common side effect of FTY720, reverses upon discontinuation of the drug. Of greater concern is the negative chronotropic effect of FTY720 on the heart, which has been observed with the first dose in up to 30% of patients.

**IMMUNOSUPPRESSION ANTIBODIES AND FUSION RECEPTOR PROTEIN**

Polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for prevention and treatment of organ transplant rejection. Polyclonal antiserum are generated by repeated injections of human thymocytes (ATG) or lymphocytes (ALG) into
animals and then purifying the serum immunoglobulin fraction. These preparations vary in efficacy and toxicity from batch to batch. The capacity to produce monoclonal antibodies has overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but monoclonal Abs are more limited in their target specificity.

Another class of biological agents being developed for both autoimmunity and transplantation are fusion receptor proteins. These agents consist of the ligand-binding domains of receptors bound to the Fc region of an immunoglobulin (usually IgG1) to provide a longer $t_{1/2}$.

**ANTITHYMOCYTE GLOBULIN**

ATG is a purified gamma globulin from the serum of rabbits immunized with human thymocytes.

**MECHANISM OF ACTION.** ATG contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes. The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

**Therapeutic Uses.** ATG is used for induction immunosuppression, although the only approved indication is in the treatment of acute renal transplant rejection in combination with other immunosuppressive agents. Antilymphocyte-depleting agents (Thymoglobulin, ATGAM, and OKT3) are not registered for use as induction immunosuppression. A course of antithymocyte-globulin often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors, thereby aiding in recovery from ischemic reperfusion injury. The recommended dose for acute rejection of renal grafts is 1.5 mg/kg/day (over 4-6 h) for 7-14 days. Mean T-cell counts fall
by day 2 of therapy. ATG also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection.

Toxicity. Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, acetaminophen, and/or an antihistamine and administration of the antiserum by slow infusion (over 4-6 h) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is rare. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined.

**MONOCLONAL ANTIBODIES**

**ANTI-CD3 MONOCLONAL ANTIBODIES.** Antibodies directed at the A chain of CD3, a trimeric molecule adjacent to the T-cell receptor on the surface of human T lymphocytes, have been used with considerable efficacy in human transplantation. The original mouse IgG\(_{2a}\) antihuman CD3 monoclonal antibody, muromonab-CD3 (OKT3, ORTHOCLONE OKT3), still is used to reverse glucocorticoid-resistant rejection episodes.

**Mechanism of Action.** Muromonab-CD3 binds to the a chain of CD3, a monomorphic component of the T-cell receptor complex involved in antigen recognition, cell signaling, and proliferation. Antibody treatment induces rapid internalization of the T-cell receptor, thereby preventing subsequent antigen recognition. Administration of the antibody is followed rapidly by depletion and of a majority of T cells from the bloodstream and peripheral lymphoid organs such as lymph nodes and spleen. This absence of detectable T cells from the usual lymphoid regions is secondary both to complement activation-induced cell death and to margination of T cells onto vascular endothelial walls and redistribution of T cells to nonlymphoid organs such as the lungs. Muromonab-CD3 also reduces function of the remaining T cells, as defined by lack of IL-2 production and great reduction in the production of multiple cytokines, perhaps with the exception of IL-4 and IL-10.
Therapeutic Uses. Muromonab-CD3 is indicated for treatment of acute organ transplant rejection. The recommended dose is 5 mg/day (in adults; less for children) in a single intravenous bolus (< 1 min) for 10-14 days. Circulating T cells disappear from the blood within minutes of administration and return within ~1 week after termination of therapy. Repeated use of muromonab-CD3 results in the immunization of the patient against the mouse determinants of the antibody and generally is contraindicated. Administration of glucocorticoids before the injection of muromonab-CD3 is standard; it prevents the release of cytokines and reduces first-dose reactions considerably, and now is a standard procedure. Volume status of patients also must be monitored carefully before therapy; a fully competent resuscitation facility must be immediately available for patients receiving their first several doses of this therapy.

Toxicity. The major side effect of anti-CD3 therapy is the “cytokine release syndrome.” The syndrome typically begins 30 min after infusion of the antibody (but can occur later) and may persist for h. The syndrome is associated with increased serum levels of cytokines (including tumor necrosis factor-α [TNF-α], IL-2, IL-6, and interferon-γ [IFN-γ]) released by activated T cells and/or monocytes. Clinical manifestations include high fever, chills/rigor, headache, tremor, nausea, vomiting, diarrhea, abdominal pain, malaise, myalgias, arthralgias, and generalized weakness. Less common complaints include skin reactions and cardiorespiratory and CNS disorders. Potentially fatal pulmonary edema, acute respiratory distress syndrome, cardiovascular collapse, cardiac arrest, and arrhythmias have been described. Other toxicities associated with anti-CD3 therapy include anaphylaxis and the usual infections and neoplasms associated with immunosuppressive therapy. “Rebound” rejection has been observed when muromonab-CD3 treatment is stopped. Anti-CD3 therapies may be limited by anti-idiotypic or antimurine antibodies in the recipient. Muromonab-CD3 rarely is used in transplantation. It has been replaced by ATG and alemtuzumab.

NEW-GENERATION ANTI-CD3 ANTIBODIES. Recently, genetically altered anti-CD3 monoclonal antibodies have been developed that are “humanized” to minimize the occurrence of anti-antibody responses and mutated to prevent binding to Fc receptors. In initial clinical trials, a humanized anti-CD3 monoclonal antibody that does not bind to Fc receptors reversed acute renal allograft rejection without causing the first-dose cytokine-release syndrome.
ANTI-IL-2 RECEPTOR (ANTI-CD25) ANTIBODIES. **Daclizumab** (ZENAPAX) is a humanized murine complementarity-determining region (CDR)/human IgG1 chimeric monoclonal antibody. **Basiliximab** (SIMULECT) is a murine-human chimeric monoclonal antibody.

**Mechanism of Action.** The anti-CD25 mAbs bind to the IL-2 receptor on the surface of activated T cells. Significant depletion of T cells does not appear to play a major role in the mechanism of action of these mAbs. Therapy with the anti IL-2R mAbs results in a relative decrease of the expression of the α chain epitope of the IL-2R on activated lymphocytes. The β chain may be downregulated by the anti-CD25 antibody. Daclizumab has a somewhat lower affinity but a longer $t_{1/2}$ (20 days) than basiliximab.

**Therapeutic Uses.** Anti–IL-2-receptor monoclonal antibodies are used for prophylaxis of acute organ rejection in adult patients.

Clinical trials indicate that the $t_{1/2}$ of daclizumab is 20 days, resulting in saturation of the IL-2Rα on circulating lymphocytes for up to 120 days after transplantation. Daclizumab was administered in 5 doses (1 mg/kg given intravenously over 15 min in 50-100 mL of normal saline) starting immediately preoperatively, and subsequently at biweekly intervals. Daclizumab was used with maintenance immunosuppressive regimens (cyclosporine, azathioprine, and steroids; cyclosporine and steroids).

The $t_{1/2}$ of basiliximab is 7 days. In trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation. This regimen of basiliximab saturated IL-2R on circulating lymphocytes for 25-35 days after transplantation. Basiliximab was used with a maintenance regimen consisting of cyclosporine and prednisone and was found to be safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone.

**Toxicity.** No cytokine-release syndrome has been noted, but anaphylactic reactions and rare lymphoproliferative disorders and opportunistic infections may occur. No drug interactions have been described.
Alemtuzumab. Alemtuzumab (CAMPATH) is a humanized mAb approved for use in chronic lymphocytic leukemia. The antibody targets CD52, a glycoprotein expressed on lymphocytes, monocytes, macrophages, and natural killer cells; the drug causes lymphotoysis by inducing apoptosis of targeted cells. It has achieved some use in renal transplantation because it produces prolonged T- and B-cell depletion and allows drug minimization.

ANTI-TNF REAGENTS. TNF-T is a proinflammatory cytokine that has been implicated in the pathogenesis of several immune-mediated intestinal, skin, and joint diseases. Several diseases (rheumatoid arthritis, Crohn disease) are associated with elevated levels of TNF-α. As a result, a number of anti-TNF agents have been developed as treatments.

**Infliximab** (REMICADE) is a chimeric IgG1 monoclonal antibody containing a human constant (Fc) region and a murine variable region. It binds with high affinity to TNF-α and prevents the cytokine from binding to its receptors. Infliximab is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is typically used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of Crohn disease, ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis. About 1 of 6 patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1-2 h after antibody administration. The development of antinuclear antibodies, and rarely a lupus-like syndrome, has been reported after treatment with infliximab.

**Etanercept** (ENBREL) is a fusion protein that targets TNF-α. Etanercept contains the ligand-binding portion of a human TNF-α receptor fused to the Fc portion of human IgG1, and binds to TNF-α, and prevents it from interacting with its receptors. It is approved for treatment of the symptoms of rheumatoid arthritis, ankylosing spondylitis, plaque psoriasis, polyarticular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred.
Adalimumab (HUMIRA) is another anti-TNF product for intravenous use. This recombinant human IgG1 monoclonal antibody is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn disease, juvenile idiopathic arthritis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis.

**Toxicity.** All anti-TNF agents (i.e., infliximab, etanercept, adalimumab) increase the risk for serious infections, lymphomas, and other malignancies. For example, fatal hepatosplenic T-cell lymphomas have been reported in adolescent and young adult patients with Crohn disease treated with infliximab in conjunction with azathioprine or 6-mercaptopurine.

**IL-1 INHIBITION**

Plasma IL-1 levels are increased in patients with active inflammation (see Chapter 34). In addition to the naturally occurring IL-1 receptor antagonist (IL-1RA), several IL-1 receptor antagonists are in development and a few have been approved for clinical use. Anakinra is an FDA-approved recombinant, nonglycosylated form of human IL-1RA for the management of joint disease in rheumatoid arthritis. It can be used alone or in combination with anti-TNF agents such as etanercept, infliximab, or adalimumab. Canakinumab (ILARIS) is an IL-1 β monoclonal antibody that is FDA-approved for Cryopyrin-associated periodic syndromes (CAPS), a group of rare inherited inflammatory diseases associated with overproduction of IL-1 that includes familial cold autoinflammatory and Muckle-Wells syndromes. Canakinumab is also being evaluated for use in chronic obstructive pulmonary disease. Rilonacept (IL-1 TRAP) is another IL-1 blocker (a fusion protein that binds IL-1) that is being evaluated for gout; IL-1 is an inflammatory mediator of joint pain associated with elevated uric acid crystals.

**LYMPHOCYTE FUNCTION–ASSOCIATED ANTIGEN-1 (LFA-1) INHIBITION**

Efalizumab (RAPTIVA) is a humanized IgG1 mAb targeting the CD11a chain of lymphocyte function–associated antigen-1 (LFA-1). Efalizumab binds to LFA-1 on lymphocytes and prevents the LFA-1 interaction with intercellular adhesion molecule (ICAM) thereby inhibiting T-cell adhesion, trafficking, and activation. Efalizumab is
approved for use in patients with psoriasis.

**Alefacept (AMEVIVE)** is a human LFA-3-IgG₁ fusion protein. The LFA-3 portion of alefacept binds to CD2 on T lymphocytes, blocking the interaction between LFA-3 and CD2 and interfering with T-cell activation. Alefacept is approved for use in psoriasis. Treatment with alefacept has been shown to produce a dose-dependent reduction in T-effector memory cells (CD45, RO+) but not in naïve cells (CD45, RA+).

**TARGETING B CELLS**

Most of the advances in transplantation can be attributed to drugs designed to inhibit T-cell responses. As a result, T cell–mediated acute rejection has become much less of a problem, while B cell–mediated responses such as antibody-mediated rejection and other effects of donor-specific antibodies have become more evident. Both biologicals and small molecules with B-cell specific effects now are in development for transplantation, including humanized monoclonal antibodies to CD20 and inhibitors of the 2 B cell–activation factors BLYS and APRIL and their respective receptors. Belimumab (BENLYSTA), a monoclonal antibody that targets BLYS, was recently approved for use in patients with systemic lupus erythematosus.

**TOLERANCE**

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunological tolerance, the active state of antigen-specific nonresponsiveness. Tolerance, if attainable, would represent a true cure for conditions discussed earlier in this section without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models. In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance.

**CO-STIMULATORY BLOCKADE.** Induction of specific immune
responses by T lymphocytes requires 2 signals: an antigen-specific signal via the T-cell receptor and a co-stimulatory signal provided by the interaction of molecules such as CD28 on the T lymphocyte and CD80 and CD86 on the antigen-presenting cell (Figure 35–2). Inhibition of the co-stimulatory signal has been shown to induce tolerance.

Figure 35–2 Co-stimulation. A. Two signals are required for T-cell activation. Signal 1 is via the T-cell receptor (TCR) and signal 2 is via a co-stimulatory receptor-ligand pair. Signal 1 in the absence of signal 2 results in an inactivated T cell. B. One important co-stimulatory pathway involves CD28 on the T cell and B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell (APC). After a T cell is activated, it expresses additional co-stimulatory molecules. CD152 is CD40 ligand, which interacts with CD40 as a co-stimulatory pair. CD154 (CTLA4) interacts with CD80 and CD86 to dampen or downregulate an immune response. Antibodies against CD80, CD86, and CD152 are being evaluated as
potential therapeutic agents. CTLA4-Ig, a chimeric protein consisting of part of an immunoglobulin molecule and part of CD154, also has been tested as a therapeutic agent. (Adapted with permission from Clayberger C, Krensky AM. Mechanisms of allograft rejection. In Neilson EG, Couser WG, eds, *Immunologic Renal Diseases*, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, pp 321–346. http://lww.com.)

**Abatacept** (CTLA4-Ig) is a fusion protein that contains the binding region of cytotoxic T-lymphocyte-associated antigen 4 (CTLA4), which is a CD28 homolog, and the Fc region of the human IgG1. CTLA4-Ig competitively inhibits CD28 binding to CD80 and CD86 and thus activation of T-cells. CTLA4-Ig is effective in the treatment of rheumatoid arthritis in patients resistant to other drugs.

**Belatacept** (NULOJIX, LEA29Y) is a second-generation CTLA4-Ig with 2 amino acid substitutions. Belatacept has higher affinity for CD80 (2-fold) and CD86 (4-fold), yielding a 10-fold increase in potency in vitro as compared to CTLA4-Ig. Preclinical renal transplant studies in nonhuman primates showed that belatacept did not induce tolerance but did prolong graft survival. Because of the risk of post-transplant lymphoproliferative disease (PTLD), EBV negative patients should not be treated with belatacept. Belatacept is approved as an immunosuppressant to prevent organ rejection in renal transplantation.

A second co-stimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, and/or antigen-presenting cells (see Figure 35–2). Among the purported activities of anti-CD154 antibody treatment is the blockade of B7 expression induced by immune activation. Two humanized anti-CD154 monoclonal antibodies have been used in clinical trials in renal transplantation and autoimmune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154-CD40 pathway is to target CD40 with monoclonal antibodies. These antibodies are undergoing trials in non-Hodgkin lymphoma but are also likely to be developed for autoimmunity and transplantation.

**DONOR CELL CHIMERICISM.** A promising approach is induction of chimerism (coexistence of cells from 2 genetic lineages in a single
individual) by first dampening or eliminating immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, and/or antibody treatment, and then providing a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells. Upon reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long lived and less likely to be complicated by the use of calcineurin inhibitors.

**ANTIGENS.** Specific antigens induce immunological tolerance in preclinical models of diabetes mellitus, arthritis, and MS. In vitro and preclinical in vivo studies demonstrate that one can selectively inhibit immune responses to specific antigens without the associated toxicity of immunosuppressive therapies. With these insights comes the promise of specific immune therapies to treat an array of immune disorders from auto-immunity to transplant rejection.

**IMMUNOSTIMULATION**

In contrast to immunosuppressive agents that inhibit the immune response in transplant rejection and autoimmunity, a few immunostimulatory drugs have been developed with applicability to infection, immunodeficiency, and cancer.

**IMMUNOSTIMULANTS**

**THALIDOMIDE.** Thalidomide (**THALOMID**) is best known for the severe, life-threatening birth defects it caused when administered to pregnant women. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.* It is indicated for the treatment of patients with erythema nodosum leprosum (see Chapter 56) and multiple myeloma. In addition, it has orphan drug status for mycobacterial infections, Crohn disease, HIV-associated wasting, Kaposi sarcoma, lupus, myelofibrosis, brain malignancies, leprosy, graft-versus-host disease, and aphthous ulcers. Its mechanism of action is unclear.

**LENALIDOMIDE.** Lenalidomide (**REVLIMID**) is a thalidomide analog with
immunomodulatory and anti-angiogenic properties. The drug is FDA-approved for the treatment of transfusion-dependent anemia. Lenalidomide causes significant neutropenia and thrombocytopenia, is associated with a significant risk for deep vein thrombosis, and carries the same risk of teratogenicity as thalidomide (pregnancy must be avoided).

**BACILLUS CALMETTE-GUéRIN (BCG).** Live BCG (TICEBCG, THERACYS) is an attenuated, live culture of the bacillus of Calmette and Guérin strain of *Mycobacterium bovis* that induces a granulomatous reaction at the site of administration. By unclear mechanisms, this preparation is active against tumors and is indicated for the treatment and prophylaxis of carcinoma in situ of the urinary bladder and for prophylaxis of primary and recurrent stage Ta and/or T1 papillary tumors after transurethral resection. Adverse effects include hypersensitivity, shock, chills, fever, malaise, and immune complex disease.

**LEVAMISOLE.** Levamisole (ERGAMISOL) was synthesized originally as an anthelmintic but appears to “restore” depressed immune function of B lymphocytes, T lymphocytes, monocytes, and macrophages. Its only clinical indication was as adjuvant therapy with 5-fluorouracil after surgical resection in patients with Dukes’ stage C colon cancer. Levamisole is associated with risk for fatal agranulocytosis and was withdrawn from the U.S. market.

**RECOMBINANT CYTOKINES**

**INTERFERONS.** Although interferons (α, β, and γ,) initially were identified by their antiviral activity, these agents also have important immunomodulatory activities. The interferons bind to specific cell-surface receptors that initiate a series of intracellular events: induction of certain enzymes, inhibition of cell proliferation, and enhancement of immune activities, including increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes.

**Recombinant IFN-a-2b (INTRON A) is obtained from Escherichia coli by recombinant expression.** It is a member of a family of naturally occurring small proteins (15-27 KDa), produced and secreted by cells in response to viral infections and other inducers. IFN-c-2b is indicated in the treatment of myriad
tumors (e.g., hairy cell leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi sarcoma) and for infectious diseases, chronic hepatitis B, and condylomata acuminata. IFN-d-2b is supplied in combination with ribavirin (Rebetron) for treatment of chronic hepatitis C in patients with compensated liver function not treated previously with IFN-α-2b or who have relapsed after IFN-α-2b therapy. Flu-like symptoms are the most common adverse effects after IFN-α-2b administration. Adverse cardiovascular effects (e.g., hypotension, arrhythmias, cardiomyopathy, and myocardial infarction) and CNS effects (e.g., depression, confusion) are less frequent. All α interferons carry a black-box warning regarding development of pulmonary hypertension.

**IFN-γ-1b** (Actimmune) is a recombinant polypeptide that activates phagocytes and induces their generation of oxygen metabolites that are toxic to a number of microorganisms. It is indicated to reduce the frequency and severity of serious infections associated with chronic granulomatous disease and to delay the time to progression in severe malignant osteopetrosis. Adverse reactions include fever, headache, rash, fatigue, GI distress, anorexia, weight loss, myalgia, and depression.

**IFN-β-1a** (Avonex, Rebif), a 166–amino acid recombinant glycoprotein, and IFN-β-1b (Betaseron), a 165–amino acid recombinant protein, have antiviral and immunomodulatory properties. They are FDA-approved for the treatment of relapsing MS to reduce the frequency of clinical exacerbations (see below). The mechanism of their action in MS is unclear. Flu-like symptoms (e.g., fever, chills, myalgia) and injection-site reactions are common adverse effects.

**INTERLEUKIN-2.** Human recombinant IL-2 (aldesleukin, Proleukin; des-alanyl-1, serine-125 human IL-2) differs from native IL-2 in that it is not glycosylated, has no amino-terminal alanine, and has a serine substituted for the cysteine at amino acid 125. Aldesleukin activates cellular immunity, with lymphocytosis, eosinophilia, thrombocytopenia, and release of multiple cytokines (e.g., TNF, IL-1, IFN-γ). Aldesleukin is indicated for the treatment of adults with metastatic renal cell carcinoma and melanoma.

The potency of the preparation is represented in International Units in a lymphocyte proliferation assay such that 1.1 mg of recombinant IL-2 protein
equals 18 million IU. Administration of aldesleukin has been associated with serious cardiovascular toxicity resulting from capillary leak syndrome, which involves loss of vascular tone and leak of plasma proteins and fluid into the extravascular space. Hypotension, reduced organ perfusion, and death may occur. An increased risk of disseminated infection due to impaired neutrophil function also has been associated with aldesleukin treatment.

**IMMUNIZATION**

*Active immunization* involves stimulation with an antigen to develop immunological defenses against a future exposure. *Passive immunization* involves administration of pre-formed antibodies to an individual who is already exposed or is about to be exposed to an antigen.

**VACCINES.** Active immunization, vaccination, involves administration of an antigen as a whole, killed (inactivated) organism; attenuated (live) organism; or a specific protein or peptide constituent of an organism. Booster doses often are required, especially when killed organisms are used as the immunogen. In the U.S., vaccination has sharply curtailed or practically eliminated a variety of major infections, including diphtheria, measles, mumps, pertussis, rubella, tetanus, *Haemophilus influenzae* type b, and pneumococcus.

Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection from specific cancers or autoimmune diseases. Because T cells optimally are activated by peptides and co-stimulatory ligands that are present on antigen-presenting cells (APCs), one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen. Multiple studies have demonstrated the efficacy of DNA vaccines in small- and large-animal models of infectious diseases and cancer. Compared to peptide immunization, DNA immunization has the advantage of permitting generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly
disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest.

**IMMUNE GLOBULIN.** Passive immunization is indicated when an individual is deficient in antibodies because of a congenital or acquired immunodeficiency, when an individual with a high degree of risk is exposed to an agent and there is inadequate time for active immunization (e.g., measles, rabies, hepatitis B), or when a disease is already present but can be ameliorated by passive antibodies (e.g., botulism, diphtheria, tetanus). Passive immunization may be provided by several different products (**Table 35–2**).

Nonspecific immunoglobulins or highly specific immunoglobulins may be provided based on the indication. The protection provided usually lasts 1-3 months. Immune globulin is derived from pooled plasma of adults by an alcohol-fractionation procedure. It contains largely IgG (95%) and is indicated for antibody-deficiency disorders, exposure to infections such as hepatitis A and measles, and specific immunological diseases such as immune
thrombocytopenic purpura and Guillain-Barré syndrome. In contrast, specific immune globulins (“hyperimmune”) differ from other immune globulin preparations in that donors are selected for high titers of the desired antibodies. Specific immune globulin preparations are available for hepatitis B, rabies, tetanus, varicella-zoster, cytomegalovirus, botulism, and respiratory syncytial virus. Rho(D) immune globulin is a specific hyperimmune globulin for prophylaxis against hemolytic disease of the newborn due to Rh incompatibility between mother and fetus. All such plasma-derived products carry the theoretical risk of transmission of infectious disease.

**RHO(D) IMMUNE GLOBULIN.** The commercial forms of Rho(D) immune globulin (see Table 35–2) consist of IgG containing a high titer of antibodies against the Rh(D) antigen on the surface of red blood cells. All donors are carefully screened to reduce the risk of transmitting infectious diseases. Fractionation of the plasma is performed by precipitation with cold alcohol followed by passage through a viral clearance system. Rho(D) immune globulin binds Rho antigens, preventing sensitization. Rh-negative women may be sensitized to the “foreign” Rh antigen on red blood cells via the fetus at the time of birth, miscarriage, ectopic pregnancy, or any transplacental hemorrhage. If the women go on to have a primary immune response, they will make antibodies to Rh antigen that can cross the placenta and damage subsequent fetuses by lysing red blood cells. This syndrome, called hemolytic disease of the newborn, is life threatening but is largely preventable by Rho(D) immune globulin. Rho(D) immune globulin is indicated whenever fetal red blood cells are suspected to have entered the circulation of an Rh-negative mother unless the fetus is known to be Rh negative. The drug is given intramuscularly. The $t_{1/2}$ of circulating immunoglobulin is ~21-29 days. Systemic reactions are extremely rare; myalgia, lethargy, and anaphylactic shock have been reported.

**INTRAVENOUS IMMUNOGLOBULIN (IVIG).** Indications for the use of IVIG have expanded beyond replacement therapy for agammaglobulinemia and other immunodeficiencies to include a variety of bacterial and viral infections, and an array of autoimmune and inflammatory diseases as diverse as thrombocytopenic purpura, Kawasaki disease, and autoimmune skin, neuromuscular, and neurological diseases. The mechanism of action of IVIG in immune modulation remains largely unknown.
IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS

CLINICAL FEATURES AND PATHOLOGY. MS is a demyelinating inflammatory disease of the CNS white matter that displays a triad of pathogenic symptoms: mononuclear cell infiltration, demyelination, and scarring (gliosis). The peripheral nervous system is uninvolved. MS may be episodic or progressive, and occurs with prevalence increasing from late adolescence to 35 years of age and then declining. MS is roughly 3-fold more common in females than in males and occurs mainly in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS; despite many suggestions, associations with infectious agents have proven inconclusive. A stronger linkage is the genetic one: people of northern European ancestry have a higher susceptibility to MS, and studies in twins and siblings suggest a strong genetic component.

MS is a complex genetic disease in which multiple allelic variants lead to disease susceptibility. HLA-DR2 clearly is associated with risk of developing MS. There also is substantial evidence of an autoimmune component to MS: In MS patients, there are activated T cells that are reactive to different myelin antigens, including myelin basic protein (MBP). In addition, there is evidence for the presence of auto-antibodies to myelin oligodendrocyte glycoprotein (MOG) and to MBP that can be eluted from the CNS plaque tissue. These antibodies may act with pathogenic T cells to produce some of the cellular pathology of MS. The neurophysiological result is altered conduction (both positive and negative) in myelinated fibers within the CNS (cerebral white matter, brain stem, cerebellar tracts, optic nerves, spinal cord); some alterations appear to result from exposure of voltage-dependent K+ channels that normally are covered by myelin.

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathological processes. Thus, physicians refer to relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurological deterioration following a long period of relapsing-remitting disease), and primary progressive MS (~15% of patients,
wherein deterioration with relatively little inflammation is apparent at onset).

**PHARMACOTHERAPY FOR MS.** Table 35–3 summarizes current immunomodulatory therapies for MS. Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability. Nonspecific therapies focus on maintaining function and quality of life. For acute attacks, pulse glucocorticoids often are employed (typically, 1 g/day of methylprednisolone administered intravenously for 3-5 days). For relapsing-remitting attacks, immunomodulatory therapies are approved: β-1 interferons [IFN-β-1a, IFN-β-1b], and glatiramer acetate (COPAXONE).

Table 35–3

Pharmacotherapy of Multiple Sclerosis
Random polymers that contain amino acids commonly used as MHC anchors and T cell–receptor contact residues have been proposed as possible “universal APLs (altered peptide ligands).” **Glatiramer acetate** (GA), a random-sequence polypeptide consisting of 4 amino acids [alanine (A), lysine (K), glutamate (E), and tyrosine (Y)] with an average length of 40-100 amino acids, binds efficiently to MHC class II DR molecules, but does not bind MHC class II DQ or MHC class I molecules in vitro. In clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by ~30%. In vivo administration of GA induces highly cross-reactive CD4+ T cells that are immune deviated to secrete Th2 cytokines and prevents the appearance of new lesions detectable by magnetic resonance imaging. This represents one of

the first successful uses of an agent that ameliorates autoimmune disease by altering signals through the T cell–receptor complex.

For relapsing-remitting attacks and for secondary progressive MS, the alkylating agent cyclophosphamide and mitoxantrone (Novantrone, others) currently are used in patients refractory to other immunomodulators. These agents, primarily used for cancer chemotherapy, have significant toxicities (see Chapter 61). Mitoxantrone generally is tolerated only up to an accumulated dose of 100-140 mg/m$^2$. However, the FDA recommends that left ventricular ejection fraction (LVEF) be evaluated before initiating therapy, prior to each dose, and annually after patients have finished treatment to detect late-occurring cardiac toxicity.

The monoclonal antibody, natalizumab (Tysabri), directed against the adhesion molecule $\alpha_4$ integrin, antagonizes interactions with integrin heterodimers containing $\alpha_4$ integrin, such as $\alpha_4 \beta_1$ integrin that is expressed on the surface of activated lymphocytes and monocytes. An interaction of $\alpha_4 \beta_1$ integrin with vascular-cellular adhesion molecule (VCAM)-1 seems critical for T-cell trafficking from the periphery into the CNS; blocking this interaction would hypothetically inhibit disease exacerbations. Use of natalizumab has been associated with the development of progressive multifocal leukoencephalopathy, and availability is limited to a special distribution program (TOUCH) administered by the manufacturer. Monoclonal antibodies directed against the IL-2 receptor and against CD52 (alemtuzumab; Campath) are in phase III clinical trials.

Each of the agents mentioned has side effects and contraindications that may be limiting: infections (for glucocorticoids), hypersensitivity and pregnancy (for immunomodulators), and prior anthracycline/anthracenedione use, mediastinal irradiation, or cardiac disease (mitoxantrone). With all of these agents, the earlier they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes the more severe disability.
This chapter discusses the pharmacotherapy of obstructive airways disease, particularly bronchodilators, which act mainly by reversing airway smooth muscle contraction, and anti-inflammatory drugs, which suppress the inflammatory response in the airways. The chapter focuses on the pulmonary pharmacology of \( \beta_2 \) agonists and corticosteroids; their basic pharmacology is presented elsewhere (see Chapters 12 and 42). This chapter also discusses other drugs used to treat obstructive airway diseases, such as mucolytics and respiratory stimulants, and covers the drug therapy of cough, the most common respiratory symptom, as well as drugs used to treat pulmonary hypertension. Drugs used in the treatment of lung infections, including tuberculosis (see Chapter 56), are covered elsewhere.

MECHANISMS OF ASTHMA

Asthma is a chronic inflammatory disease of the airways that is characterized by activation of mast cells (generally present in increased numbers), infiltration of eosinophils, and T helper 2 (\( TH2 \)) lymphocytes (Figure 36–1). Mast cell activation by allergens and physical stimuli releases bronchoconstrictor mediators, such as histamine, leukotriene D\(_4\), and PGD\(_2\), which cause bronchoconstriction, microvascular leakage, and plasma exudation (see Chapters 32 and 33). Many of the symptoms of asthma are due to airway smooth muscle contraction; thus, bronchodilators are important as symptom relievers. Whether airway smooth muscle is intrinsically abnormal in asthma is not clear, but increased contractility of airway smooth muscle may contribute to airway hyperresponsiveness, the physiological hallmark of asthma. The mechanism of chronic inflammation in asthma is still not well
understood. It may initially be driven by allergen exposure, but it appears to become autonomous so that asthma is essentially incurable. The inflammation may be orchestrated by dendritic cells that regulate T\textsubscript{H}2 cells that drive eosinophilic inflammation and IgE formation by B lymphocytes. Airway epithelium plays an important role through the release of myriad inflammatory mediators and through the release of growth factors in an attempt to repair the damage caused by inflammation.

**Figure 36–1 Cellular mechanisms of asthma.** Myriad inflammatory cells are recruited and activated in the airways, where they release multiple inflammatory mediators, which can also arise from structural cells. These mediators lead to bronchoconstriction, plasma exudation and edema, vasodilation, mucus hypersecretion, and activation of sensory nerves. Chronic inflammation leads to structural changes, including subepithelial fibrosis (basement membrane thickening), airway smooth muscle hypertrophy and hyperplasia, angiogenesis, and hyperplasia of mucus-secreting cells.
Chronic inflammation may lead to structural changes in the airways, including an increase in the number and size of airway smooth muscle cells, blood vessels, and mucus-secreting cells. A characteristic histological feature of asthma is collagen deposition (fibrosis) below the basement membrane of the airway epithelium (see Figure 36–1).

**MECHANISMS OF COPD**

COPD involves inflammation of the respiratory tract with a pattern that differs from that of asthma. In COPD, there is a predominance of neutrophils, macrophages, and cytotoxic T-lymphocytes (Tcl cells). The inflammation predominantly affects small airways, resulting in progressive small airway narrowing and fibrosis (chronic obstructive bronchiolitis) and destruction of the lung parenchyma with destruction of the alveolar walls (emphysema) (Figure 36–2). These pathological changes result in airway closure on expiration, leading to air trapping and hyperinflation, particularly on exercise. This accounts for shortness of breath on exertion and exercise limitation that are characteristic symptoms of COPD.
Cigarette smoke and other irritants activate epithelial cells and macrophages in the lung to release mediators that attract circulating inflammatory cells, including monocytes (which differentiate to macrophages within the lung), neutrophils, and T lymphocytes (T$_H$1 and T$_C$1 cells). Fibrogenic factors released from epithelial cells and macrophages lead to fibrosis of small airways. Release of proteases results in alveolar wall destruction (emphysema) and mucus hypersecretion (chronic bronchitis).

Bronchodilators reduce air trapping by dilating peripheral airways and are the mainstay of treatment in COPD. In contrast to asthma, the airflow obstruction of
COPD tends to be progressive. A discrete pattern of inflammatory mediators and cytokines mediates the inflammation in the peripheral lung of COPD patients. In contrast to asthma, the inflammation of COPD is largely corticosteroid-resistant, and there are currently no effective anti-inflammatory treatments. Many patients with COPD have systemic manifestations (skeletal muscle wasting, weight loss, depression, osteoporosis, anemia) and comorbid diseases (ischemic heart disease, hypertension, congestive heart failure, diabetes). Whether these are due to spillover of inflammatory mediators from the lung or due to common causal mechanisms (such as smoking) is not yet clear, but it may be important to treat the systemic components in the overall management of COPD.

**ROUTES OF DRUG DELIVERY TO THE LUNGS**

**INHALED ROUTE**

Inhalation (Figure 36–3) is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and COPD. The major advantage of inhalation is the delivery of drug to the airways in doses that are effective with a much lower risk of systemic side effects. This is particularly important with the use of inhaled corticosteroids (ICS), which largely avoids systemic side effects. In addition, inhaled bronchodilators have a more rapid onset of action than when taken orally.
**Figure 36–3** Deposition of inhaled drugs (e.g., corticosteroids, $\beta_2$ agonists). Inhalation therapy deposits drugs directly, but not exclusively, in the lungs. Distribution between lungs and oropharynx depends mostly on the particle size and the efficiency of the delivery method. Most material will be swallowed and absorbed, entering systemic circulation after undergoing the first-pass effect in the liver. Some drug will also be absorbed into the systemic circulation from the lungs. Use of a large-volume spacer will reduce the amount of drug deposited on oropharynx, thereby reducing amount swallowed and absorbed from GI tract, thus limiting systemic effects. MDI, metered-dose inhaler.

**PARTICLE SIZE.** The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2-5 μm mass median aerodynamic diameter (MMAD). Larger particles settle out in the upper airways, whereas smaller particles remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma. This involves delivering drug particles of ~1 μm MMAD, which is now possible using drugs formulated in hydrofluoroalkane (HFA) propellant.

**PHARMACOKINETICS.** Of the total drug delivered, only 10-20% enters the lower airways with a conventional pressurized metered-dose inhaler. Drugs are absorbed from the airway lumen and have direct effects on target cells of the airway. Drugs may also be absorbed into the bronchial circulation and then distributed to more peripheral airways. Drugs with higher molecular weights tend to be retained to a greater extent in the airways. Nevertheless, several drugs have greater therapeutic efficacy when given by the inhaled route. More extensive pulmonary distribution of a drug with a smaller MMAD increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation resulting in more systemic side effects.
DELIVERY DEVICES

Pressurized Metered-Dose Inhalers (pMDIs). Drugs are propelled from a canister with the aid of a propellant, previously with a chlorofluorocarbon (Freon) but now replaced by an HFA that is “ozone friendly.” These devices are convenient, portable, and typically deliver 100-400 doses of drug.

Spacer Chambers. Large-volume spacer devices between the pMDI and the patient reduce the velocity of particles entering the upper airways and the size of the particles by allowing evaporation of liquid propellant. This reduces the amount of drug that impinges on the oropharynx and gets swallowed, and increases the proportion of drug inhaled into the lower airways. Application of spacer chambers is useful in the reduction of the oropharyngeal deposition of ICS and the consequent reduction in the local and systemic side effects of these drugs. Spacer devices are also useful in delivering inhaled drugs to small children who are not able to use a pMDI.

Dry Powder Inhalers. Drugs may also be delivered as a dry powder using devices that scatter a fine powder dispersed by air turbulence on inhalation. Children <7 years of age find it difficult to use a dry powder inhaler (DPI). DPIs have been developed to deliver peptides and proteins, such as insulin (e.g., Exubera, Afresa), systemically.

Nebulizers. Two types of nebulizer are available. Jet nebulizers are driven by a stream of gas (air or oxygen), whereas ultrasonic nebulizers use a rapidly vibrating piezo-electric crystal and thus do not require a source of compressed gas. The nebulized drug is inspired during tidal breathing, and it is possible to deliver much higher doses of drug compared with pMDI. Nebulizers are useful in treating acute exacerbations of asthma and COPD, for delivering inhaled drugs to infants and small children, and for giving drugs such as antibiotics when relatively high doses must be delivered.

ORAL ROUTE

Drugs for treatment of pulmonary diseases may also be given orally. The oral dose is much higher than the inhaled dose required to achieve the same effect (typically by a ratio of ~20:1), so that systemic side
effects are more common. *When there is a choice of inhaled or oral route for a drug (e.g., \( \beta_2 \) agonist or corticosteroid), the inhaled route is always preferable, and the oral route should be reserved for the few patients unable to use inhalers (e.g., small children, patients with physical problems such as severe arthritis of the hands)*. Theophylline is ineffective by the inhaled route; it must be given systemically. Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases).

**PARENTERAL ROUTE**

The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the GI tract. Side effects are generally frequent due to the high plasma concentrations.

**BRONCHODILATORS**

Bronchodilator drugs relax constricted airway smooth muscle in vitro and cause immediate reversal of airway obstruction in asthma in vivo. They also prevent bronchoconstriction (and thereby provide bronchoprotection). Three main classes of bronchodilator are in current clinical use:

- \( \beta_2 \) Adrenergic agonists (sympathomimetics)
- Theophylline (a methylxanthine)
- Anticholinergic agents (muscarinic receptor antagonists)

Drugs such as cromolyn sodium, which prevent bronchoconstriction, have no direct bronchodilator action and are ineffective once bronchoconstriction has occurred. Anti-leukotrienes (leukotriene receptor antagonists and 5-\( \text{L} \)-lipoxygenase inhibitors) have a small bronchodilator effect in some asthmatic patients and appear to prevent bronchoconstriction. Corticosteroids, although gradually improving
airway obstruction, have no direct effect on contraction of airway smooth muscle and are not therefore considered to be bronchodilators.

**β₂ ADRENERGIC AGONISTS**

Inhaled β₂ agonists are the bronchodilator treatment of choice in asthma because they are the most effective bronchodilators and have minimal side effects when used correctly. The basic pharmacology of these agents (albuterol, terbutaline, salmeterol, formoterol, indacaterol, and related compounds) is presented in Chapters 8 and 12.

**MODE OF ACTION**

Agonist stimulation of β₂ receptors in airway smooth muscle results in the activation of the Gₛ-adenylyl cyclase-cAMP-PKA pathway and consequent phosphorylative events leading to bronchial smooth muscle relaxation (Figure 36–4), effectively reversing the Ca²⁺-stimulated events that initiate contraction.

![Figure 36–4 Molecular actions of β₂ agonists to induce relaxation of airway](image-url)
smooth muscle cells. A rise in \([\text{Ca}^{2+}]_i\) initiates contraction by activating myosin light-chain kinase (MLCK), thereby enhancing the level of phosphorylation of myosin light chains and increasing the contractile interaction of actin and myosin. Stimulation of \(\beta_2\) receptors activates cyclic AMP-PKA pathway and reverses the contractile process by reducing \([\text{Ca}^{2+}]_i\), reducing MLCK activation, and promoting dephosphorylation of light chains. PKA phosphorylates a variety of target substrates, resulting in: opening of \(\text{Ca}^{2+}\)-activated \(\text{K}^+\) channels (\(\text{K}_{\text{Ca}}\)) [which facilitates hyperpolarization], decreased phosphoinositide (PI) hydrolysis, increased \(\text{Na}^+/{\text{Ca}^{2+}}\) exchange, increased \(\text{Na}^+\), \(\text{Ca}^{2+}\)-ATPase activity, decreased MLCK activity, and increased MLC phosphatase activity. \(\beta_2\) Receptors may also couple to \(\text{K}_{\text{Ca}}\) via \(\text{G}_s\). PDE, cyclic nucleotide phosphodiesterase.

\(\beta_2\) agonists may cause bronchodilation in vivo not only via a direct action on airways smooth muscle, but also indirectly by inhibiting the release of bronchoconstrictor mediators from inflammatory cells and of bronchoconstrictor neurotransmitters from airway nerves. These mechanisms include:

- Prevention of mediator release from isolated human lung mast cells (via \(\beta_2\) receptors)
- Prevention of microvascular leakage and thus the development of bronchial mucosal edema after exposure to mediators, such as histamine and leukotriene \(D_4\)
- Increase in mucus secretion from submucosal glands and ion transport across airway epithelium (may enhance mucociliary clearance, reversing defective clearance found in asthma)
- Reduction in neurotransmission in human airway cholinergic nerves by an action at presynaptic \(\beta_2\) receptors to inhibit acetylcholine release

\(\beta_2\) agonists do not appear to have a significant inhibitory effect on the chronic inflammation of asthmatic airways, which is suppressed by corticosteroids. This may be related to the fact that effects of \(\beta_2\) agonists on macrophages, eosinophils, and lymphocytes are rapidly desensitized.
CLINICAL USE

SHORT-ACTING $\beta_2$ AGONISTS. Inhaled short-acting $\beta_2$ agonists are the most widely used and effective bronchodilators in the treatment of asthma due to their functional antagonism of bronchoconstriction. These agents also are effective in protecting against various challenges, such as exercise, cold air, and allergens. Inhalation is preferable to the oral administration because inhalation may be more effective and systemic side effects are less. *Short-acting inhaled $\beta_2$ agonists, such as albuterol, should be used “as required” by symptoms and not on a regular basis in the treatment of mild asthma; increased use indicates the need for more anti-inflammatory therapy.*

Slow-release preparations (e.g., slow-release albuterol and bambuterol) may be indicated in nocturnal asthma; however, these agents have an increased risk of side effects. All short-acting $\beta_2$ agonists currently available are usable by inhalation and orally, have a similar duration of action (~3-4 h; less in severe asthma), and similar side effects. Drugs in clinical use include *albuterol (salbutamol), levalbuterol metaproterenol, terbutaline* (in the U.S.), *fenoterol, tulobuterol, rimiterol,* and *pirbuterol* (in other countries).

LONG-ACTING INHALED $\beta_2$ AGONISTS. The long-acting inhaled $\beta_2$ agonists (LABA) *salmeterol, formoterol,* and *arformoterol* have a bronchodilator action of $>12$ h and protect against bronchoconstriction for a similar period. They improve asthma control (when given twice daily) compared with regular treatment with short-acting $\beta_2$ agonists (4-6 times daily). *Indacaterol* is a once-daily “ultra-LABA” approved for treatment of COPD but not asthma; its duration of action exceeds those of salmeterol and formoterol.

In COPD, LABA are effective bronchodilators that may be used alone or in combination with anticholinergics or ICS. LABA improve symptoms and exercise tolerance by reducing both air trapping and exacerbations. In asthma patients, LABA should never be used alone because they do not treat the
underlying chronic inflammation; rather, LABA should always be used in combination with ICS (preferably in a fixed-dose combination inhaler). LABA are an effective add-on therapy to ICS and are more effective than increasing the dose of ICS when asthma is not controlled at low doses. Tolerance to the bronchodilator effect of formoterol and the bronchoprotective effects of formoterol and salmeterol has been demonstrated but is of doubtful clinical significance. No significant clinical differences between salmeterol and formoterol have been found in the treatment of patients with severe asthma.

**COMBINATION INHALERS.** Combination inhalers that contain a LABA and a corticosteroid (e.g., fluticasone/salmeterol [ADVAIR], budesonide/formoterol [SYMBICORT]) are now widely used in the treatment of asthma and COPD. Combining LABA with a corticosteroid offers complementary synergistic actions. The combination inhaler is more convenient for patients, simplifies therapy, and improves compliance. These combination inhalers are also more effective in COPD patients than LABA and ICS alone.

**SIDE EFFECTS.** Unwanted effects are dose related and due to stimulation of extrapulmonary β receptors (Table 36–1 and Chapter 12). Side effects are not common with inhaled therapy but quite common with oral or intravenous administration, usually only after large systemic doses. Short-acting inhaled β₂ agonists should only be used on demand for symptom control, and with an ICS if they are required more than 3 times weekly. LABA should only be used when ICS are also prescribed. All LABA approved in the U.S. carry a black box warning cautioning against overuse. There are less safety concerns with LABA use in COPD.

METHYLXANTHINES

The methylxanthine, theophylline, is still widely used in developing countries because it is inexpensive. However, the frequency of side effects and the relative low efficacy of theophylline have led to reduced use because inhaled $\beta_2$ agonists are far more effective as bronchodilators and ICS have a greater anti-inflammatory effect. In patients with severe asthma and COPD, theophylline remains a very useful drug.

MECHANISM OF ACTION. The mechanisms of action of theophylline are still uncertain. In addition to its bronchodilator action, theophylline has many nonbronchodilator effects that may be relevant to its effects in asthma and COPD (Figure 36–5). Several molecular mechanisms of action have been proposed:
Figure 36–5 Theophylline affects multiple cell types in the airway.

- **Inhibition of cyclic nucleotide phosphodiesterases.** Theophylline is a nonselective PDE inhibitor. PDE inhibition and the concomitant elevation of cellular cyclic AMP and cyclic GMP likely account for the bronchodilator action of theophylline (see Figure 36–4). The PDE isoenzymes recognized in smooth muscle relaxation include PDE3, PDE4, and PDE5.

- **Adenosine receptor antagonism.** Theophylline antagonizes adenosine receptors at therapeutic concentrations. Adenosine causes bronchoconstriction in airways from asthmatic patients by releasing histamine and leukotrienes. Antagonism of A₁ receptors may be responsible for serious side effects, including cardiac arrhythmias and seizures.

- **Interleukin-10 release.** IL-10 has a broad spectrum of anti-inflammatory effects, and there is evidence that its secretion is reduced in asthma. IL-10 release is increased by theophylline, and this effect may be mediated via inhibition of PDE activities.

- **Effects on gene transcription.** Theophylline prevents the translocation of the pro-inflammatory transcription factor NF-kB into the nucleus, potentially reducing the expression of inflammatory genes in asthma and COPD. However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.
• **Effects on apoptosis.** Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in asthma (eosinophils) and COPD (neutrophils). Theophylline promotes apoptosis in eosinophils and neutrophils in vitro. This effect may be mediated by antagonism of adenosine A<sub>2A</sub> receptors. Theophylline also induces apoptosis in T lymphocytes via PDE inhibition.

• **Histone deacetylase activation.** Recruitment of histone deacetylase-2 (HDAC2) by glucocorticoid receptors switches off inflammatory genes. Therapeutic concentrations of theophylline activate HDAC, thereby enhancing the anti-inflammatory effects of corticosteroids. This mechanism appears to be mediated by inhibition of PI3-kinase-δ, which is activated by oxidative stress.

**NONBRONCHODILATOR EFFECTS.** There is increasing evidence that theophylline has anti-inflammatory effects in asthma. For example, chronic oral treatment with theophylline inhibits the late response to inhaled allergen and reduces infiltration of eosinophils and CD4<sup>+</sup> lymphocytes into the airways after allergen challenge. In patients with COPD, theophylline reduces the total number and proportion of neutrophils in induced sputum, the concentration of IL-8, and neutrophil chemotactic responses. Theophylline withdrawal in COPD patients results in worsening of disease. In vitro theophylline is able to increase responsiveness to corticosteroids and to reverse corticosteroid resistance in cells from COPD subjects.

**PHARMACOKINETICS AND METABOLISM.** Theophylline has anti-asthma effects other than bronchodilation below 10 mg/L, so the therapeutic range is now taken as 5-15 mg/L. The dose of theophylline required to give these therapeutic concentrations varies among subjects, largely because of differences in clearance of the drug. In addition, there may be differences in bronchodilator response to theophylline; furthermore, with acute bronchoconstriction, higher concentrations may be required to produce bronchodilation. Theophylline is rapidly and completely absorbed, but there are large interindividual variations in clearance, due to differences in hepatic metabolism. Theophylline is metabolized in the liver, mainly by CYP1A2; myriad factors influence metabolism and clearance of theophylline (*Table 36–2*). Because of these variations in clearance,
individualization of theophylline dosage is required and plasma concentrations should be measured 4 h after the last dose with slow-release preparations when steady state has been achieved.

PREPARATIONS AND ROUTES OF ADMINISTRATION. Intravenous aminophylline (the ethylenediamine salt of theophylline, with better solubility at neutral pH) is used in the treatment of acute severe asthma, at a recommended dose of 6 mg/kg over 20-30 min, followed by a maintenance dose of 0.5 mg/kg/h. If the patient is already taking theophylline, or has decreased clearance, these doses should be halved and the plasma level checked more frequently. Oral immediate-release theophylline tablets or elixir, which are rapidly absorbed, give wide fluctuations in plasma levels, and are not recommended. Sustained-release preparations provide steady plasma concentrations over a 12- to 24-h period. Both slow-release aminophylline and theophylline are equally effective. For continuous treatment twice daily therapy (~8 mg/kg twice daily) is needed.

CLINICAL USE. In patients with acute asthma, intravenous aminophylline is less effective than nebulized β₂ agonists and should therefore be reserved for those patients who fail to respond to, or are intolerant of, β agonists. Addition of
low-dose theophylline to either a high or low dose of ICS in patients who are not adequately controlled provides better symptom control and lung function than doubling the dose of inhaled steroid. Although theophylline is less effective than a β₂ agonist and corticosteroids, a minority of asthmatic patients appears to derive unexpected benefit; even patients on oral steroids may show a deterioration in lung function when theophylline is withdrawn. Although LABA are more effective as an add-on therapy, theophylline is considerably less expensive when the costs of medication are limiting.

Theophylline is still used as a bronchodilator in COPD, but inhaled anticholinergics and β₂ agonists are preferred. Theophylline tends to be added to these inhaled bronchodilators in more severe patients and has been shown to give additional clinical improvement when added to a long-acting β₂ agonist.

**SIDE EFFECTS.** Unwanted effects of theophylline are usually related to plasma concentration and tend to occur at $C_p > 15$ mg/L. The most common side effects are headache, nausea, and vomiting, abdominal discomfort, and restlessness (Table 36–3). There may also be increased acid secretion and diuresis. Theophylline may lead to behavioral disturbance and learning difficulties in schoolchildren. At high concentrations, cardiac arrhythmias and seizures may occur. Using low doses of theophylline to achieve plasma concentrations of 5-10 mg/L largely avoids side effects and drug interactions.

**MUSCARINIC CHOLINERGIC ANTAGONISTS**
MODE OF ACTION

As competitive antagonists of endogenous ACh at muscarinic receptors, these agents inhibit the direct constrictor effect on bronchial smooth muscle mediated via the M₃-Gᵦ₉-PLC-IP₃-Ca²⁺ pathway (see Chapters 3 and 9). Their efficacy stems from the role of the parasympathetic nervous system in regulating bronchomotor tone. The effects of ACh on the respiratory system include not only bronchoconstriction but also increased tracheobronchial secretion and stimulation of the chemoreceptors of the carotid and aortic bodies. However, the myriad inflammatory mediators involved in the pathogenesis of asthma and COPD may also induce components of muscarinic responsiveness, such as Goq and rho, and contribute to hyperresponsiveness of the airway. Thus, the contractility of bronchial smooth muscle and antagonism of muscarinic responsiveness could be moving targets in asthma and COPD.

CLINICAL USE. In asthmatic patients, anticholinergic drugs are less effective as bronchodilators than β₂ agonists and offer less efficient protection against bronchial challenges. Anticholinergics are currently used as an additional bronchodilator in asthmatic patients not controlled on an LABA. In the acute and chronic treatment of asthma, anticholinergic drugs may have an additive effect with β₂ agonists and should be considered when control of asthma is not adequate with nebulized β₂ agonists. In COPD, anticholinergic drugs may be as effective as or even superior to β₂ agonists. Their relatively greater effect in COPD than in asthma may be explained by an inhibitory effect on vagal tone (Figure 36–6).
Anticholinergic drugs inhibit vagally mediated airway tone, thereby producing bronchodilation. This effect is small in normal airways but is greater in airways of patients with chronic obstructive pulmonary disease (COPD), which are structurally narrowed and have higher resistance to airflow because airway resistance is inversely related to the fourth power of the radius \( r \). ACh, acetylcholine.

**Figure 36–6** Anticholinergic drugs inhibit vagally mediated airway tone, thereby producing bronchodilation. This effect is small in normal airways but is greater in airways of patients with chronic obstructive pulmonary disease (COPD), which are structurally narrowed and have higher resistance to airflow because airway resistance is inversely related to the fourth power of the radius \( r \). ACh, acetylcholine.

**THERAPEUTIC CHOICES.** *Ipratropium bromide* (Atrovent, others) is available as a pMDI and nebulized preparation. The onset of bronchodilation is relatively slow and is usually maximal 30-60 min after inhalation, but may persist for 6-8 h. It is usually given by MDI 3 to 4 times daily on a regular basis, rather than intermittently for symptom relief, in view of its slow onset of action. *Oxitropium bromide* (not available in the U.S.) is a quaternary anticholinergic bronchodilator that is similar to ipratropium bromide. It is available in higher doses by inhalation and may therefore have a more prolonged effect.
Combination inhalers of an anticholinergic and \(\beta_2\) agonist, such as ipratropium/albuterol (COMBIVENT, DUONEB, others), are popular, particularly among patients with COPD. The additive effects of these 2 drugs may provide an advantage over increasing the dose of \(\beta_2\) agonist in patients who have side effects.

Tiotropium bromide is a long-acting anticholinergic drug that is suitable for once-daily dosing as a DPI (SPIRIVA) or via a soft mist mini-nebulizer device (not available in the U.S.). Tiotropium binds to all muscarinic receptor subtypes but dissociates very slowly from \(M_3\) and \(M_1\) receptors, giving it a degree of kinetic receptor selectivity for these receptors compared with \(M_2\) receptors, from which it dissociates more rapidly. Thus, compared with ipratropium, tiotropium is less likely to antagonize \(M_2\)-mediated inhibition of ACh release. It is an effective bronchodilator in patients with COPD and is more effective than ipratropium 4 times daily without any loss of efficacy over a 1-year treatment period. Over a 4-year period, tiotropium improves lung function and health status and reduces exacerbations and all-cause mortality, although there is no effect on disease progression. As a result, tiotropium is becoming the bronchodilator of choice for COPD patients.

Aclidinium bromide (TUDORZA Pressair) is a long-acting, anticholinergic inhalation powder approved for long-term maintenance treatment of COPD.

ADVERSE EFFECTS. Systemic side effects after ipratropium bromide and tiotropium bromide are uncommon because there is little systemic absorption. A significant unwanted effect is the unpleasant bitter taste of inhaled ipratropium, which may reduce compliance. Nebulized ipratropium bromide may precipitate glaucoma in elderly patients due to a direct effect of the nebulized drug on the eye. This may be prevented by nebulization with a mouthpiece rather than a face mask. Occasionally, bronchoconstriction may occur with ipratropium bromide given by MDI. Tiotropium causes dryness of the mouth in 10-15% of patients, but this usually disappears during continued therapy. Urinary retention is occasionally seen in elderly patients.

CORTICOSTEROIDS
The introduction of ICS, has revolutionized the treatment of chronic
asthma. Because asthma is a chronic inflammatory disease, ICS are considered as first-line therapy in all but the mildest of patients. In marked contrast, ICS are much less effective in COPD and should only be used in patients with severe disease who have frequent exacerbations. Oral corticosteroids remain the mainstay of treatment of several other pulmonary diseases, such as sarcoidosis, interstitial lung diseases, and pulmonary eosinophilic syndromes (see Chapter 42).

**MECHANISM OF ACTION.** Probably the most important action of ICS in suppressing asthmatic inflammation is the inhibition of expression of multiple inflammatory genes in airway epithelial cells. Corticosteroids reverse the activating effect of pro-inflammatory transcription factors on histone acetylation by recruiting HDAC2 to inflammatory genes that have been activated through acetylation of associated histones (see molecular details in Figure 36–7). Steroids have inhibitory effects on many inflammatory and structural cells that are activated in asthma and prevent the recruitment of inflammatory cells into the airways (Figure 36–8). Steroids potently inhibit the formation of cytokines (e.g., IL-1, IL-3, IL-4, IL-5, IL-9, IL-13, TNF-α, and granulocyte-macrophage colony-stimulating factor, GM-CSF) that are secreted in asthma by T-lymphocytes, macrophages, and mast cells.
Figure 36–7 Mechanism of anti-inflammatory action of corticosteroids in asthma. Inflammatory stimuli activate the NF-kB pathway, leading to increased histone acetyltransferase (HAT) activity, resulting in acetylation of core histones and increased expression of genes encoding multiple inflammatory proteins. Corticosteroids, acting via cytosolic glucocorticoid receptors (GR), antagonize HAT activity in two ways: directly and, more importantly, by recruiting histone deacetylase-2 (HDAC2), which reverses histone acetylation, leading to the suppression of activated inflammatory genes. CBP, CREB binding protein.
Corticosteroids have no direct effect on contractile responses of airway smooth muscle; improvement in lung function after ICS is presumably due to an effect on the chronic airway inflammation and airway hyperresponsiveness. A single dose of ICS has no effect on the early response to allergen (reflecting their lack of effect on mast cell mediator release) but inhibits the late response (which may be due to an effect on macrophages, eosinophils, and airway wall edema) and also inhibits the increase in airway hyperresponsiveness. Corticosteroids suppress inflammation in the airways but do not cure the underlying disease. When steroids are withdrawn, there is a recurrence of the same degree of airway hyperresponsiveness, although in patients with mild asthma it may take several months to return.

**Figure 36–8** Effect of corticosteroids on inflammatory and structural cells in the airways.

**RECI PROCAL SYNER GISTIC EFFECTS OF β₂AGONISTS AND CORTICOSTEROIDS.** Steroids potentiate the effects of β agonists on
bronchial smooth muscle and prevent and reverse β receptor desensitization in airways. At a molecular level, corticosteroids increase the transcription of the β₂ receptor gene in human lung in vitro and in the respiratory mucosa in vivo and increase the stability of its messenger RNA. They also prevent or reverse uncoupling of β₂ receptors from Gₛ. In animal systems, corticosteroids prevent downregulation of β₂ receptors. β₂ Agonists also increase the association of liganded glucocorticoid receptors (GR) with DNA, an effect demonstrated in sputum macrophages of asthmatic patients after an ICS and inhaled LABA, suggesting that β₂ agonists and corticosteroids enhance each other’s beneficial effects in asthma therapy.

PHARMACOKINETICS. The pharmacokinetics of oral corticosteroids are described in Chapter 42. The pharmacokinetics of ICS are important in relation to systemic effects. The fraction of steroid that is inhaled into the lungs acts locally on the airway mucosa but may be absorbed from the airway and alveolar surface and reaches the systemic circulation. Furthermore, the fraction of inhaled steroid that is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver (first-pass metabolism) before reaching the systemic circulation (see Figure 36–3). The use of a spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of ICS. Beclomethasone dipropionate and ciclesonide are prodrugs that release the active corticosteroid after the ester group is cleaved by esterases in the lung. Ciclesonide is available as an MDI (ALVESCO) for asthma and as a nasal spray for allergic rhinitis (OMNARIS). Budesonide and fluticasone propionate have a greater first-pass metabolism than beclomethasone dipropionate and are therefore less likely to produce systemic effects at high inhaled doses.

ROUTES OF ADMINISTRATION AND DOSING

INHALED CORTICOSTEROIDS IN ASTHMA. Inhaled corticosteroids are recommended as first-line therapy for all patients with persistent asthma. They should be started in any patient who needs to use a β₂ agonist inhaler for symptom control more than twice weekly.

Most of the benefit may be obtained from doses <400 <g beclomethasone
dipropionate or equivalent. However, some patients (with relative corticosteroid resistance) may benefit from higher doses (up to 2000 <g/day). For most patients, ICS should be used twice daily, a regimen that improves compliance once control of asthma has been achieved (which may require 4-times daily dosing initially or a course of oral steroids if symptoms are severe). Administration once daily of some steroids (e.g., budesonide, mometasone, and ciclesonide) is effective when doses ≤400 <g are needed. If a dose >800 <g daily via pMDI is used, a spacer device should be employed to reduce the risk of oropharyngeal side effects. ICS may be used in children in the same way as in adults.

INHALED CORTICOSTEROIDS IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Patients with COPD occasionally respond to steroids, and these patients are likely to have concomitant asthma. Corticosteroids do not appear to have any significant anti-inflammatory effect in COPD; there appears to be an active resistance mechanism, which may be explained by impaired activity of HDAC2 as a result of oxidative stress. Patients with cystic fibrosis, which involves inflammation of the airways, are also resistant to high doses of ICS.

SYSTEMIC STEROIDS. Intravenous steroids are indicated in acute asthma if lung function is <30% predicted and in patients who show no significant improvement with nebulized β₂ agonist. Hydrocortisone is the steroid of choice because it has the most rapid onset (5-6 h after administration), compared with 8 h with prednisolone.

It is common to give hydrocortisone 4 mg/kg initially, followed by a maintenance dose of 3 mg/kg every 6 h. Oral prednisolone (40-60 mg) has a similar effect to intravenous hydrocortisone. Prednisolone and prednisone are the most commonly used oral steroids. The usual maintenance dose is ~10-15 mg/day. Oral steroids are usually given as a single dose in the morning because this coincides with the normal diurnal increase in plasma cortisol and produces less adrenal suppression than if given in divided doses or at night.
**Adverse Effects.** Corticosteroids inhibit ACTH and cortisol secretion by a negative feedback effect on the pituitary gland (see Chapter 42). Hypothalamic-pituitary-adrenal (HPA) axis suppression depends on dose and usually only occurs with doses of prednisone >7.5-10 mg/day. Significant suppression after short courses of corticosteroid therapy is not usually a problem. *Steroid doses after prolonged oral therapy must be reduced slowly.* Symptoms of “steroid withdrawal syndrome” include lassitude, musculoskeletal pains, and, occasionally, fever. HPA suppression with inhaled steroids is usually seen only when the daily inhaled dose exceeds 2000 <g beclomethasone dipropionate or its equivalent daily.

Side effects of long-term oral corticosteroid therapy include fluid retention, increased appetite, weight gain, osteoporosis, capillary fragility, hypertension, peptic ulceration, diabetes, cataracts, and psychosis. Their frequency tends to increase with age. Very occasionally adverse reactions (such as anaphylaxis) to intravenous hydrocortisone have been described, particularly in aspirin-sensitive asthmatic patients.

ICS may have *local side effects* due to the deposition of inhaled steroid in the oropharynx. The most common problem is hoarseness and weakness of the voice (dysphonia) due to atrophy of the vocal cords following laryngeal deposition of steroid; it may occur in up to 40% of patients and is noticed particularly by patients who need to use their voices during their work (lecturers, teachers, and singers). Throat irritation and coughing after inhalation are common with MDI and appear to be due to additives since these problems are not usually seen if the patient switches to a DPI. Oropharyngeal candidiasis occurs in ~5% of patients. Growing evidence suggests that high doses of ICS increase the risk of pneumonia in patients with COPD using high doses of fluticasone propionate. The incidence of *systemic side effects* after ICS is an important consideration, particularly in children (Table 36–4). Adrenal suppression can occur with inhaled doses >1500-2000 <g/day, possibly less. It is important to reduce the likelihood of systemic effects by using the lowest dose of inhaled steroid needed to control the asthma, and by use of a large-volume spacer to reduce oropharyngeal deposition.

**Therapeutic Choices.** Numerous ICS are now available including beclomethasone dipropionate (QVAR), triamcinolone, flunisolide (AEROBID), budesonide (PULMICORT, others), fluticasone hemihydrate (AEROSPAN), fluticasone propionate (FLOVENT), mometasone furoate (ASMANEX), and ciclesonide (ALVESCO). All are equally effective as anti-asthma drugs, but there are differences in their pharmacokinetics: Budesonide, fluticasone, mometasone, and ciclesonide have a lower oral bioavailability than beclomethasone dipropionate because they are subject to greater first-pass hepatic metabolism; this results in reduced systemic absorption and thus reduced adverse effects. Ciclesonide is another choice; it is a prodrug that is converted to the active metabolite by esterases in the lung, giving it a low oral bioavailability and a high therapeutic index.

**CROMONES**

*Cromolyn* sodium (sodium cromoglycate) is a derivative of khellin, an Egyptian herbal remedy. A structurally related drug, *nedocromil* sodium, was subsequently developed. The use of cromolyn has sharply declined with the widespread use of the more effective ICS.

**MEDIATOR ANTAGONISTS**

Both H<sub>1</sub> antihistamines and antileukotrienes have been applied to airway disease, but their added benefit over β<sub>2</sub> agonists and corticosteroids is slight.

**ANTIHISTAMINES.** Histamine mimics many of the features of asthma and is released from mast cells in acute asthmatic responses, suggesting that antihistamines may be useful in asthma therapy. There is little evidence that
histamine H₁ receptor antagonists provide any useful clinical benefit, as demonstrated by a meta-analysis. Newer antihistamines, including cetirizine and azelastine, have some beneficial effects, but this may be unrelated to H₁ receptor antagonism.

**ANTILEUKOTRIENES.** There is considerable evidence that cysteinyl-leukotrienes (LTs) are produced in asthma and that they have potent effects on airway function, inducing bronchoconstriction, airway hyperresponsiveness, plasma exudation, mucus secretion, and eosinophilic inflammation (Figure 36–9; also see Chapter 33). These data motivated the development of 5’-lipoxygenase (5-LO) enzyme inhibitors (of which zileuton [ZYFLO] is the only drug marketed) and several antagonists of the cys-LT₁ receptor, including montelukast (SINGULAIR), zafirlukast (ACCOLATE), and pranlukast.
Clinical Studies. In patients with mild to moderate asthma, antileukotrienes cause a significant improvement in lung function and asthma symptoms, with a reduction in the use of rescue inhaled $\beta_2$ agonists. However, antileukotrienes are considerably less effective than ICS in the treatment of mild asthma and cannot be considered the treatment of first choice. Antileukotrienes are indicated as an add-on therapy in patients who are not well controlled on ICS. The added benefit is small and less effective than adding an LABA.

Antileukotrienes are effective in preventing exercise-induced asthma, with efficacy similar to that of LABA. Antileukotrienes appear to act mainly as antibronchoconstrictor drugs, and they are clearly less broadly effective than $\beta_2$ agonists because they antagonize only one of several bronchoconstrictor mediators. Cys-LT1 receptor antagonists have no role in the therapy of COPD.

Adverse Effects. Zileuton, zafirlukast, and montelukast are all associated with rare cases of hepatic dysfunction; thus, liver-associated enzymes should be monitored. Several cases of Churg-Strauss syndrome have been associated with the use of zafirlukast and montelukast.

IMMUNOMODULATORY THERAPIES

IMMUNOSUPPRESSIVE THERAPY

Immunosuppressive therapies (e.g., methotrexate, cyclosporine A, gold, intravenous immunoglobulin) have been considered in asthma when other treatments have been unsuccessful or to reduce the dose of oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity for side effects than oral corticosteroids.

ANTI-IgE RECEPTOR THERAPY

Omalizumab is a humanized monoclonal antibody that blocks the
binding of IgE to high-affinity IgE receptors (FceRI) on mast cells and thus prevents their activation by allergens (Figure 36–10). It also blocks binding on IgE to low-affinity IgE receptors (FceRII, CD23) on other inflammatory cells, including T and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. Omalizumab also reduces levels of circulating IgE.

**Figure 36–10** Immunoglobulin (Ig) E plays a central role in allergic diseases. Blocking IgE using an antibody, such as omalizumab, is a rational therapeutic approach. IgE may activate high-affinity receptors (FceRI) on mast cells as well as low-affinity receptors (FceRII, CD23) on other inflammatory cells. Omalizumab prevents these interactions and the resulting inflammation. cys-LT, cysteinyl-leukotriene; IL, interleukin; PG, prostaglandin.

**Clinical Use.** Omalizumab is used for the treatment of patients with severe asthma. The antibody is administered by subcutaneous injection every 2-4 weeks, and the dose is determined by the titer of circulating IgE. Omalizumab
reduces the requirement for oral and ICS and markedly reduces asthma exacerbations. Because of its very high cost, this treatment is generally used only in patients with very severe asthma who are poorly controlled even on oral corticosteroids and in patients with very severe concomitant allergic rhinitis. The major side effect of omalizumab is an anaphylactic response, which is uncommon (<0.1%).

**MUCOREGULATORS**

Mucus hypersecretion occurs in chronic bronchitis, COPD, cystic fibrosis, and asthma. In chronic bronchitis, mucus hypersecretion is related to chronic irritation by cigarette smoke and may involve neural mechanisms and the activation of neutrophils to release enzymes such as neutrophil elastase and proteinase-3 that have powerful stimulatory effects on mucus secretion. Mast cell–derived chymase is also a potent mucus secretagogue. Systemic anticholinergic drugs appear to reduce mucociliary clearance, but this is not observed with either ipratropium bromide or tiotropium bromide, presumably reflecting their poor absorption from the respiratory tract. β₂ Agonists increase mucus production and mucociliary clearance. Because inflammation leads to mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion; ICS are very effective in reducing increased mucus production in asthma.

Sensory nerves and neuropeptides are important in the secretory activities of the submucosal gland and goblet cell (more notable in peripheral airways). Opioids and K⁺ channel openers inhibit mucus secretion mediated via sensory neuropeptide release; peripherally acting opioids may be developed to control mucus hypersecretion due to irritants in the future.

**ANTITUSSIVES**

*Whenever possible, treat the underlying cause, not the cough.*

Viral infections of the upper respiratory tract are the most common cause of cough; postviral cough is usually self-limiting and commonly patient-medicated. Because cough is a defensive reflex, its suppression may be inappropriate in bacterial lung infection. Before treatment with antitussives, it is important to
identify underlying causal mechanisms that may require therapy. Asthma commonly presents as cough, and the cough will usually respond to ICS. A syndrome characterized by cough in association with sputum eosinophilia but no airway hyperresponsiveness and termed *eosinophilic bronchitis* also responds to ICS. Nonasthmatic cough does not respond to ICS but sometimes responds to anticholinergic therapy. The cough associated with postnasal drip of sinusitis responds to antibiotics (if warranted), nasal decongestants, and intranasal steroids. The cough associated with ACE inhibitors (in ~15% of patients treated) responds to lowering the dose or withdrawal of the drug and substitution of an AT1 receptor antagonist (see Chapter 26). Gastroesophageal reflux is a common cause of cough through a reflex mechanism and occasionally as a result of acid aspiration into the lungs. This cough may respond to suppression of gastric acid with an H2 receptor antagonist or a proton pump inhibitor (see Chapter 45). Some patients have a chronic cough with no obvious cause, and this chronic idiopathic cough may be due to airway sensory neural hyperesthesia.

**OPIATES.** Opiates have a central mechanism of action on < opioid receptors in the medullary cough center, but there is some evidence that they may have additional peripheral action on cough receptors in the proximal airways. Codeine and pholcodine (not available in the U.S.) are commonly used, but there is little evidence that they are clinically effective, particularly on postviral cough; in addition, they are associated with sedation and constipation. Morphine and methadone are effective but indicated only for intractable cough associated with bronchial carcinoma.

**DEXTROMETHORPHAN.** Dextromethorphan is a centrally active N-methyl-D-aspartate (NMDA) receptor antagonist. It may also antagonize opioid receptors. Despite the fact that it is in numerous over-the-counter cough suppressants and used commonly to treat cough, it is poorly effective. It can cause hallucinations at higher doses and has significant abuse potential.

**BENZONATATE.** (Tessalon, others), a local anesthetic, acts peripherally by anesthetizing the stretch receptors located in the respiratory passages, lungs, and pleura. By dampening the activity of these receptors, benzonatate may reduce the cough reflex at its source. The recommended dose is 100 mg, three times daily, and up to 600 mg/day, if needed. Side effects include dizziness and dysphagia. Seizures and cardiac arrest have occurred following an acute
ingestion. Severe allergic reactions have been reported in patients allergic to para-aminobenzoic acid, a metabolite of benzonatate.

**OTHER DRUGS.** Several other drugs reportedly have small benefits in reducing cough in pulmonary diseases. These drugs include *moguisteine* (not available in the U.S.), which acts peripherally and appears to open ATP-sensitive K⁺ channels; *baclofen*, a GABA_B-selective agonist; and *theobromine*, a naturally occurring methylxanthine.

**DRUGS FOR DYSPNEA AND VENTILATORY CONTROL**

**DRUGS FOR DYSPNEA**

Bronchodilators should reduce breathlessness in patients with airway obstruction. Chronic oxygen may have a beneficial effect, but in a few patients dyspnea may be extreme. Drugs that reduce breathlessness may also depress ventilation and may therefore be dangerous. Some patients show a beneficial response to dihydrocodeine and diazepam; however, these drugs must be used with great caution because of the risk of ventilatory depression. Slow-release morphine tablets may also be helpful in COPD patients with extreme dyspnea. Nebulized morphine may also reduce breathlessness in COPD and could act in part on opioid receptors in the lung.

**VENTILATORY STIMULANTS**

Selective respiratory stimulants are indicated if ventilation is impaired as a result of overdose with sedatives, in post-anesthetic respiratory depression, and in idiopathic hypoventilation. Respiratory stimulants are rarely indicated in COPD because respiratory drive is already maximal and further stimulation of ventilation may be counterproductive because of the increase in energy expenditure caused by the drugs.

**DOXAPRAM.** (DOPRAM, others). At low doses (0.5 mg/kg IV), doxapram stimulates carotid chemoreceptors; at higher doses it stimulates medullary respiratory centers. Its effect is transient; thus, intravenous infusion (0.3-3 mg/kg/min) is needed for sustained effect. Unwanted effects include nausea, sweating, anxiety, and hallucinations. At higher doses, increased pulmonary and
systemic pressures may occur. Both the kidney and the liver participate in the clearance of doxapram, which should be used with caution if hepatic or renal function is impaired. In COPD, the infusion of doxapram is restricted to 2 h. The use of doxapram to treat ventilatory failure in COPD has now largely been replaced by noninvasive ventilation.

**ALMITRINE.** Almitrine bismesylate is a piperazine derivative that appears to selectively stimulate peripheral chemoreceptors and is without central actions. Almitrine stimulates ventilation only when there is hypoxia. Long-term use of almitrine is associated with peripheral neuropathy, limiting its availability in most countries.

**ACETAZOLAMIDE.** The carbonic anhydrase inhibitor acetazolamide (see Chapter 25) induces metabolic acidosis and thereby stimulates ventilation, but it is not widely used because the metabolic imbalance it produces may be detrimental in the face of respiratory acidosis. It has a very small beneficial effect in respiratory failure in COPD patients. The drug has proved useful in prevention of high altitude sickness.

**NALOXONE.** Naloxone is a competitive opioid antagonist that is indicated only if ventilatory depression is due to overdose of opioids.

**FLUMAZENIL.** Flumazenil is a benzodiazepine receptor antagonist that can reverse respiratory depression due to overdose of benzodiazepines.

**PHARMACOTHERAPY OF PULMONARY ARTERIAL HYPERTENSION**

Pulmonary arterial hypertension (PAH) is characterized by vascular proliferation and remodeling of small pulmonary arteries, resulting in a progressive increase in pulmonary vascular resistance that may lead to right heart failure and death. PAH involves dysfunction of pulmonary vascular endothelial and smooth muscle cells and their interplay and results from an imbalance in vasoconstrictor and vasodilator mediators. Vasodilators are the mainstay of drug therapy for PAH. However, the vasodilators used to treat systemic hypertension lower systemic blood pressure, which may result in
reduced pulmonary perfusion. Calcium channel blockers, such as nifedipine, are poorly effective, but a few patients may benefit. In PAH, there is an increase in the vasoconstrictor mediators ET-1, TxA₂, and 5HT, and a decrease in the vasodilating mediators prostacyclin (PGI₂), NO, and VIP. Therapies aim at antagonizing the vasoconstrictive mediators and enhancing vasodilation (Figure 36–11).
Figure 36–11 Interactions of endothelium and vascular smooth muscle in pulmonary artery hypertension (PAH). A. In normal pulmonary artery, there is a balance between constrictor and relaxant influences that may be viewed as competition between Ca²⁺ signaling pathways and cyclic nucleotide signaling pathways in vascular smooth muscle (VSM). Endothelin (ET-1) binds to the ETₐ receptor on VSM cells and activates the G_q-PLC-IP₃ pathway to increase cytosolic Ca²⁺; ET-1 may also couple to Gᵢ to inhibit cyclic AMP (cAMP) production. In depolarizing VSM cells, Ca²⁺ may enter via the L-type Ca²⁺ channel (Caᵥ1.2). Endothelial cells also produce relaxant factors, prostacyclin (PGI₂) and NO. NO stimulates the soluble guanylyl cyclase (sGC), causing accumulation of cyclic GMP (cGMP) in VSM cells; PGI₂ binds to the IP receptor and stimulates cAMP production; elevation of these cyclic nucleotides promotes VSM relaxation (see Figures 36–4 and 3–11). B. In PAH, ET-1 production is enhanced, production of PGI₂ and NO is reduced, and the balance
is shifted toward constriction and proliferation of vascular smooth muscle. In treating PAH, ET$_A$ receptor antagonists can reduce the constrictor effects of ET-1, and Ca$^{2+}$ channel antagonists can further reduce Ca$^{2+}$-dependent contraction. Exogenous PGI$_2$ and NO can be supplied to promote vasodilation (relaxation of VSM); inhibition of PDE5 can enhance the relaxant effect of NO by inhibiting the degradation of cGMP. Thus, these drugs can reduce Ca$^{2+}$ signaling and enhance cyclic nucleotide signaling, restoring the balance between the forces of contraction/proliferation and relaxation/antiproliferation. Remodeling and deposition of extracellular matrix by adjacent fibroblasts is influenced positively and negatively by the same contractile and relaxant signaling pathways, respectively.

Most cases of pulmonary hypertension are associated with connective tissue disorders, such as systemic sclerosis, or they are secondary to hypoxic lung diseases, such as interstitial lung disease and COPD, where chronic hypoxia leads to hypoxic pulmonary vasoconstriction. In secondary pulmonary hypertension due to chronic hypoxia, the initial treatment is correction of hypoxia using supplementary O$_2$ therapy. Right heart failure is treated initially with diuretics. Anticoagulants are indicated for the treatment of pulmonary hypertension secondary to chronic thromboembolic disease, but they may also be indicated for patients with severe pulmonary hypertension who have an increased risk of venous thrombosis.

**PROSTACYCLIN**

Prostacyclin (PGI$_2$; epoprostenol) is produced by endothelial cells in the pulmonary circulation and directly relaxes pulmonary vascular smooth muscle cells by increasing intracellular cyclic AMP concentrations (see Chapter 33). Reduced prostacyclin production in PAH has led to the therapeutic use of epoprostenol and other stable prostacyclin derivatives. Functionally, PGI$_2$ opposes the effects of TXA$_2$.

Intravenous epoprostenol (FloLan, others) is effective in lowering pulmonary arterial pressures, improving exercise performance, and prolonging survival in primary PAH (PPAH). Because of its short plasma t$_{1/2}$, prostacyclin must be
administered by continuous intravenous infusion using an infusion pump. Common side effects are headache, flushing, diarrhea, nausea, and jaw pain. Continuous intravenous infusion is inconvenient and very expensive. This has led to the development of more stable prostacyclin analogs. Treprostinil (Remodulin) is given by continuous subcutaneous infusion or as an inhalation (Tyvaso), consisting of 4 daily treatment sessions with 9 breaths per session. Iloprost (Ventavis) is a stable analog that is given by inhalation, but it needs to be given by nebulizer 6 to 9 times daily. It is associated with the vasodilator side effects of prostacyclin, including syncope. It may also cause cough and bronchoconstriction because it sensitizes airway sensory nerves.

ENDOTHELIN RECEPTOR ANTAGONISTS

Endothelin-1 (ET-1) is a potent pulmonary vasoconstrictor that is produced in increased amounts in PAH. ET-1 contracts vascular smooth muscle cells and causes proliferation mainly via ET\textsubscript{A} receptors. ET\textsubscript{B} receptors mediate the release of prostacyclin and NO from endothelial cells. Several endothelin antagonists are now on the market for the treatment of PPAH.

**Bosentan** (Tracleer) is an ET\textsubscript{A}/ET\textsubscript{B} receptor antagonist. Bosentan is effective in reducing symptoms and improving mortality in PPAH. Starting dose is 62.5 mg twice daily for 4 weeks, and maintenance dose is 125 mg twice daily. The drug is generally well tolerated. Adverse effects include abnormal liver function tests, anemia, headaches, peripheral edema, and nasal congestion. Liver aminotransferases should be monitored monthly. A class effect is a risk of testicular atrophy and infertility; bosentan is potentially teratogenic.

**Ambrisentan** (Letairis) is a selective ET\textsubscript{A} receptor antagonist. It is given orally once daily at a dose of 5-10 mg with clinical efficacy and adverse effects similar to that of bosentan. Use of ambrisentan also requires monthly monitoring of liver aminotransferases. Sitaxsentan (Thelin, not available in the U.S.) is a selective ET\textsubscript{A} receptor antagonist that was withdrawn from the market because of post-marketing reports of fatal liver complications in patients with PAH related to its use.
PDE5 INHIBITORS

Nitric oxide activates soluble guanylate cyclase to increase cyclic GMP, which is hydrolyzed to 5’GMP by PDE5 (see Chapter 27). Elevation of cGMP in smooth muscle causes relaxation (see Chapter 3), which the inhibition of PDE5 prolongs and accentuates. In the pulmonary bed, inhibition of PDE5 induces vasodilation.

SILDENAFIL. Sildenafil (Revatio) is a selective PDE5 inhibitor that is given at a dose (20 mg 3 time daily orally) that is lower than used for erectile dysfunction (100 mg; see Chapter 27). It is effective in lowering pulmonary resistance and improving exercise tolerance in patients with PAH. Side effects include headache, flushing, dyspepsia, and visual disturbances.

TADALAFIL. Tadalafil (Adcirca) has a longer duration of action than sildenafil so may be suitable for once-daily dosing.

PDE4 INHIBITORS

Roflumilast. Roflumilast (Daliresp) and its active metabolite (roflumilast N-oxide) selectively inhibit PDE4, have anti-inflammatory effects, and are used to decrease exacerbations of severe COPD. Roflumilast is metabolized by CYPs to roflumilast N-oxide and then to conjugates that are mostly excreted in urine. Adverse effects include diarrhea, weight loss, nausea, headache, and can be dose-limiting. Some patients may experience anxiety, depression, and suicidal thoughts.
Chapter 37
Hematopoietic Agents: Growth Factors, Minerals, and Vitamins

The finite life span of most mature blood cells requires their continuous replacement, a process termed hematopoiesis. New cell production must respond to basal needs and states of increased demand. Red blood cell production can increase >20-fold in response to anemia or hypoxemia, white blood cell production increases dramatically in response to a systemic infection, and platelet production can increase 10- to 20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare bone marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the 9 distinct blood-cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma, and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. Some of these hormones and cytokines have been identified and cloned, permitting their production in quantities sufficient for therapeutic use. Clinical applications range from the treatment of primary hematologic diseases to use as adjuncts in the treatment of severe infections and in the management of patients who are undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin); deficiencies generally result in characteristic anemias or, less frequently, a general failure of
hematopoiesis. Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state, and on knowledge about the correct dose, the use of these agents in appropriate combinations, and the expected response.

**Hematopoietic Growth Factors**

**GROWTH FACTOR PHYSIOLOGY.** Steady-state hematopoiesis encompasses the production of >400 billion blood cells each day. This production is tightly regulated and can be increased several-fold with increased demand. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Stem cell differentiation can be described as a series of steps that produce so-called burst-forming units (BFUs) and colony-forming units (CFUs) for each of the major cell lines. These early progenitors (BFU and CFU) are capable of further proliferation and differentiation, increasing their number by some 30-fold. Subsequently, colonies of morphologically distinct cells form under the control of an overlapping set of additional growth factors (granulocyte colony-stimulating factor [G-CSF], macrophage colony-stimulating factor [M-CSF], erythropoietin, and thrombopoietin). Proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating >1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than 1 committed cell lineage. Most
interact synergistically with other factors and also stimulate production of additional growth factors, a process called \textit{networking}. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia.

\textit{Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 37–1 and Table 37–1.}

\textbf{Figure 37–1} Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells
differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), ligand (FL), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF), together with cell–cell interactions in the marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFU): CFU-GEMM (granulocyte, erythrocyte, monocyte and megakaryocyte), CFU-GM (granulocyte and macrophage), CFU-Meg (megakaryocyte), BFU-E (erythrocyte), and CFU-E (erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and in some cases the function of the derivative cell line (Table 37–1).

ERYTHROPOIESIS-STIMULATING AGENTS

Erythropoiesis-stimulating agent (ESA) is the term given to a pharmacological substance that stimulates red blood cell production.

Erythropoietin is the most important regulator of the proliferation of committed erythroid progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present, commonly seen in patients with renal failure. Erythropoiesis is controlled by a feedback system in which a sensor in the kidney detects changes in oxygen delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level.

Hypoxia-inducible factor (HIF-1), a heterodimeric (HIF-1α and HIF-1β) transcription factor, enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and
degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1α and activating erythropoietin expression, which in turn stimulates a rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1α and erythropoietin, with a resultant polycythemia.

Erythropoietin is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of ~30 kDa. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramatically stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin.

PREPARATIONS. Available preparations of recombinant human erythropoietin (epoetin alfa) include EPOGEN, PROCRIT, and EPREX, supplied in single-use vials containing 2000-40,000 units/mL for intravenous or subcutaneous administration. When injected intravenously, epoetin alfa is cleared from plasma with a t₁/₂ of 4-8 h. However, the effect on marrow progenitors lasts much longer, and once-weekly dosing can be sufficient to achieve an adequate response. A novel erythropoiesis-stimulating protein, darbepoetin alfa (ARANESP), has been approved for clinical use in patients with indications similar to those for epoetin alfa. It is a genetically modified form of erythropoietin in which 4 amino acids have been mutated such that additional carbohydrate side chains are added during its synthesis, prolonging the circulatory survival of the drug to 24-26 h. Another erythropoiesis-stimulating peptide, Peginesatide (OMONTYS), was approved in 2012 for the treatment of anemia due to chronic kidney disease. Postmarketing reports of serious hypersensitivity reactions and anaphylaxis have necessitated a recall.
Recombinant human erythropoietin (epoetin alfa) is nearly identical to the endogenous hormone. The carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. Modern assays can detect these differences and thereby identify athletes who use the recombinant product for “blood doping.”

THERAPEUTIC USES, MONITORING, AND ADVERSE EFFECTS.
Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with a poor erythropoietic response. Epoetin alfa is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is <100 μg/L or whose serum transferrin saturation is <20%. During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (HIV-infected and cancer patients) or twice a week (renal failure patients) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by >4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2-6 weeks. The dose of darbepoetin should be decreased if the hemoglobin increase exceeds 1 g/dL in any 2-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbepoetin may require increased anticoagulation. The risk of thrombotic events is higher in adults with ischemic heart disease or congestive heart failure receiving epoetin alfa therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30%. ESA use is associated with increased rates of cancer recurrence and decreased on-study survival in patients in whom the drugs are
administered for cancer-induced or for chemotherapy-induced anemia. The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20-30% of patients and most often is associated with a rapid rise in hematocrit. ESAs should not be used in patients with preexisting uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Hypertensive encephalopathy and seizures have occurred in chronic renal failure patients treated with epoetin alfa. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (e.g., arthralgias and myalgias) also have been reported in conjunction with epoetin alfa therapy.

**Anemia of Chronic Renal Failure.** Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy. The response in predialysis, peritoneal dialysis, and hemodialysis patients depends on the severity of the renal failure, the erythropoietin dose and route of administration, and iron availability. The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20-40%. The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hematocrit of 33-36%. Treatment to hematocrit levels >36% is not recommended.

Patients are started on doses of 80-120 units/kg of epoetin alfa, given subcutaneously, 3 times a week. The final maintenance dose of epoetin alfa can vary from 10 units/kg to >300 units/kg, with an average dose of 75 units/kg, 3 times a week. Children <5 years of age generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism. Darbepoetin alfa is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 µg/kg administered intravenously or subcutaneously once weekly, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of <1 g/dL every 2 weeks generally is considered safe.
Anemia in AIDS Patients. Epoetin alfa therapy has been approved for the treatment of HIV-infected patients, especially those on zidovudine therapy. Excellent responses to doses of 100-300 units/kg, given subcutaneously 3 times a week, generally are seen in patients with zidovudine-induced anemia.

Cancer-Related Anemias. Epoetin alfa therapy, 150 units/kg 3 times a week or 450-600 units/kg once a week, can reduce the transfusion requirement in cancer patients undergoing chemotherapy. Therapeutic guidelines recommend the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dL, basing the decision to treat less severe anemia (Hb, 10-12 g/dL) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels >500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experience an improvement in their anemia and their sense of well-being.

Recent case reports suggest a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells. A meta-analysis of a large number of patients and clinical trials estimates the risk at ~10% higher than nontreated cancer patients. This finding is being evaluated by the FDA and warrants serious attention.

Surgery and Autologous Blood Donation. Epoetin alfa has been used perioperatively to treat anemia (hematocrit 30-36%) and reduce the need for erythrocyte transfusion. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150-300 units/kg of epoetin alfa once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days 21, 14, and 7 before surgery, with an additional dose on the day of surgery. Epoetin alfa also has been used to improve autologous blood donation.

Other Uses. Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the latter case, even very high doses >1000 units/kg 2 to 3 times a week have had limited success. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels (“blood doping”) and improve performance.
Unfortunately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

**MYELOID GROWTH FACTORS**

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell lines. Recombinant forms of several growth factors have been produced, including granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, IL-3, M-CSF or CSF-1, and stem cell factor (SCF) (see [Table 37–1](#)).

Myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells ([Figure 37–2](#)). These factors are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the JAK/STAT signal transduction pathway. GM-CSF can stimulate proliferation, differentiation, and function of a number of the myeloid cell lineages (see [Figure 37–1](#)). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates CFU-granulocyte(G)/erythrocyte(E)/monocyte(M)/megakaryocyte(Meg) [CFU-GEMM], CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. GM-CSF also enhances the migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils.
Figure 37–2 Cytokine-cell interactions. Macrophages, T cells, B cells, and marrow stem cells interact via several cytokines (IL-1, IL-2, IL-3, IL-4, IFN [interferon]-γ, GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge. See Table 37–1 for the functional activities of these various cytokines.

The G-CSF activity is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on the CFU-G, although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. G-CSF reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon gamma. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood. This observation has virtually transformed the practice of stem cell transplantation, such that >90% of all such procedures today use G-CSF–mobilized peripheral blood stem cells as the donor product.

**GRANULOCYTE-MACРОPHAGE COLONY-STIMULATING FACTOR.** Recombinant human GM-CSF (*sargramostim*) is a 127–amino acid glycoprotein. The primary therapeutic effect of sargramostim is to stimulate myelopoiesis.

The initial clinical application of sargramostim was in patients undergoing autologous bone marrow transplantation. By shortening the duration of
neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process. The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment for graft-versus-host disease (GVHD). However, it may improve survival in transplant patients who exhibit early graft failure. It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell collection for transplantation after myeloablative chemotherapy. Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy. It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia.

Sargramostim (LEUKINE) is administered by subcutaneous injection or slow intravenous infusion at doses of 125-500 µg/m²/day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a t½ of 2-3 h. When given intravenously, infusions should be maintained over 3-6 h. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to margination and sequestration in the lungs. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7-10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2-10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, whereas monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. Higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects include transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.
GRANULOCYTE COLONY-STIMULATING FACTOR.

Recombinant human G-CSF, *filgrastim* (NEUPOGEN), is a 175–amino acid glycoprotein. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (see Figure 37–1).

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy. Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections. G-CSF also is effective in the treatment of severe congenital neutropenias. Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of AIDS patients receiving zidovudine also can be partially or completely reversed. Filgrastim is routinely used in patients undergoing peripheral blood stem cell (PBSC) collection for stem cell transplantation. It promotes the release of CD34⁺ progenitor cells from the marrow, reducing the number of collections necessary for transplant. G-CSF–induced mobilization of stem cells into the circulation has been promoted as a way to enhance repair of other damaged organs in which PBSC might play a role.

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 min at doses of 1-20 µg/kg/day. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 µg/kg/day. The distribution and clearance rate from plasma (t₁/₂ of 3.5 h) are similar for both routes of administration. As with GM-CSF therapy, filgrastim given daily after hematopoietic stem cell transplantation or intensive cancer chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for ≥14-21 days may be necessary to correct the neutropenia. Adverse reactions to filgrastim include mild to moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *Escherichia coli* should not receive the drug. Mild to moderate splenomegaly has been observed in patients on long-term therapy.
Pegylated recombinant human G-CSF *pegfilgrastim* (Neulasta) is available. The clearance of pegfilgrastim by glomerular filtration is minimized, thus making neutrophil-mediated clearance the primary route of elimination. Consequently the circulating $t_{1/2}$ of pegfilgrastim is longer than that of filgrastim, allowing for more sustained duration of action and less frequent dosing. The recommended dose for pegfilgrastim is fixed at 6 mg administered subcutaneously.

**THROMBOPOIETIC GROWTH FACTORS**

**INTERLEUKIN-11.** Interleukin-11 is a cytokine that stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. Interleukin-11 also enhances megakaryocyte maturation in vitro. Recombinant human IL-11 oprolvekin (NeumeGA) leads to a thrombopoietic response in 5-9 days when administered daily to normal subjects.

The drug is administered to patients at 25-50 μg/kg per day subcutaneously with a $t_{1/2}$ ~7 h. Oprolvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies with severe thrombocytopenia (platelet count <20,000/μL), and it is administered until the platelet count returns to >100,000/μL. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Also reported are blurred vision, injection-site rash or erythema, and paresthesias.

**THROMBOPOIETIN.** Thrombopoietin, a glycoprotein produced by the liver, marrow stromal cells, and other organs, is the primary regulator of platelet production. Two forms of recombinant thrombopoietin have been developed for clinical use. One is a truncated version of the native protein, termed *recombinant human megakaryocyte growth and development factor* (rHuMGDF) that is covalently modified with polyethylene glycol to increase the circulatory $t_{1/2}$. The second is the full-length polypeptide termed
recombinant human thrombopoietin (rHuTPO).

In clinical trials, both drugs are safe but data on efficacy are mixed. Due to several concerns including the immunogenicity of these agents, efforts are under way to develop small molecular mimics of recombinant thrombopoietin. Two of these agents are FDA-approved for use in patients with immune thrombocytopenic purpura (ITP) who have failed to respond to more conventional treatments. *Romiplostim* (NPLATE) contains 4 copies of a small peptide that binds with high affinity to the thrombopoietin receptor, grafted onto an immunoglobulin scaffold. Romiplostim is safe and efficacious in patients with ITP. The drug is administered weekly by subcutaneous injection, starting with a dose of 1 μg/kg, titrated to a maximum of 10 μg/kg, until platelet count increases above 50,000/μL. *Eltrombopag* (PROMACTA) is a small molecule that is a thrombopoietin receptor agonist. Eltrombopag is administered orally; the recommended starting dose is 50 mg/day, titrated to 75 mg depending on platelet response.

Drugs Effective in Iron Deficiency and Other Hypochromic Anemias

**IRON AND IRON SALTS**

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. In addition to its role in hemoglobin, iron also is an essential component of myoglobin, heme enzymes (e.g., cytochromes, catalase, and peroxidase), and the metalloflavoprotein enzymes (e.g., xanthine oxidase and the α-glycerophosphate oxidase). Iron deficiency can affect metabolism in muscle independently of the effect of anemia on O$_2$ delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly, impaired heat production.
METABOLISM OF IRON. The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage (Table 37–2).

<table>
<thead>
<tr>

<tr>
<td><strong>Total</strong></td>
</tr>
</tbody>
</table>

Hemoglobin (Hb) dominates the essential fraction. Each Hb molecule contains 4 atoms of iron, amounting to 1.1 mg (20 μmol) of iron/mL of red blood cells. Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin (MW ~450 kDa) is composed of 24 polypeptide subunits that form an outer shell around a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as hemosiderin and visible by light microscopy, constitute about one-third of normal stores. The 2 predominant sites of iron storage are the reticuloendothelial system and the hepatocytes.

Internal exchange of iron is accomplished by the plasma protein transferrin, a 76-kDa glycoprotein that has 2 binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron-transferrin complex binds to the receptor, and the ternary complex is internalized through clathrin-coated pits by receptor-mediated endocytosis. A proton-pumping ATPase lowers the pH of the intracellular vesicular compartment (the endosomes) to ~5.5. Iron subsequently dissociates and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment. Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply. The
synthesis of apoferritin and transferrin receptors is regulated post-
transcriptionally by 2 iron-regulating proteins 1 and 2 (IRP1 and IRP2). These
IRPs are cytosolic RNA-binding proteins that bind to iron-regulating elements
(IREs) present in the 5′ or 3′ untranslated regions of mRNA encoding apoferritin
or the transferrin receptors, respectively. Binding of these IRPs to the 5′ IRE of
apoferritin mRNA represses translation, whereas binding to the 3′ IRE of mRNA
encoding the transferrin receptors enhances transcript stability, thereby
increasing protein production.

The flow of iron through the plasma amounts to a total of 30-40 mg/day in the
adult (~0.46 mg/kg of body weight). The major internal circulation of iron
involves the erythron and reticuloendothelial cells (Figure 37–3). About 80% of
the iron in plasma goes to the erythroid marrow to be packaged into new
erythrocytes; these normally circulate for ~120 days before being catabolized by
the reticuloendothelial system. At that time, a portion of the iron is immediately
returned to the plasma bound to transferrin, while another portion is incorporated
into the ferritin stores of reticuloendothelial cells and returned to the circulation
more gradually. With abnormalities in erythrocyte maturation, the predominant
portion of iron assimilated by the erythroid marrow may be rapidly localized in
the reticuloendothelial cells as defective red-cell precursors are broken down;
this is termed ineffective erythropoiesis. The rate of iron turnover in plasma may
be reduced by half or more with red-cell aplasia, with all the iron directed to the
hepatocytes for storage.
The human body conserves its iron stores to a remarkable degree. Only 10% of the total is lost per year by normal men (i.e., ~1 mg/day). Two-thirds of this iron is excreted from the GI tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Additional losses of iron occur in women due to menstruation. Although the average loss in menstruating women is ~0.5 mg per day, 10% of menstruating women lose >2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 37–3). Other causes of iron loss include blood donation, the use of anti-inflammatory drugs that cause bleeding from the gastric mucosa, and GI disease with associated bleeding.

**Table 37–3**  
Iron Requirements for Pregnancy
The limited physiological losses of iron point to the primary importance of absorption in determining the body’s iron content. After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either inorganic iron or heme iron. A ferrireductase, duodenal cytochrome B (Dcytb), located on luminal surface of absorptive cells of the duodenum and upper small intestine, reduces the iron to the ferrous state, which is the substrate for the divalent metal (ion) transporter 1 (DMT1). DMT1 transports the iron to basolateral membrane, where it is taken up by another transporter, ferroportin (Fpn; SLC40A1), and subsequently reoxidized to Fe$^{3+}$, primarily by hephaestin (Hp; HEPH), a transmembrane copper-dependent ferroxidase. Apo-transferrin (Tf) binds the resultant oxidized Fe$^{3+}$.

**IRON REQUIREMENTS AND THE AVAILABILITY OF DIETARY IRON.** Adult men must absorb only 13 μg of iron/kg of body weight/day (~1 mg/day), whereas menstruating women require ~21 μg/kg (~1.4 mg) per day. In the last 2 trimesters of pregnancy, requirements increase to ~80 μg/kg (5-6 mg) per day; infants have similar requirements due to their rapid growth (Table 37–4).

The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable. In infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men (see Table 37–2).

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed. The nonheme fraction represents the larger amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed very poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. In developed countries, the normal adult diet contains ~6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer’s yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. Iron also may be added from cooking in iron pots. In assessing dietary iron intake, it is important to consider not just the amount of iron ingested but its bioavailability.

**IRON DEFICIENCY.** The prevalence of iron-deficiency anemia in
the U.S. is on the order of 1-4% and depends on the economic status of the population. In developing countries, up to 20-40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron-deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption. More severe iron deficiency is usually the result of blood loss, either from the GI tract, or in women, from the uterus. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency. Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast-fed and/or do not receive iron-fortified formula. After the age of 2-3 years, the requirement for iron declines until adolescence when rapid growth combined with irregular dietary habits again increases the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11-18 is insufficient to meet their requirements.

TREATMENT OF IRON DEFICIENCY

GENERAL THERAPEUTIC PRINCIPLES. The response of iron-deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.
THERAPY WITH ORAL IRON. Orally administered ferrous sulfate is the treatment of choice for iron deficiency. Ferrous salts are absorbed about 3 times as well as ferric salts. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate (FEOSOL, others), fumarate (HEMOCYTE, FEOSTAT, others), succinate, gluconate (FERGON, others), aspartate, other ferrous salts, and polysaccharide-ferrihydrite complex (NIFEREX, others) are absorbed to approximately the same extent.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have a much lower bioavailability. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food. The amount of iron in iron tablets is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Delayed-release preparations are available, but absorption from such preparations varies. Ascorbic acid (≥200 mg) increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with an increase in the incidence of side effects. Preparations that contain other compounds with therapeutic action, such as vitamin B₁₂, folate, or cobalt, are not recommended because the patient’s response to the combination cannot easily be interpreted.

The average dose for the treatment of iron-deficiency anemia is ~200 mg of iron per day (2-3 mg/kg), given in 3 equal doses of 65 mg. Children weighing 15-30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron, e.g., 5 mg/kg. When the object is the prevention of iron deficiency in pregnant women, e.g., doses of 15 to 30 mg of iron per day are adequate. Bioavailability of iron is reduced with food and by concurrent antacids. For a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered 4 times a day. The duration of treatment is governed by the rate of recovery of hemoglobin (Table 37–5) and the desire to create iron stores.

**UNTOWARD EFFECTS OF ORAL PREPARATIONS OF IRON.** Side effects include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage, and then gradually to increase the dosage to that desired. Only individuals with underlying disorders that augment the absorption of iron run the hazard of developing iron overload (hemochromatosis).

**IRON POISONING.** Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1-2 g of iron may cause death, but 2-10 g usually is ingested in fatal cases. All iron preparations should be kept in childproof bottles. Signs and symptoms of severe poisoning may occur within 30 min after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 h, there may be a transient period of apparent recovery, followed by death in 12-24 h. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and determination of the concentration of iron in plasma can be performed. If the latter is >63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an X-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg/L), deferoxamine should be administered (see Chapter 67). The speed of diagnosis and therapy is very important. With early treatment, the mortality from iron poisoning can be reduced from 45% to ~1%. Deferiprone is an oral iron chelator approved to treat iron overload due to blood transfusions in patients.
with thalassemia.

**THERAPY WITH PARENTERAL IRON.** When oral iron therapy fails, parenteral iron administration may be an effective alternative. Common indications are iron malabsorption (e.g., sprue, short bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin. Parenteral iron can be given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route.

The rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1-3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Parenteral iron therapy should be used only when clearly indicated because acute hypersensitivity, including anaphylactic and anaphylactoid reactions, can occur. Other reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and in some patients with rheumatoid arthritis, exacerbation of the disease. Four iron formulations are available in the U.S. These are iron dextran (Dexferrum or InfEd), sodium ferric gluconate (Ferrlecit), ferumoxytol (Feraheme), and iron sucrose (Venofer). Ferumoxytol is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle that is approved for treatment of iron-deficiency anemia in patients with chronic kidney disease. The indications for the iron dextran preparations include treatment of any patient with documented iron deficiency and intolerance or irresponsiveness to oral iron. Indications for the ferric gluconate and iron sucrose are limited to patients with chronic kidney disease.

**Iron Dextran.** Iron dextran injection (InfEd or Dexferrum) is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight, ~180,000 Da) that contains 50 mg/mL of elemental iron. The use of low-molecular-weight iron dextran has reduced the incidence of toxicity relative to that observed with high-molecular-weight preparations (Imferon). Iron dextran
can be administered by either intravenous (preferred) or intramuscular injection. Given intravenously in a dose <500 mg, the iron dextran complex is cleared exponentially with a plasma $t_{1/2}$ of 6 h. When $\geq 1$ g is administered intravenously as total dose therapy, reticuloendothelial cell clearance is constant at 10-20 mg/h.

Intramuscular injection of iron dextran should be initiated only after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing <4.5 kg (10 lb), 1 mL (50 mg of iron) for children weighing <9 kg (20 lb), and 2 mL (100 mg of iron) for other patients. However, local reactions and the concern about malignant change at the site of injection make intramuscular administration inappropriate except when the intravenous route is inaccessible. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Use iron dextran with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases, and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned. With multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss — accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 μg/L.

**Sodium Ferric Gluconate.** Sodium ferric gluconate is an intravenous iron preparation with a molecular size of ~295 kDa and an osmolality of 990 mOsm/kg$^{-1}$. Administration of ferric gluconate at doses ranging from 62.5-125 mg during hemodialysis is associated with transferrin saturation exceeding 100%. Unlike iron dextran, which requires processing by macrophages that may require several weeks, ~80% of sodium ferric gluconate is delivered to transferrin with in 24 h. Sodium ferric gluconate also has a lower risk of inducing serious anaphylactic reactions than iron dextran.
Iron Sucrose. Iron sucrose is complex of polynuclear iron (III)-hydroxide in sucrose. Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. Iron sucrose is generally administered in daily amounts of 100-200 mg within a 14-day period to a total cumulative dose of 1000 mg. Like sodium ferric gluconate, iron sucrose appears to be better tolerated and to cause fewer adverse events than iron dextran. This agent is FDA-approved for the treatment of iron deficiency in patients with chronic kidney disease.

COPPER

Copper has redox properties similar to that of iron and is simultaneously essential and potentially toxic to the cell. Cells have virtually no free copper; rather, copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of copper’s redox properties.

Copper deficiency is extremely rare. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery, in those who are receiving parenteral nutrition, in malnourished infants, and in patients ingesting excessive amounts of zinc. Copper deficiency interferes with the absorption of iron and its release from reticuloendothelial cells. In humans, the prominent findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1-2 mg per day may be added to the solution of nutrients for parenteral administration.

PYRIDOXINE. Patients with either hereditary or acquired sideroblastic anemia characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs isoniazid and
pyrazinamide, which act as vitamin B₆ antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (see Chapter 56). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead. Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50-500 mg/day.

**RIBOFLAVIN.** The spontaneous appearance in humans of red-cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

**B₁₂, Folic Acid, and the Treatment of Megaloblastic Anemias**

Vitamin B₁₂ and folic acid are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins.

**METABOLIC ROLES OF VITAMIN B₁₂ AND FOLIC ACID.** The major roles of vitamin B₁₂ and folic acid in intracellular metabolism are summarized in Figure 37–4. Intracellular vitamin B₁₂ is maintained as 2 active coenzymes: *methylcobalamin* and *deoxyadenosylcobalamin.*
**Figure 37–4** Interrelationships and metabolic roles of vitamin B₁₂ and folic acid. See text for explanation and Figure 37–5 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II; CH₃H₄PteGlu₁, methyltetrahydrofolate. Methylcobalamin (CH₃B₁₂) supports the *methionine synthetase* reaction, which is essential for normal metabolism of folate. Methyl groups contributed by methyltetrahydrofolate (CH₃H₄PteGlu₁) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate–cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product, S-adenosylmethionine (SAM), the maintenance of a number of methylation reactions.

Deoxyadenosylcobalamin (deoxyadenosyl B₁₂) is a cofactor for the
mitochondrial mutase enzyme that catalyzes the isomerization of \( \text{l-methylmalonyl CoA} \) to succinyl CoA, an important reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate.

Because methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate (\( \text{H}_4\text{PteGlu}_1 \)). Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a 1-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate (\( 5,10\text{-CH}_2\text{H}_4\text{PteGlu} \)). The latter derivative donates the methylene group to deoxyuridylate (dUMP) for the synthesis of thymidylate (dTMP)—an extremely important reaction in DNA synthesis. In the process, the \( 5,10\text{-CH}_2\text{H}_4\text{PteGlu} \) is converted to dihydrofolate (\( \text{H}_2\text{PteGlu} \)). The cycle then is completed by the reduction of the \( \text{H}_2\text{PteGlu} \) to \( \text{H}_4\text{PteGlu} \) by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 61). As shown in Figure 37–4, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid (FIGLU) and purines and pyrimidines.

Deficiency of either vitamin \( \text{B}_{12} \) or folate decreases the synthesis of methionine and SAM, which interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin \( \text{B}_{12} \) deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methylenetetrahydrofolate pool (not shown in Figure 37–4). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin \( \text{B}_{12} \) to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin \( \text{B}_{12} \) or folic acid.

The mechanisms responsible for the neurological lesions of vitamin \( \text{B}_{12} \) deficiency are less well understood. Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion
that the deoxyadenosyl B₁₂–dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to SAM are more likely to be responsible.

**VITAMIN B₁₂**

Humans depend on exogenous sources of vitamin B₁₂ (see structure in Figure 37–5). In nature, the primary sources are certain microorganisms that grow in soil, or the intestinal lumen of animals that synthesize the vitamin. The daily nutritional requirement of 3-5 μg must generally be obtained from animal by-products in the diet. However, some vitamin B₁₂ is available from legumes, which are contaminated with bacteria that can synthesize vitamin B₁₂, and vegetarians often fortify their diets with a wide range of vitamins and minerals; thus, strict vegetarians rarely develop vitamin B₁₂ deficiency. The terms vitamin B₁₂ and cyanocobalamin are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin because only these derivatives remain active after storage.
Figure 37–5 *The structures and nomenclature of vitamin B$_{12}$ congeners.* The vitamin B$_{12}$ molecule has the 3 major portions:

1. A planar group porphyrin-like ring structure with 4 reduced pyrrole rings (A-D) linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues.

2. A 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the planar nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring.

3. A variable R group—the most important of which are found in the stable compounds cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

**METABOLIC FUNCTIONS.** The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative S-adenosylmethionine. In addition, when concentrations of vitamin B$_{12}$ are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid (see Figure 37–4). The hematologic abnormalities in vitamin B$_{12}$–deficient patients result from this process. Deoxyadenosylcobalamin is required for the rearrangement of methylmalonyl CoA to succinyl CoA (see Figure 37–4).

**ABSORPTION, DISTRIBUTION, ELIMINATION, AND DAILY REQUIREMENTS.** In the presence of gastric acid and pancreatic proteases, dietary vitamin B$_{12}$ is released from food and salivary binding protein and bound to gastric intrinsic factor. When the vitamin B$_{12}$–intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Vitamin B$_{12}$ deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 37–6). Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. Several intestinal conditions can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.
Absorbed vitamin B\textsubscript{12} binds to transcobalamin II, a plasma β-globulin, for transport to tissues. The supply of vitamin B\textsubscript{12} available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B\textsubscript{12} bound to transcobalamin II (see Figure 37–6). Vitamin B\textsubscript{12} bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. As much as 90% of the body’s stores of vitamin B\textsubscript{12}, from 1-10 mg, is in the liver. Vitamin B\textsubscript{12} is stored as the active coenzyme with a turnover rate of 0.5-8 μg per day. The recommended daily intake of the vitamin in adults is 2.4 μg. Approximately 3 μg of cobalamins are secreted into bile each day, 50-60% of which is not destined for reabsorption. Interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the...
VITAMIN B12 DEFICIENCY. Vitamin B12 deficiency is recognized clinically by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (e.g., mucosa and cervical epithelium) also have high requirements for the vitamin. As a result of an inadequate supply of vitamin B12, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as ineffective hematopoiesis. Severe deficiency affects all cell lines, and a pronounced pancytopenia results.

The diagnosis of a vitamin B12 deficiency usually can be made using measurements of the serum vitamin B12 and/or serum methylmalonate (which is somewhat more sensitive and useful in identifying metabolic deficiency in patients with normal serum vitamin B12 levels). In managing a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red-cell production. The Schilling test can be used to measure the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease. Vitamin B12 deficiency can irreversibly damage the nervous system. Because the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B12 deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic.

VITAMIN B12 THERAPY. Vitamin B12 is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Oral administration cannot be relied on for effective therapy in
the patient with a marked deficiency of vitamin B₁₂ and abnormal hematopoiesis or neurological deficits. The treatment of choice for vitamin B₁₂ deficiency is cyanocobalamin administered by intramuscular or subcutaneous injection. Effective use of the vitamin B₁₂ depends on accurate diagnosis and an understanding of the following general principles of therapy:

1. Vitamin B₁₂ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist (i.e., dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B₁₂ in patients who have had a gastrectomy, and certain diseases of the small intestine). When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B₁₂, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.

2. The relative ease of treatment with vitamin B₁₂ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by a macrocytic anemia or an unexplained neuropsychiatric disorder.

3. Therapy always should be as specific as possible. Although a large number of multivitamin preparations are available, the use of shotgun vitamin therapy in the treatment of vitamin B₁₂ deficiency can be dangerous: sufficient folic acid may be given to result in a hematologic recovery that can mask continued vitamin B₁₂ deficiency and permit neurological damage to develop or progress.

4. Although a classical therapeutic trial with small amounts of vitamin B₁₂ can help confirm the diagnosis, acutely ill elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B₁₂ to guarantee rapid recovery.

5. Long-term therapy with vitamin B₁₂ must be evaluated at intervals of 6-12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

**FOLIC ACID**
Pteroylglutamic acid (PteGlu) (Figure 37–7) is the common pharmaceutical form of folic acid. It is not the principal folate congener in food or the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 37–4, and each plays a specific role in intracellular metabolism:

Figure 37–7 The structures and nomenclature of pteroylglutamic acid (folic acid) and its congeners. X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The number of residues of glutamate is variable.

- Conversion of Homocysteine to Methionine. This reaction requires \( \text{CH}_3\text{H}_4\text{PteGlu} \) as a methyl donor and uses vitamin B₁₂ as a cofactor.
- Conversion of Serine to Glycine. This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and uses pyridoxal phosphate.
as a cofactor. It results in the formation of 5,10-CH$_2$H$_4$PteGlu, an essential coenzyme for the synthesis of thymidylate.

- **Synthesis of Thymidylate.** 5,10-CH$_2$H$_4$PteGlu donates a methylene group and reducing equivalents to deoxyuridylate for the synthesis of thymidylate—a rate-limiting step in DNA synthesis.

- **Histidine Metabolism.** H$_4$PteGlu also acts as an acceptor of a formiminogroup in the conversion of formimino glutamic acid to glutamic acid.

- **Synthesis of Purines.** Two steps in the synthesis of purine nucleotides require the participation of 10-CHOH$_4$PteGlu as a formyl donor in reactions catalyzed by ribotide transformylases: the formylation of glycinamide ribonucleotide and the formylation of 5-aminoimidazole-4-carboxamide ribonucleotide. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.

- **Utilization or Generation of Formate.** This reversible reaction uses H$_4$PteGlu and 10-CHOH$_4$PteGlu.

**DAILY REQUIREMENTS.** Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food. Generally, a standard U.S. diet provides 50-500 μg of absorbable folate per day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg per day. In the normal adult, the recommended daily intake is 400 μg; pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500-600 μg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 μg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine.

**ADME.** As with vitamin B$_{12}$, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 37–8). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a *pteroylglutamyl carboxypeptidase* associated with mucosal cell
membranes. The mucosae of the duodenum and upper part of the jejunum are rich in *dihydrofolate reductase* and can methylate most or all of the reduced folate that is absorbed. Because most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprues are common causes of folate deficiency and megaloblastic anemia.

![Figure 37–8](image)

**Figure 37–8 Absorption and distribution of folate derivatives.** Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to CH₃H₄PteGlu₁ during gastrointestinal transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease there may be defects in (3) the concentration of folate-binding proteins in plasma and (4) the flow of CH₃H₄PteGlu₁ into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B₁₂ deficiency will (5) “trap” folate as CH₃H₄PteGlu₁, thereby reducing the availability of H₄PteGlu₁ for its essential roles in purine and pyrimidine synthesis.

Once absorbed, folate is transported rapidly to tissues as CH₃H₄PteGlu₁. do bind folate derivatives, they have a greater affinity for nonmethylated analogs. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain
disease states, such as uremia, cancer, and alcoholism. A constant supply of CH$_3$H$_4$PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H$_2$ or H$_4$PteGlu) and then transports the CH$_3$H$_4$PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide ≥200 μg of folate each day for recirculation to tissues. The importance of the enterohepatic cycle is suggested by animal studies that show a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of CH$_3$H$_4$PteGlu from hepatic parenchymal cells.

**FOLATE DEFICIENCY.** Folate deficiency is a common complication of diseases of the small intestine that interferes with the absorption of folate from food and the recirculation of folate through the enterohepatic cycle. In acute or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis and the most amenable to therapy, via reinstitution of a normal diet. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. Additionally, drugs that inhibit dihydrofolate reductase (e.g., methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia.

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B$_{12}$, this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B$_{12}$ deficiency. In contrast to vitamin B$_{12}$ deficiency, folate deficiency is rarely if ever associated with neurological abnormalities. After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B$_{12}$ absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1-4 weeks, depending on the individual’s dietary habits and stores of the vitamin. Folate deficiency is implicated in the incidence of neural tube defects. An
inadequate intake of folate also can result in elevations in plasma homocysteine. Because even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is getting increased attention.

Folic acid is marketed as oral tablets containing pteroylglutamic acid or L-methylfolate, as an aqueous solution for injection (5 mg/mL), and in combination with other vitamins and minerals. Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folinic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (see Chapter 61). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. Folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency.

UNTOWARD EFFECTS. There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. Oral folic acid usually is not toxic. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children. The FDA recommends that oral tablets of folic acid be limited to strengths of ≤1 mg.

GENERAL PRINCIPLES OF THERAPY. The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are operative in a specific disease state. The following general principles of therapy should be respected:

• Dietary supplementation is necessary when there is a requirement that may not be met by a “normal” diet. The daily ingestion of a multivitamin preparation containing 400-500 μg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breast-feeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger
A dose of 4 mg/day has been recommended. Patients on total parenteral nutrition should receive folic acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (e.g., hemolytic anemia) generally require 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.

• As with vitamin B₁₂ deficiency, any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient’s history of travel, and the function of the GI tract.

• Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.

• The potential danger of mistreating a patient who has vitamin B₁₂ deficiency with folic acid must be kept in mind. The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate reductase to H₄PteGlu; this circumvents the methylfolate “trap.” However, folate therapy does not prevent or alleviate the neurological defects of vitamin B₁₂ deficiency, and these may progress and become irreversible.

See the 12th edition of the parent text for details on treating the patient who is acutely ill with megaloblastic anemia.
Section V
Hormones and Hormone Antagonists
Endocrinology analyzes the biosynthesis of hormones, their sites of production, and the sites and mechanisms of their action and interaction. The major functions of hormones include the regulation of energy storage, production, and utilization; the adaptation to new environments or conditions of stress; the facilitation of growth and development; and the maturation and function of the reproductive system. Although hormones were originally defined as products of ductless glands, we now appreciate that many organs not classically considered as “endocrine” (e.g., the heart, kidneys, GI tract, adipocytes, and brain) synthesize and secrete hormones that play key physiological roles. In addition, the field of endocrinology has expanded to include the actions of growth factors acting by means of autocrine and paracrine mechanisms, the influence of neurons—particularly those in the hypothalamus—that regulate endocrine function, and the reciprocal interactions of cytokines and other components of the immune system with the endocrine system.

Conceptually, hormones may be divided into 2 classes:

- Hormones that act predominantly via nuclear receptors to modulate transcription in target cells (e.g., steroid hormones, thyroid hormone, and vitamin D)
- Hormones that typically act via membrane receptors to exert rapid effects on signal transduction pathways (e.g., peptide and amino acid hormones)

The receptors for both classes of hormones provide tractable targets for a diverse group of compounds that are among the most widely used drugs in clinical medicine.
THE HYPOTHALAMIC-PITUITARY-ENDOCRINE AXIS

Many of the classic endocrine hormones (e.g., cortisol, thyroid hormone, sex steroids, growth hormone) are regulated by complex reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (Table 38–1). The basic organization of the hypothalamic-pituitary-endocrine axis is summarized in Figure 38–1.

Figure 38–1 Organization of the anterior and posterior pituitary gland. Hypothalamic neurons in the supraoptic (SON) and paraventricular (PVN) nuclei synthesize arginine vasopressin (AVP) or oxytocin (OXY). Most of their axons project directly to the posterior pituitary, from which AVP and OXY are secreted into the systemic circulation to regulate their target tissues. Neurons that regulate the anterior lobe cluster in the mediobasal hypothalamus, including the PVN and the arcuate (ARC) nuclei. They secrete hypothalamic releasing hormones, which reach the anterior pituitary via the hypothalamic-adenohypophyseal portal system and stimulate distinct populations of pituitary cells. These cells, in turn, secrete the trophic (signal) hormones that regulate endocrine organs and other tissues. See Table 38–1 for abbreviations.

Discrete sets of hypothalamic neurons produce different releasing hormones, which are axonally transported to the median eminence. Upon stimulation, these neurons secrete their respective hypothalamic-releasing hormones into the hypothalamic-
adenohypophyseal plexus, which flows to the anterior pituitary gland. The *hypothalamic-releasing hormones* bind to membrane receptors on specific subsets of pituitary cells and stimulate the secretion of the corresponding *pituitary hormones*. The pituitary hormones, which can be thought of as the *master signals*, then circulate to the target endocrine glands where they activate specific receptors to stimulate the synthesis and secretion of the target *endocrine hormones*. These interactions are *feed-forward regulation* in which the master (signal) hormones stimulate the production of target hormones by the endocrine organs.

Superimposed on this positive feed-forward regulation is *negative feedback* regulation, which permits precise control of hormone levels (*Figure 38–2*; see *Figure 38–6*). Typically, the endocrine target hormone circulates to both the hypothalamus and pituitary, where it acts via specific receptors to inhibit the production and secretion of both its hypothalamic-releasing hormone and the regulatory pituitary hormone. In addition, other brain regions have inputs to the hypothalamic-releasing neurons, further integrating the regulation of hormone levels in response to diverse stimuli.
Growth hormone secretion and actions. Two hypothalamic factors, growth hormone-releasing hormone (GHRH) and somatostatin (SST) stimulate or inhibit the release of growth hormone (GH) from the pituitary, respectively. Insulin-like growth factor-1 (IGF-1), a product of GH action on peripheral tissues, causes negative feedback inhibition of GH release by acting at the hypothalamus and the pituitary. The actions of GH can be direct or indirect (mediated by IGF-1). See text for discussion of the other agents that modulate GH secretion and of the effects of locally produced IGF-1. Inhibition, -; stimulation, +;.

PITUITARY HORMONES AND THEIR HYPOTHALAMIC-RELEASING FACTORS

The anterior pituitary hormones can be classified into 3 different groups based on their structural features (Table 38–2):

*See Chapter 42 for further discussion of POMC-derived peptides, including ACTH and α-MSH.*

- Pro-opiomelanocortin (POMC)-derived hormones include *corticotropic* (adrenocorticotropic hormone [ACTH]) and *α-melanocyte-stimulating hormone* (α-MSH). These are derived from POMC by proteolytic processing (see Chapters 18 and 42).
- Somatotropic hormones include *growth hormone* (GH) and *prolactin*. In humans the somatotropic family also includes placental lactogen.
- The glycoprotein hormones—*thyroid-stimulating hormone* (TSH; also called thyrotropin), *luteinizing hormone* (LH; also called lutropin), and *follicle-stimulating hormone* (FSH; also called follitropin). In humans, the glycoprotein hormone family also includes *human chorionic gonadotropin* (hCG).

The synthesis and release of anterior pituitary hormones are influenced by the central nervous system (CNS). Their secretion is positively regulated by a group of peptides referred to as *hypothalamic-releasing hormones* (see Figure 38–1). These include *corticotropin-releasing hormone* (CRH), *growth hormone-releasing hormone* (GHRH), *gonadotropin-releasing hormone* (GnRH), and *thyrotropin-releasing hormone* (TRH). Somatostatin (SST), another
hypothalamic peptide, negatively regulates secretion of pituitary GH and TSH. The neurotransmitter dopamine inhibits the secretion of prolactin by lactotropes.

The posterior pituitary gland, also known as the neurohypophysis, contains the endings of nerve axons arising from the hypothalamus that synthesize either arginine vasopressin or oxytocin (see Figure 38–1). Arginine vasopressin plays an important role in water homeostasis (see Chapter 25); oxytocin plays important roles in labor and parturition and in milk letdown, as discussed in the following sections and in Chapter 66.

SOMATOTROPIC HORMONES: GROWTH HORMONE AND PROLACTIN

GH and prolactin are structurally related members of the somatotropic hormone family and share many biological features. The somatotropes and lactotropes, the pituitary cells that produce and secrete GH and prolactin, respectively, are subject to strong inhibitory input from hypothalamic neurons; for prolactin, this negative dopaminergic input is the dominant regulator of secretion. GH and prolactin act via membrane receptors that belong to the cytokine receptor family and modulate target cell function via very similar signal transduction pathways (see Chapter 3). Several drugs that are used to treat excessive secretion of these hormones are effective to varying degrees for both GH and prolactin.

PHYSIOLOGY

Table 38–2 presents some features of the somatotrophic hormones.

GH is secreted by somatotropes as a heterogeneous mixture of peptides; the principal form is a single polypeptide chain of 22 kDa that has 2 disulfide bonds and is not glycosylated. Alternative splicing produces a smaller form (~20 kDa) with equal bioactivity that makes up 5-10% of circulating GH. Recombinant human GH consists entirely of the 22 kDa form, which provides a way to detect GH abuse. In the circulation, a 55 kDa protein binds approximately 45% of the 22 kDa and 25% of the 20 kDa forms. A second protein unrelated to the GH receptor also binds approximately 5-10% of circulating GH with lower affinity.
Bound GH is cleared more slowly and has a biological $t_{1/2} \sim 10$ times that of unbound GH, suggesting that the bound hormone may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion.

**REGULATION OF SECRETION**

GH secretion is high in children, peaks during puberty, and then decreases in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses. The amplitude of secretory pulses is greatest at night. GHRH, produced by hypothalamic neurons, stimulates GH secretion (see Figure 38–2) by binding to a specific GPCR on somatotropes. The stimulated GHRH receptor couples to $G_s$ to raise intracellular levels of cyclic AMP and $Ca^{2+}$, thereby stimulating GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of short stature in humans. GH and its major peripheral effector, *insulin-like growth factor 1* (IGF-1), act in negative feedback loops to suppress GH secretion. The negative effect of IGF-1 is predominantly through direct effects on the anterior pituitary gland, while the negative feedback action of GH is mediated in part by SST, synthesized in more widely distributed neurons.

SST is synthesized as a 92–amino acid precursor and processed by proteolytic cleavage to generate 2 peptides: SST-28 and SST-14 (Figure 38–3). SST exerts its effects by binding to and activating a family of 5 related GPCRs that signal through $G_i$ to inhibit cyclic AMP formation and to activate $K^+$ channels and protein phosphotyrosine phosphatases.
Figure 38–3 Structures of somatostatin-14 and selected synthetic analogs. Residues that play key roles in binding to SST receptors are shown in red. Octreotide and lanreotide are clinically available synthetic analogs of somatostatin. D-Nal, 3-(2-napthyl)-D-alanyl.

Ghrelin, a 28-amino acid peptide, stimulates GH secretion. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach but also is produced at lower levels at a number of other sites. Both fasting and hypoglycemia stimulate circulating ghrelin levels. Ghrelin acts primarily through a GPCR called the GH secretagogue receptor. Ghrelin also stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. Thus, ghrelin and its receptor act in a complex manner to integrate the functions of the GI tract, the hypothalamus, and the anterior pituitary.

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH and/or SST and thereby affect GH secretion. DA, 5HT, and α₂ adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, glucose, IGF-1, and GH itself inhibit release. Many of the physiological factors that influence prolactin secretion also affect GH secretion. Thus, sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of prolactin secretion is DA, which interacts with the D₂ receptor, a GPCR on lactotropes, to inhibit prolactin secretion (Figure 38–4). Prolactin acts predominantly in women, both during pregnancy and in the postpartum period in women who breast-feed. During pregnancy, the maternal serum prolactin level starts to increase at 8 weeks of gestation, peaks to 250 ng/mL at term, and declines thereafter to prepregnancy levels unless the mother breast-feeds the infant. Suckling or breast manipulation in nursing mothers cause elevation of circulating prolactin levels. Prolactin levels can rise 10- to 100-fold within 30 min of stimulation. This response is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The suckling response becomes less pronounced after several months of breastfeeding, and
prolactin concentrations eventually decline to prepregnancy levels. Prolactin also is synthesized in lactotropes near the end of the luteal phase of the menstrual cycle and by decidual cells early in pregnancy (accounting for the high levels of prolactin in amniotic fluid during the first trimester of human pregnancy).

Figure 38–4 Prolactin secretion and actions. Prolactin is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. Thyrotropin-releasing hormone (TRH), however, can stimulate prolactin release; dopamine inhibits it. Suckling induces prolactin secretion, and prolactin affects lactation and reproductive functions but also has effects on many other tissues. Prolactin is not under feedback control by peripheral hormones.

MOLECULAR AND CELLULAR BASES OF SOMATOTROPIC HORMONE ACTION

Receptors for GH and prolactin belong to the cytokine receptor superfamily; they contain an extracellular hormone-binding domain, a single membrane-spanning region, and an intracellular domain that mediates signal transduction.

GH receptor activation results in the binding of a single GH to 2 receptor monomers and to form a GH-GH receptor ternary complex (initiated by high-affinity interaction of GH with 1 monomer of the GH receptor dimer [mediated by GH site 1], followed by a second, lower affinity interaction of GH with the GH receptor [mediated by GH site 2]); these interactions induce a conformational change that activates downstream signaling. The ligand-occupied GH receptor dimer lacks inherent tyrosine kinase activity but provides docking sites for 2 molecules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase
family. The juxtaposition of 2 JAK2 molecules leads to trans-phosphorylation and autoactivation of JAK2, with consequent tyrosine phosphorylation of cytoplasmic proteins that mediate downstream signaling events (Figure 38–5). Pegvisomant is a GH analog with amino acid substitutions that disrupt the interaction at site 2; pegvisomant binds to the receptor and causes its internalization but cannot trigger the conformational change that stimulates downstream events in the signal transduction pathway.

Figure 38–5 Mechanisms of growth hormone and prolactin action and of GH receptor antagonism. A. Binding of GH to a growth hormone receptor (GHR) homodimer induces autophosphorylation of JAK2. JAK2 then phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of MAPK, which ultimately modulate gene expression. The structurally related prolactin receptor also is a ligand activated homodimer that recruits the JAK-STAT signaling pathway. GHR also activates IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. B. Pegvisomant, a recombinant pegylated variant of human GH, is a high affinity GH antagonist that interferes with GH signaling.
The effects of prolactin on target cells also result from interactions with a cytokine family receptor that is widely distributed and signals through many of the same pathways as the GH receptor. Unlike human GH and placental lactogen, which also bind to the prolactin receptor and thus are lactogenic, prolactin binds specifically to the prolactin receptor and has no somatotropic (GH-like) activity.

**PHYSIOLOGICAL EFFECTS OF THE SOMATOTROPIC HORMONES**

The most striking physiological effect of GH is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after the epiphyses have closed. GH also increases muscle mass (in human subjects with GH deficiency), increases glomerular filtration rate, and stimulates of preadipocyte differentiation into adipocytes. Growth hormone acts directly on adipocytes to increase lipolysis and on hepatocytes to stimulate gluconeogenesis, but its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1. IGF-1 interacts with receptors on the cell surface that mediate its biological activities.

Prolactin effects are limited to tissues that express the prolactin receptor, particularly the mammary gland. Prolactin plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelia and is essential for lactation. Prolactin receptors are present in many other sites, including the hypothalamus, liver, adrenal, testes, ovaries, prostate, and immune system, suggesting that prolactin may play multiple roles outside of the breast. The physiological effects of prolactin at these sites remain poorly characterized.

**PATHOPHYSIOLOGY OF THE SOMATOTROPIC HORMONES**

**EXCESS PRODUCTION OF SOMATOTROPIC HORMONES.** Syndromes of excess secretion of GH and prolactin typically are caused by somatotrope or lactotrope adenomas that oversecrete the respective hormones.
Clinical Manifestations of Excess GH. GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis often is delayed. Mortality is increased at least 2-fold relative to age-matched controls, predominantly due to increased death from cardiovascular disease.

Clinical Manifestations of Excess Prolactin. Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated with increased TRH levels, or from treatment with dopamine receptor antagonists. Most often, hyperprolactinemia is caused by prolactin-secreting pituitary adenomas. Manifestations of prolactin excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, erectile dysfunction, and infertility.

Impaired Production of the Somatotropic Hormones

Clinical Manifestations of Growth Hormone Deficiency. Children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. GH deficiency in adults is associated with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes. The diagnosis of GH deficiency should be entertained in children with height >2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height. In adults, overt GH deficiency usually results from pituitary lesions caused by a functioning or nonfunctioning pituitary adenoma, secondary to trauma, or related to surgery or radiotherapy for a pituitary or suprasellar mass. Almost all patients with multiple deficits in other pituitary hormones also have deficient GH secretion.

Prolactin Deficiency. Prolactin deficiency may result from conditions that damage the pituitary gland, but prolactin is not given as part of endocrine
replacement therapy.

PHARMACOTHERAPY OF SOMATOTROPIN HORMONE DISORDERS

GROWTH HORMONE EXCESS

Treatment options in gigantism/acromegaly include transsphenoidal surgery, radiation, and drugs that inhibit GH secretion or action.

SOMATOSTATIN ANALOGS. The development of synthetic analogs of SST has revolutionized the medical treatment of acromegaly. The goal of treatment is to decrease GH levels to <2.5 ng/mL after an oral glucose-tolerance test and to bring IGF-1 levels to within the normal range for age and sex. The 2 SST analogs used widely are octreotide and lanreotide, synthetic derivatives that have longer half-lives and bind preferentially to SST₂ and SST₅ receptors (see Figure 38–3). Octreotide (100 μg) administered subcutaneously 3 times daily is 100% bioactive; peak effects are seen within 30 min, serum t½ is ~90 min, and duration of action is ~12 h. A long-acting, slow-release form (SANDOSTATIN-LAR DEPOT) greatly reduces the injection frequency. Administered intramuscularly in a dose of 20 or 30 mg once every 4 weeks, octreotide LAR is at least as effective as the regular formulation and as well tolerated. A lower dose of 10 mg per injection should be used in patients requiring hemodialysis or with hepatic cirrhosis. In addition to its effect on GH secretion, octreotide can decrease tumor size, although tumor growth generally resumes after octreotide treatment is stopped.

Lanreotide is a long-acting octapeptide SST analog that causes prolonged suppression of GH secretion when administered in a 30-mg dose intramuscularly. Its efficacy appears comparable to that of the long-acting formulation of octreotide; its duration of action is shorter; thus, it is administered at 10- or 14-day intervals. A supersaturated aqueous formulation of lanreotide, lanreotide autogel (SOMATULINE DEPOT), has been approved for use in the U.S. It is supplied in prefilled syringes containing 60, 90, or 120 mg lanreotide and administered by deep subcutaneous injection once every 4 weeks.

Pasireotide (SIGNIFOR) is a cyclohexapeptide SST analog that is approved for the
treatment of Cushing disease in patients who are ineligible for pituitary surgery or in whom surgery has failed. Pasireotide binds to multiple SST receptors (1, 2, 3, and 5) but has the highest affinity for SST\textsubscript{5} receptor. The recommended dose range is 0.3 to 0.9 mg administered by subcutaneous injection twice daily.

**Adverse Effects.** GI side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving octreotide. These symptoms usually diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving octreotide develop gallstones, presumably due to decreased gallbladder contraction and bile secretion. Compared with SST, octreotide reduces insulin secretion to a lesser extent and only infrequently affects glycemic control. Bradycardia and QT prolongation may occur in patients with underlying cardiac disease. Inhibitory effects on TSH secretion may lead to hypothyroidism, and thyroid function tests should be evaluated periodically. The incidence and severity of side effects associated with lanreotide and pasireotide are similar to those of octreotide. Pasireotide suppresses of ACTH secretion in Cushing disease and may lead to a decrease in cortisol secretion and to hypocortisolism.

**Other Therapeutic Uses.** SST blocks not only GH secretion but also the secretion of other hormones, growth factors, and cytokines. Thus, octreotide and the slow-release formulations of SST analogs have been used to treat symptoms associated with metastatic carcinoid tumors (e.g., flushing and diarrhea) and adenomas secreting vasoactive intestinal peptide (e.g., watery diarrhea). Octreotide also is the treatment of choice for patients who have thyrotrope adenomas that oversecrete TSH.

**GROWTH HORMONE ANTAGONISTS.** Pegvisomant (SOMAVERT) is a GH receptor antagonist approved for the treatment of acromegaly. Pegvisomant binds to the GH receptor but does not activate JAK-STAT signaling or stimulate IGF-1 secretion (see Figure 38–5). Pegvisomant is administered subcutaneously as a 40-mg loading dose followed by administration of 10 mg/day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 40 mg/day. Pegvisomant should not be used in patients with an unexplained elevation of hepatic transaminases, and liver function tests should be monitored in all patients. In addition, lipohypertrophy has occurred at injection sites, sometimes requiring cessation of therapy; this is believed to reflect the inhibition
of direct actions of GH on adipocytes. Because of concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is strongly recommended.

PROLACTIN EXCESS

The therapeutic options for patients with prolactinomas include transsphenoidal surgery, radiation, and treatment with DA receptor agonists that suppress prolactin production via activation of D₂ receptors.

DOPAMINE RECEPTOR AGONISTS. Bromocriptine, cabergoline, and quinagolide relieve the inhibitory effect of prolactin on ovulation and permit most patients with prolactinomas to become pregnant. Bromocriptine generally is recommended for fertility induction in patients with hyperprolactinemia. Quinagolide should not be used when pregnancy is intended. These agents generally decrease both prolactin secretion and the size of the adenoma. Over time, especially with cabergoline, the prolactinoma may decrease in size to the extent that the drug can be discontinued without recurrence of the hyperprolactinemia.

BROMOCRIPTINE. Bromocriptine (Parlodel) is the dopamine receptor agonist against which newer agents are compared. Bromocriptine is a semisynthetic ergot alkaloid that interacts with D₂ receptors to inhibit spontaneous and TRH-induced release of prolactin; to a lesser extent, it also activates D₁ receptors. The oral dose of bromocriptine is well absorbed; however, only 7% of the dose reaches the systemic circulation because of extensive first-pass metabolism in the liver. Bromocriptine has a short elimination t₁/₂ (between 2 and 8 h). A slow-release oral form is available outside of the U.S. Bromocriptine may be administered vaginally (2.5 mg once daily), with fewer GI side effects. Bromocriptine normalizes serum prolactin levels patients with prolactinomas and decreases tumor size in >50% of patients. The underlying adenoma, and hyperprolactinemia and tumor growth recur upon cessation of therapy. At higher concentrations, bromocriptine is used in the management of acromegaly, and at still higher concentrations is used in the management of Parkinson disease (see Chapter 22).
**Adverse Effects.** Frequent side effects include nausea and vomiting, headache, and postural hypotension. Less frequently, nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia are observed. These adverse effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack. Patients often develop tolerance to the adverse effects.

**CABERGOLINE.** Cabergoline (DOSTINEX) is an ergot derivative with a longer $t_{1/2}$ (~65 h), higher affinity, and greater selectivity for the D$_2$ receptor than bromocriptine. It undergoes significant first-pass metabolism in the liver. Cabergoline is the preferred drug for the treatment of hyperprolactinemia. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. The dose can be increased to a maximum of 1.5-2 mg 2 or 3 times a week as tolerated; the dose should only be increased once every 4 weeks. Cabergoline induces remission in a significant number of patients with prolactinomas. At higher doses, cabergoline is used in some patients with acromegaly.

**Adverse Effects.** Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. Cabergoline has been linked to valvular heart disease, an effect proposed to reflect agonist activity at the serotonin 5HT$_{2B}$ receptor.

**QUINAGOLIDE.** Quinagolide (NORPROLAC) is a non-ergot D$_2$ agonist with a $t_{1/2}$ (22 h). Quinagolide is administered once daily at doses of 0.1-0.5 mg/day. It is not approved for use in the U.S. but has been used in the E.U.

**GROWTH HORMONE DEFICIENCY**

**SOMATROPIN.** Replacement therapy is well established in GH-deficient children and is gaining wider acceptance for GH-deficient adults. Currently, human GH is produced by recombinant DNA technology. *Somatropin* refers to the many GH preparations whose sequences match that of native GH (ACCRETROPIN, GENOTROPIN, HUMATROPE, NORDITROPIN, NUTROPIN, OMNITROPE, SAIZEN, SEROSTIM, TEV-TROPIN, VALTROPIN, and ZORBTIVE); *somatrem* refers to a derivative of GH with an additional methionine at the
amino terminus that is no longer available in the U.S.

**Pharmacokinetics.** As a peptide hormone, GH is administered subcutaneously, with a bioavailability of 70%. Although the circulating \( t_{1/2} \) of GH is only 20 min, its biological \( t_{1/2} \) is considerably longer, and once-daily administration is sufficient.

**Indications for Growth Hormone Treatment.** GH deficiency in children is a well-accepted cause of short stature. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner syndrome, Noonan syndrome, Prader-Willi syndrome, chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., >2.25 standard deviations below mean height for age and sex but with normal laboratory indices of GH levels). Severely affected GH-deficient adults may benefit from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short bowel syndrome (based on the finding that GH stimulates the adaptation of GI epithelial cells).

**Contraindications.** GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of neoplasia, and antitumor therapy should be completed before GH therapy is initiated. Other contraindications include proliferative retinopathy or severe nonproliferative diabetic retinopathy. In Prader-Willi syndrome, sudden death has been observed when GH was given to children who were severely obese or who had severe respiratory impairment.

**Therapeutic Uses.** In GH-deficient children, somatropin typically is administered in a dose of 25-50 μg/kg/day subcutaneously in the evening; higher daily doses (e.g., 50-67 μg/kg) are employed for patients with Noonan syndrome or Turner syndrome, who have partial GH resistance. In children with overt GH deficiency, measurement of serum IGF-1 levels sometimes is used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. GH is continued until the epiphyses are fused and also may be
extended into the transition period from childhood to adulthood. For adults, a typical starting dose is 150-300 μg/day, with higher doses used in younger patients transitioning from pediatric therapy. Either an elevated serum IGF-1 level or persistent side effects mandates a decrease in dose; conversely, the dose can be increased (typically by 100-200 μg/day) if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen inhibits GH action, women taking oral—but not transdermal—estrogen may require larger GH doses to achieve the target IGF-1 level.

**Adverse Effects of Growth Hormone Therapy.** In children, GH therapy is associated with remarkably few side effects. Rarely, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, and/or vomiting. Because of this, funduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. The consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. Because an increased incidence of type 2 diabetes mellitus has been reported, fasting glucose levels should be followed periodically during therapy. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis. Side effects associated with the initiation of GH therapy in adults include peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias, which occur most frequently in patients who are older or obese and generally respond to a decrease in dose. Estrogens (e.g., birth control medications and estrogen supplements) inhibit GH action. GH therapy can increase the metabolic inactivation of glucocorticoids in the liver.

**INSULIN-LIKE GROWTH FACTOR 1.** Based on the hypothesis that GH predominantly acts via increases in IGF-1 (see Figure 38–2), IGF-1 has been developed for therapeutic use. Recombinant human IGF-1 (mecasermin [INCRELEX]) and a combination of recombinant human IGF-1 with its binding protein, IGFBP-3 (mecasermin rinfabate [PLEX]), are FDA-approved. The latter formulation was subsequently discontinued for use in short stature due to patent issues, although it remains available for other conditions such as severe insulin resistance, muscular dystrophy, and HIV-related adipose redistribution syndrome.
**ADME.** Mecasermin is administered by subcutaneous injection and absorption is virtually complete. IGF-1 in circulation is bound by 6 proteins; a ternary complex that includes IGFBP-3 and the acid labile subunit accounts for >80% of the circulating IGF-1. This protein binding prolongs the $t_{1/2}$ of IGF-1 to ~6 h. Both the liver and kidney have been shown to metabolize IGF-1.

**Therapeutic Uses.** Mecasermin is FDA-approved for patients with impaired growth secondary to mutations in the GH receptor or postreceptor signaling pathway, patients who develop antibodies against GH that interfere with its action, and patients with IGF-1 gene defects that lead to primary IGF-1 deficiency. Typically the starting dose is 40-80 μg/kg per dose twice daily by subcutaneous injection, with a maximum of 120 μg/kg per dose twice daily. In patients with impaired growth secondary to GH deficiency or with idiopathic short stature, mecasermin stimulates linear growth but is less effective than conventional therapy using recombinant GH.

**Adverse Effects.** Side effects of mecasermin include hypoglycemia and lipohypertrophy. To diminish the frequency of hypoglycemia, mecasermin should be administered shortly before or after a meal or snack. Lymphoid tissue hypertrophy, including enlarged tonsils, also is seen and may require surgical intervention. Other adverse effects are similar to those associated with GH therapy.

**Contraindications.** Mecasermin should not be used for growth promotion in patients with closed epiphyses. It should not be given to patients with active or suspected neoplasia and should be stopped if evidence of neoplasia develops.

**GROWTH HORMONE-RELEASING HORMONE**

Ser morelin (Sermorelin) is a synthetic form of human GHRH that corresponds in sequence to the first 29 amino acids of human GHRH (a 44–amino acid peptide) and has full biological activity. Although sermorelin is FDA-approved for treatment of GH deficiency and as a diagnostic agent to differentiate between hypothalamic and pituitary disease, the drug was withdrawn from the U.S. market in late 2008.

**THE GLYCOPROTEIN HORMONES: TSH AND THE GONADOTROPINS**
The gonadotropins include \textit{LH}, \textit{FSH}, and \textit{hCG}. They are referred to as the gonadotropins because of their actions on the gonads. Together with TSH, they constitute the glycoprotein family of pituitary hormones (see Table 38–2). Each hormone is a glycosylated heterodimer containing a common \(\alpha\) subunit and a distinct \(\beta\) subunit that confers specificity of action.

LH and FSH are synthesized and secreted by gonadotropes, which make up \~10\% of the hormone-secreting cells in the anterior pituitary. hCG is produced by the placenta only in primates and horses. GnRH stimulates pituitary gonadotropin production, which is further regulated by feedback effects of the gonadal hormones (Figure 38–6; see Figure 40–2 and Chapters 40 and 41). TSH is measured in the diagnosis of thyroid disorders, and recombinant TSH is used in the evaluation and treatment of well-differentiated thyroid cancer (see Chapter 39).
Figure 38–6 The hypothalamic-pituitary-gonadal axis. A single hypothalamic-releasing factor, gonadotropin-releasing hormone (GnRH), controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) exert feedback inhibition at the level of the pituitary and the hypothalamus. The preovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, a family of polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

PHYSIOLOGY OF THE GONADOTROPINS

STRUCTURE-FUNCTION ASPECTS OF THE GONADOTROPINS. The carbohydrate residues on the gonadotropins influence their rates of clearance from the circulation, and also play a role in activating the gonadotropin receptors. Among the gonadotropin β subunits, that of hCG is most divergent
because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues that prolong its $t_{1/2}$. The longer $t_{1/2}$ of hCG has some clinical relevance for its use in assisted reproduction technologies (see Chapter 66).

**REGULATION OF GONADOTROPIN SYNTHESIS AND SECRETION.** The predominant regulator of gonadotropin synthesis and secretion is the hypothalamic peptide GnRH. It is a decapeptide with blocked amino and carboxyl termini derived by proteolytic cleavage of a 92–amino acid precursor peptide.

GnRH release is pulsatile and is governed by a hypothalamic neural pulse generator (primarily in the arcuate nucleus) that controls the frequency and amplitude of GnRH release. The GnRH pulse generator is active late in fetal life and for ~1 year after birth but decreases considerably thereafter. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and downregulation of GnRH receptors on pituitary gonadotropes.

**Molecular and Cellular Bases of GnRH Action.** GnRH signals through a specific GPCR on gonadotropes that activates $G_{q/11}$ and stimulates the PLC-IP$_3$-Ca$^{2+}$ pathway (see Chapter 3), resulting in increased synthesis and secretion of LH and FSH. Although cyclic AMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenylyl cyclase activity. GnRH receptors also are present in the ovary, testis, and other sites, where their physiological significance remains to be determined.

**Other Regulators of Gonadotropin Production.** Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate (see Figure 38–6). The feedback effects of gonadal steroids are dependent on sex, concentration, and time. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator. Higher and more sustained levels of estradiol have positive feedback effects that
ultimately result in the gonadotropin surge that triggers ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part via its conversion by aromatase to estradiol. Gonadotropin production also is regulated by the inhibins, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibin A and B are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to inhibit FSH secretion without affecting that of LH.

MOLECULAR AND CELLULAR BASES OF GONADOTROPIN ACTION. The actions of LH and hCG on target tissues are mediated by the LH receptor; those of FSH are mediated by the FSH receptor. The FSH and LH receptors couple to Gs to activate the adenylyl cyclase-cyclic AMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate PKC and Ca2+ signaling pathways via Gq-mediated effects on PLCβ. Most actions of the gonadotropins can be mimicked by cyclic AMP analogs.

PHYSIOLOGICAL EFFECTS OF GONADOTROPINS. In men, LH acts on testicular Leydig cells to stimulate the de novo synthesis of androgens, primarily testosterone, from cholesterol. FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation. In women, the actions of FSH and LH are more complicated. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the expression of aromatase in granulosa cells, thereby stimulating the production of estradiol. LH acts on the theca cells to stimulate the de novo synthesis of androstenedione, the major precursor of ovarian estrogens in premenopausal women (see Figure 40–1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

CLINICAL DISORDERS OF THE HYPOTHALAMIC-PITUITARY-GONADAL AXIS

Clinical disorders of the hypothalamic-pituitary-gonadal axis can manifest either as alterations in levels and effects of sex steroids (hyper- or hypogonadism) or as impaired reproduction. Deficient sex steroid production resulting from hypothalamic or pituitary defects is
termed hypogonadotropic hypogonadism because circulating levels of gonadotropins are either low or undetectable. In contrast, reproductive disorders caused by processes that directly impair gonadal function are termed hypergonadotropic because the impaired production of sex steroids leads to a loss of negative feedback inhibition, thereby increasing the synthesis and secretion of gonadotropins.

**GnRH AND ITS SYNTHETIC AGONIST ANALOGS**

A synthetic peptide comprising the native sequence of GnRH has been used both diagnostically and therapeutically in human reproductive disorders. In addition, a number of GnRH analogs with structural modifications have been synthesized and brought to market.

**SYNTHETIC GnRH.** Synthetic GnRH (gonadorelin [FACTREL, LUTREPULSE]) is FDA-approved; problems with availability have limited its clinical use in the U.S. As a peptide, gonadorelin is administered either subcutaneously or intravenously. It is well absorbed following subcutaneous injection and has a circulating $t_{1/2}$ of 2-4 min. For therapeutic uses, it must be administered in a pulsatile manner to avoid downregulation of the GnRH receptor.

**GnRH CONGENERS.** Synthetic agonist congeners of GnRH have longer half-lives than native GnRH. After a transient stimulation of gonadotropin secretion, they downregulate the GnRH receptor and inhibit gonadotropin secretion. The available GnRH agonists contain substitutions of the native sequence at position 6 that protect against proteolysis and substitutions at the carboxyl terminus that improve receptor-binding affinity. Compared to GnRH, these analogs exhibit enhanced potency and prolonged duration of action (see Table 38–3 in the 12th edition of the parent text).

**Pharmacokinetics.** The myriad formulations of GnRH agonists provide for diverse applications, including relatively short-term effects (e.g., assisted reproduction technology) and more prolonged action (e.g., depot forms that inhibit gonadotropin secretion in GnRH-dependent precocious puberty). The rates and extents of absorption thus vary considerably. The intranasal formulations have bioavailability (~4%) that is considerably lower than those of
the parenteral formulations.

**Clinical Uses.** The depot form of the GnRH agonist leuprolide (LUPRON) has been used diagnostically to differentiate between GnRH-dependent and GnRH-independent precocious puberty. Leuprolide depot (3.75 mg) is injected subcutaneously, and serum LH is measured 2 h later. A plasma LH level of >6.6 mIU/mL is diagnostic of GnRH-dependent (central) disease. Clinically, the various GnRH agonists are used to achieve pharmacological castration in disorders that respond to reduction in gonadal steroids. A clear indication is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a depot form of a GnRH agonist. Long-acting GnRH agonists are used for palliative therapy of hormone responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (see Chapters 40-42). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine fibroids, acute intermittent porphyria, and priapism. Depot preparations can be administered subcutaneously or intramuscularly monthly or every 3 months. The long-lasting GnRH agonists have been used to avoid a premature LH surge, and thus ovulation, in various ovarian stimulation protocols for in vitro fertilization.

**Adverse Effects.** The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes and decreased bone density in both sexes, vaginal dryness and atrophy in women, and erectile dysfunction in men). Because of these effects, therapy in non-life-threatening diseases such as endometriosis or uterine fibroids generally is limited to 6 months. Postmarketing surveillance noted an increase in the incidence of pituitary apoplexy, a syndrome of headache, neurological manifestations, and impaired pituitary function that usually results from infarction of a pituitary adenoma. GnRH agonists are contraindicated in pregnant women (FDA Category X).

**Formulations and Indications.** Leuprolide (LUPRON, ELIGARD) is formulated in multiple doses for injection: subcutaneous (500 mg/day), subcutaneous depot (7.5 mg/month; 22.5 mg/3 months; 30 mg/4 months; 45 mg/6 months), and intramuscular depot (3.75 mg/month; 11.25 mg/3 months). It is approved for endometriosis, uterine fibroids, advanced prostate cancer, and central precocious
puberty. **Goserelin (ZOLADEX)** is formulated as a subcutaneous implant (3.6 mg/month; 10.8 mg/12 weeks). It is approved for endometriosis and advanced prostate and breast cancer. **Histrelin (VANTAS, SUPRELIN LA)** is formulated as a subcutaneous implant (50 mg/12 months). It is approved for central precocious puberty and advanced prostate cancer. **Nafarelin (SYNAREL)** is formulated as a nasal spray (200 μg/spray). It is approved for endometriosis (400 μg/day) and central precocious puberty (1600 μg/day). **Triptorelin (TRELSTAR DEPOT, TRELSTAR LA)** is formulated for depot intramuscular injection (3.75 mg/month; 11.25 mg/12 weeks) and approved for advanced prostate cancer. **Buserelin** and **Deslorelin** are not available in the U.S.

**GnRH ANTAGONIST ANALOGS**

Two GnRH antagonists, **ganirelix (ANTAGON)** and **cetrorelix (CETROTIDE)**, are FDA-approved to suppress the LH surge and thus prevent premature ovulation in ovarian-stimulation protocols (see Chapter 66).

Both GnRH antagonists are formulated for subcutaneous administration. Bioavailability exceeds 90% within 1-2 h, and the t$_{1/2}$ varies depending on the dose. Once-daily administration suffices for therapeutic effect. Hypersensitivity reactions, including anaphylaxis, have been noted in postmarketing surveillance, some with the initial dose. When used in conjunction with gonadotropin injections for assisted reproduction, the effects of estrogen withdrawal (e.g., hot flashes) are not seen. GnRH antagonists are contraindicated in pregnant women (FDA Category X).

Cetrorelix is also used off label for endometriosis and uterine fibroids, both of which are estrogen dependent. As antagonists rather than agonists, these drugs do not transiently increase gonadotropin secretion and sex steroid biosynthesis.

**NATURAL AND RECOMBINANT GONADOTROPINS**

The gonadotropins are used for both diagnosis and therapy in reproductive endocrinology. For further discussion of the uses of gonadotropins in female reproduction, see Chapter 66.
The original gonadotropin preparations for clinical therapy were prepared from human urine and included chorionic gonadotropin, obtained from the urine of pregnant women, and menotropins, obtained from the urine of postmenopausal women. Highly purified preparations of human gonadotropins now are prepared using recombinant DNA technology and exhibit less batch-to-batch variation. This technology is being used to produce forms of gonadotropins with increased half-lives or higher clinical efficacy. One such “designer” gonadotropin, FSH-CTP, contains the β subunit of FSH fused to the carboxy-terminal extension of hCG, thereby increasing considerably the $t_{1/2}$ of the recombinant protein.

**PREPARATIONS**

**FOLLICLE-STIMULATING HORMONE**

FSH has long been a mainstay of regimens for either ovarian stimulation or in vitro fertilization. The original menotropin formulations (Repronex) contained roughly equal amounts of FSH and LH, as well as a number of other urinary proteins, and were administered intramuscularly to diminish local reactions. Urofollitropin (uFSH; Bravelle, Menopur), prepared by immunoconcentration of FSH with monoclonal antibodies, is pure enough to be administered subcutaneously. The amount of LH contained in such preparations is diminished considerably. Recombinant FSH (rFSH) is prepared by expressing cDNAs encoding the α and β subunits of human FSH in mammalian cell lines, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The 2 available rFSH preparations (follitropin [Gonal-F] and follitropin [Follistim, Puregon]) differ slightly in their carbohydrate structures; both can be administered subcutaneously because they are considerably purer. The relative advantages of recombinant FSH versus urine-derived gonadotropins have not been definitively established.

**HUMAN CHORIONIC GONADOTROPIN**

The hCG used clinically originally came from the urine of pregnant women. Several urine-derived preparations are available (Novarel, Pregnyl, Profasi); all of them are administered intramuscularly due to local reactions. Recombinant hCG (choriogonadotropin alfa [Ovidrel]) also has reached clinical use.

**RECOMBINANT HUMAN LH**
Human LH produced using recombinant DNA technology and designated lutropin alfa (Luveris, LHadi) now is available (see Chapter 66).

**DIAGNOSTIC USES**

*Pregnancy Testing.* During pregnancy, the placenta produces significant amounts of hCG, which can be detected in maternal urine. Over-the-counter pregnancy kits containing antibodies specific for the unique β subunit of hCG qualitatively assay for the presence of hCG and can detect pregnancy within a few days after a woman’s first missed menstrual period.

*Timing of Ovulation.* Ovulation occurs ~36 h after the onset of the LH surge. Therefore, urinary concentrations of LH, as measured with an over-the-counter radioimmunoassay kit, can be used to predict the time of ovulation.

*Localization of Endocrine Disease.* Measurements of plasma LH and FSH levels with β subunit–specific radioimmunoassays are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotrophic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. A plasma FSH level of ≥ 10-12 mIU/mL on day 3 of the menstrual cycle, is associated with reduced fertility.

The administration of hCG can be used to stimulate testosterone production and thus to assess Leydig cell function in males suspected of having primary hypogonadism (e.g., in delayed puberty). Serum testosterone levels are assayed after multiple injections of hCG. A diminished testosterone response to hCG indicates Leydig cell failure; a normal testosterone response suggests a hypothalamic-pituitary disorder and normal Leydig cells.

**THERAPEUTIC USES**

*Male Infertility.* In men with impaired fertility secondary to gonadotropin deficiency (hypogonadotrophic hypogonadism), gonadotropins can establish or restore fertility. Treatment typically is initiated with hCG (1500-2000 IUs intramuscularly or subcutaneously) 3 times per week until the plasma testosterone level indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to 2000 IU twice a week or 1000 IU 3 times a week, and menotropins (FSH + LH) or recombinant FSH is injected 3 times a week (typical
dose of 150 IU) to fully induce spermatogenesis.

The most common side effect of gonadotropin therapy in males is gynecomastia, which presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for >6 months. Once spermatogenesis has been initiated, ongoing treatment with hCG alone usually is sufficient to support sperm production.

**Cryptorchidism.** Cryptorchidism, the failure of 1 or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG has been used by some to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for 6 doses.

**POSTERIOR PITUITARY HORMONES: OXYTOCIN AND VASOPRESSIN**

The structures of the neurohypophyseal hormones oxytocin and arginine vasopressin (also called antidiuretic hormone, or ADH) and the physiology and pharmacology of vasopressin are presented in Chapter 25. The following discussion emphasizes the physiology of oxytocin. Therapeutic uses of synthetic oxytocin as a uterine-stimulating agent to induce or augment labor in selected pregnant women and to decrease postpartum hemorrhage are described in Chapter 66.

**PHYSIOLOGY OF OXYTOCIN**

Oxytocin is a cyclic nonapeptide that differs from vasopressin by only 2 amino acids (see Chapter 25). It is synthesized as a larger precursor in neurons whose cell bodies reside in the paraventricular nucleus and, to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor peptide is rapidly cleaved
to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta. Oxytocin acts via a specific GPCR (OXT) closely related to the V$_{1a}$ and V$_2$ vasopressin receptors. In the human myometrium, OXT couples to G$_q$/G$_{11}$, activating the PLC$\beta$-IP$_3$-Ca$^{2+}$ pathway and enhancing activation of voltage-sensitive Ca$^{2+}$ channels.

Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits its release. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release: ethanol inhibits release; pain, dehydration, hemorrhage, and hypovolemia stimulate release. Based on the behavior of intravenously administered oxytocin during labor induction, the plasma $t_{1/2}$ of oxytocin is ~13 min.

**PHYSIOLOGICAL EFFECTS OF OXYTOCIN**

**Uterus.** Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the oxytocin receptors. Because of difficulties associated with the measurement of oxytocin levels and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy is debated. Exogenous oxytocin can enhance rhythmic contractions at any time, but an 8-fold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy, and is accompanied by a 30-fold increase in oxytocin receptor numbers. The oxytocin antagonist atosiban is effective in suppressing preterm labor. Progesterone antagonizes the stimulatory effect of oxytocin in vitro, and refractoriness to progesterone in late pregnancy may contribute to the normal initiation of human parturition.

**Breast.** Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces
oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

**Brain.** Studies in rodents and humans have implicated oxytocin as an important CNS regulator of trust and of autonomic systems linked to anxiety and fear.

**CLINICAL USE OF OXYTOCIN**

Oxytocin is used therapeutically only to induce or augment labor and to treat or prevent postpartum hemorrhage (see Chapter 66). Deficiencies of oxytocin associated with disorders of the posterior pituitary impair milk letdown after delivery and may be one of the earliest signs of pituitary insufficiency secondary to postpartum hemorrhage (Sheehan syndrome); oxytocin is not used clinically in this setting.
Thyroid hormone is essential for normal development, especially of the central nervous system (CNS). In the adult, thyroid hormone maintains metabolic homeostasis and influences the function of virtually all organ systems. Thyroid hormone contains iodine that must be supplied by nutritional intake. The thyroid gland contains large stores of thyroid hormone in the form of thyroglobulin. These stores maintain systemic concentrations of thyroid hormone despite variations in iodine availability and nutritional intake. The thyroidal secretion is predominantly the prohormone thyroxine, which is converted in the liver and other tissues to the active form, triiodothyronine. Local activation of thyroxine also occurs in target tissues (e.g., brain and pituitary) and is increasingly recognized as an important regulatory step in thyroid hormone action. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone, thyrotropin (TSH), in a negative-feedback system. The predominant actions of thyroid hormone are mediated via nuclear thyroid hormone receptors (TRs) and modulating transcription of specific genes.

Overt hyperthyroidism and hypothyroidism, thyroid hormone excess or deficiency, are usually associated with dramatic clinical manifestations. Milder disease often has a more subtle clinical presentation and is identified based on abnormal biochemical tests of thyroid function. Maternal and neonatal hypothyroidism, due to iodine deficiency, remains the major preventable cause of mental retardation worldwide. Treatment of the hypothyroid patient consists of thyroid hormone replacement. Treatments for hyperthyroidism include antithyroid drugs to decrease hormone synthesis and secretion, destruction of the gland by the administration of radioactive iodine, or surgical removal. In most patients, disorders of thyroid function can be either cured or have their diseases controlled. Likewise, thyroid malignancies are most often localized and
resectable. Metastatic disease often responds to radioiodide treatment but may become highly aggressive and unresponsive to conventional treatment.

**THYROID**

The thyroid gland produces 2 fundamentally different types of hormones. The thyroid follicle produces the iodothyronine hormones *thyroxine* (T4) and *3,5,3'-triiodothyronine* (T3). The thyroid’s parafollicular cells (C cells) produce calcitonin (see Chapter 44).

**BIOSYNTHESIS OF THYROID HORMONES.** The thyroid hormones are synthesized and stored as amino acid residues of *thyroglobulin*, a complex glycoprotein made up of 2 apparently identical subunits (330 kDa each) and constituting the vast majority of the thyroid follicular colloid. The thyroid gland is unique in storing great quantities of potential hormone in this way, and extracellular thyroglobulin can represent a large portion of the thyroid mass. The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are summarized in Figure 39–1 and described as follows:
**Figure 39–1 Major pathways of thyroid hormone biosynthesis and release.**

Abbreviations: Tg, thyroglobulin; DIT, diiodotyrosine; MIT, monoidotyrosine; TPO, thyroid peroxidase; HOI, hypoiodous acid; EOI, enzyme-linked species; D1 and D2, deiodinases; PTU, propylthiouracil; MMI, methimazole.

**A. Uptake of Iodide.** Iodine ingested in the diet reaches the circulation in the form of iodide ion (I\(^–\)). Under normal circumstances, the I\(^–\) concentration in the blood is very low (0.2-0.4 μg/dL; ~15-30 nM), but the thyroid actively transports the ion via a specific membrane-bound protein, termed the \textit{sodium-iodide symporter} (NIS). As a result, the ratio of thyroid to plasma iodide concentration is usually between 20 and 50 and can exceed 100 when the gland is stimulated. Iodide transport is inhibited by a number of ions such as thiocyanate and perchlorate. Thyrotropin (thyroid-stimulating hormone [TSH]) stimulates NIS gene expression and promotes insertion of NIS protein into the membrane in a functional configuration. Thus, decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression. Iodine accumulation throughout the body is mediated by a single NIS gene. Individuals with congenital NIS gene mutations have absent or defective iodine concentration in all tissues known to concentrate iodine.

**B. Oxidation and Iodination.** The oxidation of iodide to its active form is accomplished by \textit{thyroid peroxidase}. The reaction results in the formation of monoidotyrosyl (MIT) and diiodotyrosyl (DIT) residues in thyroglobulin just prior to its extracellular storage in the lumen of the thyroid follicle.

**C. Formation of Thyroxine and Triiodothyronine from Iodotyrosines.** The remaining synthetic step is the coupling of 2 diiodotyrosyl residues to form thyroxine (T\(_4\)) or of a monoidotyrosyl and a diiodotyrosyl residue to form triiodothyronine (T\(_3\)). These oxidative reactions also are catalyzed by \textit{thyroid peroxidase}. Intrathyroidal and secreted T\(_3\) are also generated by the 5′- deiodination of thyroxine.

**D. Resorption; and Proteolysis of Colloid; E. Deiodination of DIT/MIT; F. deiodination of T\(_4\); G. Secretion of Thyroid Hormones.** Because T\(_4\) and T\(_3\) are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a
thyroglobulin receptor, *megalin*. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. TSH enhances the degradation of thyroglobulin by increasing the activity of *thiol endopeptidases* of the lysosomes, which selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases. The liberated hormones then exit the cell mostly as T₄, some as T₃, via a process of deiodination (*Figure 39–2*) that also occurs peripherally (*Figure 39–3*).

![Pathways of iodothyronine deiodination.](image)

*Figure 39–2* Pathways of iodothyronine deiodination.
**Figure 39–3** Deiodinase isozymes. D1, type I iodothyronine 5'-deiodinase; D2, type II iodothyronine 5'-deiodinase; D3, type III iodothyronine 5-deiodinase; BAT, brown adipose tissue.

**CONVERSION OF T₄ TO T₃ IN PERIPHERAL TISSUES.** The normal daily production of T₄ is estimated to range between 80 and 100 μg; that of T₃ is between 30 and 40 μg. Although T₃ is secreted by the thyroid, metabolism of T₄ by 5', or outer ring, deiodination in the peripheral tissues accounts for ~80% of circulating T₃. In contrast, removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3',5'-triiodothyronine (reverse T₃ or rT₃; **Figure 39–2**). Under normal conditions, ~40% of T₄ is converted to each of T₃ and rT₃, and ~20% is metabolized via other pathways, such as glucuronidation in the liver and excretion in the bile. Normal circulating concentrations of T₄ in plasma range from 4.5-11 μg/dL; those of T₃ are ~1/100 of that (60-180 ng/dL). Triiodothyronine has a much higher affinity for the nuclear thyroid hormone receptor compared with thyroxine and is much more potent biologically on a molar basis.

There are 3 iodothyronine deiodinases. Forms 1 and 2 (D1, D2) convert T₄ to T₃. D1 is expressed primarily in the liver and kidney, and also in the thyroid and pituitary (**Figure 39–3**). It is upregulated in hyperthyroidism; downregulated in hypothyroidism, and inhibited by the anti-thyroid drug *propylthiouracil*. D2 is expressed primarily in the CNS (including the pituitary and hypothalamus) and brown adipose tissue, also in the thyroid, and at very low levels in skeletal
muscle. The activity of D2 is unaffected by propylthiouracil. D2 localizes to the endoplasmic reticulum, which facilitates access of D2-generated T₃ to the nucleus. Hence organs that express D2 tend to use the locally generated T₃. D2 is regulated by T₄ such that elevated levels of the enzyme are found in hypothyroidism and suppressed levels are found in hyperthyroidism. Type 3 deiodinase (D3) catalyzes inner ring- or 5-deiodination, the main inactivating pathway of T₃ metabolism; D1 performs this function to some extent. D3 is found at highest levels in the CNS and placenta, and is also expressed in skin and uterus. The 3 deiodinases contain the rare amino acid selenocysteine in their active sites. Mutations in 1 such protein, SECIS binding protein 2, are associated with abnormal circulating thyroid hormone levels.

**TRANSPORT OF THYROID HORMONES IN THE BLOOD.** The thyroid hormones are transported in the blood in strong but noncovalent association with certain plasma proteins.

*Thyroxine-binding globulin* (TBG) is the major carrier of thyroid hormones. It is a glycoprotein that binds 1 molecule of T₄ per molecule of protein with a very high affinity (*Kₐ*’ is ~10⁻¹⁰ M). T₃ is bound less avidly. T₄, but not T₃, also is bound by *transthyretin* (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and primarily binds T₄ with a *Kₐ* ~10⁻⁷ M. Albumin also can bind T₄ when the more avid carriers are saturated, but its physiological importance is unclear. Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage (~0.03% of T₄ and ~0.3% of T₃) of the total hormone in plasma. The differential binding affinities for serum proteins also contribute to establishing the 10- to 100-fold differences in circulating hormone concentrations and half-lives of T₄ and T₃.

Only the unbound hormone has metabolic activity. Because of the high degree of binding of thyroid hormones to plasma proteins, changes in either the concentrations of these proteins or the binding affinity of the hormones for the proteins has major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (*Table 39–1*).

**DEGRADATION AND EXCRETION.** T₃ and T₄ can be deiodinated but can also be metabolized by ether cleavage, conjugation, and oxidative decarboxylation.

T₄ is eliminated slowly from the body, with a $t_{1/2}$ of 6-8 days. In hyperthyroidism, the $t_{1/2}$ is shortened to 3-4 days, whereas in hypothyroidism it may be 9-10 days. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The opposite effect is observed when binding to protein is inhibited by certain drugs (see Table 39–1). T₃, which is less avidly bound to protein, has a $t_{1/2}$ of 1 day.

The liver is the major site of non-deiodinative degradation of thyroid hormones; T₄ and T₃ are conjugated with glucuronic and sulfuric acids and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

**FACTORS REGULATING OF THYROID HORMONE SECRETION.**
Thyrotropin or TSH is a glycoprotein hormone with α and β subunits analogous to those of the gonadotropins (see Table 38–2). TSH is secreted in a pulsatile manner and circadian pattern (levels are highest during sleep at night). TSH secretion is controlled by the hypothalamic peptide thyrotropin-releasing hormone (TRH) and by the concentration of free thyroid hormones in the circulation. Extra thyroid hormone inhibits transcription of both the TRH gene
and the genes encoding the α and β subunits of TSH, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress. Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH. Additional mechanisms mediating the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells (Figure 39–4).

Figure 39–4 Regulation of thyroid hormone secretion. Myriad neural inputs influence hypothalamic secretion of thyrotropin-releasing hormone (TRH). TRH stimulates release of thyrotropin (TSH, thyroid-stimulating hormone) from the anterior pituitary; TSH stimulates the synthesis and release of the thyroid hormones $T_3$ and $T_4$. $T_3$ and $T_4$ feed back to inhibit the synthesis and release of TRH and TSH. Somatostatin (SST) can inhibit TRH action, as can dopamine and high concentrations of glucocorticoids. Low levels of I− are required for thyroxine synthesis, but high levels inhibit thyroxin synthesis and release.
**THYROTROPIN-RELEASING HORMONE.** TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-proline amide) synthesized by the hypothalamus and released into the hypophyseal-portal circulation where it interacts with TRH receptors on thyrotropes in the anterior pituitary. The binding of TRH to its receptor, a GPCR, stimulates the G_q-PLC-IP_3-Ca^{2+} pathway and activates PKC, ultimately stimulating the synthesis and release of TSH. Two TRH receptors have now been identified, TRH-R1 and TRH-R2, as well as selective analogs for these receptors. Somatostatin, dopamine, and glucocorticoids inhibit TRH-stimulated TSH secretion.

**ACTIONS OF TSH ON THE THYROID.** TSH increases the synthesis and secretion of thyroid hormone. These effects follow the binding of TSH to its receptor (a GPCR) on the plasma membrane of thyroid cells. Binding of TSH to its receptor stimulates the G_s-adenylyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the G_q-PLC pathway. Multiple mutations of the TSH receptor result in clinical thyroid dysfunction.

**IODINE AND THYROID FUNCTION.** Normal thyroid function requires an adequate intake of iodine; without it, normal amounts of hormone cannot be made, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be 10 times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting T_3. In more severe iodine deficiency, adult hypothyroidism and cretinism may occur. High levels of iodine inhibit thyroxine synthesis and release. In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine. The addition of iodate to table salt (NaCl) provides a convenient iodine supplement. In the U.S., iodized salt provides 100 μg of iodine per gram. The recommended daily allowances for iodine range from 90-120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 290 μg for lactation. Vegetables, meat, and poultry contain minimal amounts of iodine, whereas dairy products and fish are relatively high in iodine.

**THYROID HORMONE TRANSPORT.** Transmembrane passage of thyroid hormones appears to be mediated by monocarboxylic acid transporter 8 (MCT8, SLC16A2; see Table 5–2). MCT8 is widely expressed, including in liver, heart,
and brain. MCT10 also transports T₄ and T₃ and is widely expressed, but its physiological importance for thyroid hormone transport in vivo is unknown. The organic anion transporter OATP1C1 preferentially transports T₄ rather than T₃, is highly expressed in brain capillaries, and has been hypothesized to be responsible for the transport of T₄ across the blood-brain barrier (see Chapter 5).

**MEDIATION OF EFFECTS BY NUCLEAR RECEPTORS.** Thyroid hormone action is mediated largely by the binding of T₃ to TRs, which are members of the nuclear receptor superfamily of transcription factors.

T₃ binds to TRs with ~10-fold greater affinity than does T₄, and T₄ is not thought to be biologically active in normal physiology. TRs bind to specific DNA sequences (thyroid hormone response elements [TREs]) in the promoter/regulatory regions of target genes. The transcription of most target genes is repressed by unliganded TRs and induced following the binding of T₃. In the unliganded state, the TR ligand-binding domain interacts with a corepressor complex that includes histone deacetylases and other proteins. The binding of T₃ causes replacement of the corepressor complex by a coactivator complex that includes histone acetyltransferases, methyltransferases, and other proteins. Other thyroid hormone target genes, such as those encoding TRH and the TSH subunits, are negatively regulated by T₃. The mechanism is not well defined, but these genes tend to be induced by the unliganded TR in addition to being repressed by T₃.

Two genes encode TRs: THRA and THRFB. THRA encodes the receptor TRα1. TRα1 is expressed in most cell types, but its major activities are in the regulation of heart rate, body temperature, skeletal muscle function, and the development of bone and small intestine. Alternative splicing of the TRα primary transcript results in the production of TRα2, which lacks part of the ligand-binding domain (LBD), does not bind T₃, and has not known function. A cryptic promoter within intron 7 of THRA drives the production of small proteins that contain only a portion of the TRα LBD and appear to play a role, along with TRα1, in GI development. The THRFB gene has 2 promoters that lead to the production of TRβ1 and TRβ2. These receptors have unique amino terminal domains but otherwise are identical. TRβ1 is ubiquitous; TRβ2 has a highly restricted pattern of expression. Mutations in THRFB cause the syndrome of resistance to thyroid hormone. TRβ1 mediates specific effects in liver metabolism (including the
hypocholesterolemic effect of T\(_3\)); TR\(\beta2\) has roles in the negative feedback by T\(_3\) on hypothalamic TRH and pituitary TSH and in the development of retinal cones and the inner ear.

**NONGENOMIC EFFECTS OF THYROID HORMONE.** TRs are found outside the nucleus where they can exert biological effects via rapid nongenomic mechanisms.

TRs associate in a T\(_3\)-dependent manner with the p85\(\alpha\) subunit PI3 kinase, resulting in the activation of PKB/Akt. The PI3K/Akt pathway has myriad effects. For example, it stimulates NO production by endothelial cells, which leads to vasodilation; hence, T\(_3\) administration causes rapid vasodilation. There also is evidence for nongenomic actions of thyroid hormone via a plasma membrane receptor within integrin \(\alphaV\beta3\). This putative receptor binds extracellular T\(_4\) in preference to T\(_3\), resulting in activation of MAP kinase. The importance of nongenomic actions in thyroid hormone physiology and pathophysiology remains uncertain.

*Effects of Thyroid Hormone Metabolites.* 3-Iodothyronamine and thyronamine, naturally occurring metabolites of T\(_4\), are ligands for the GPCR trace amine-associated receptor 1 (TAAR1), an interaction of unknown relevance in humans.

**MAJOR CLINICAL EFFECTS OF THYROID HORMONES**

**GROWTH AND DEVELOPMENT.** Thyroid hormone plays a critical role in brain development by mechanisms that are incompletely understood. The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation during the first 2 weeks of postnatal life prevents the development of these disturbed morphological changes. The actions of thyroid hormones on protein synthesis and enzymatic activity are not limited to the brain; most tissues are affected by the administration
of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as endemic (caused by extreme iodine deficiency) or sporadic (a consequence abnormal thyroid development or a defect in the synthesis of thyroid hormone). The affected child is dwarfed, with short extremities, mentally retarded, inactive, uncomplaining, and listless. Other manifestations include puffy face, enlarged tongue, dry and doughy skin, slow heart rate, and decreased body. For treatment to be fully effective, the diagnosis must be made long before these changes are obvious. In regions of endemic iodine deficiency, iodine replacement is best instituted before pregnancy. Screening of newborn infants for deficient thyroid function is carried out in the U.S. and in most industrialized countries.

**THERMOGENIC EFFECTS.** Thyroid hormone is necessary for both obligatory thermogenesis (the heat resulting from vital processes) as well as for facultative or adaptive thermogenesis.

Only a few organs, including the brain, gonads, and spleen, are unresponsive to the thermogenic effects of T₃. Obligatory thermogenesis is the result of T₃ making most biological processes thermodynamically less efficient for the sake of producing heat, but the pathways involved and their quantitative contributions have yet to be fully defined. The capacity of T₃ to induce the skeletal muscle Ca++-dependent ATPase (SERCA1) contributes to thermogenesis by stimulating the cycling of calcium between cytosol and sarcoplasmic reticulum. Other than in brown adipose tissue, there is no evidence that uncoupling of phosphorylation is a major thermogenic mechanism. Regardless of the mechanism, thermogenesis is highly sensitive to thyroid hormone around the physiological range: small changes in L-thyroxine replacement doses may significantly alter resting energy expenditure in the hypothyroid patient. The ability of T₃ to stimulate thermogenesis has evolved along with ancillary effects to support this action, such as the stimulation of appetite and lipogenesis.

**CARDIOVASCULAR EFFECTS.** Hyperthyroid patients have tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure. Hyperthyroidism is
a relatively common cause of atrial fibrillation. Hypothyroid patients have bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

T₃ regulates myocardial gene expression primarily through TRα1, which is expressed at a higher level in cardiomyocytes than TRβ. T₃ shortens diastolic relaxation (lusitropic effect) by inducing expression of the sarcoplasmic reticulum ATPase SERCA2 and decreasing phospholamban, a SERCA2 inhibitor. T₃ increases the force of myocardial contraction (inotropic effect) in part by inducing expression of the ryanodine channel, the calcium channel of the sarcoplasmic reticulum. T₃ induces the gene encoding the myosin heavy chain (MHC) α isoform and decreases expression of the MHC β gene. Because MHCα endows the myosin holoenzyme with greater ATPase activity, this is one mechanism by which T₃ enhances the velocity of contraction. The chronotropic effect of T₃ is mediated by increases in the pacemaker ion current Iᵣ in the sinoatrial node. Several proteins that comprise the Iᵣ channel are induced by T₃ including HCN2 and HCN4. T₃ also appears to have a direct nongenomic vasodilating effect on vascular smooth muscle, which may contribute to the decreased systemic vascular resistance and increased cardiac output of hyperthyroidism.

**METABOLIC EFFECTS.** Thyroid hormone stimulates the expression of hepatic low-density lipoprotein (LDL) receptors and the metabolism of cholesterol to bile acids, such that hypercholesterolemia is a characteristic feature of hypothyroidism.

Thyroid hormone has complex effects on carbohydrate metabolism. Thyrotoxicosis is an insulin-resistant state. Post-receptor defects are manifested by depleted glycogen stores, enhanced gluconeogenesis, and increased rate of glucose absorption from the gut. Compensatory increases in insulin secretion result in hyperinsulinemia. There may be impaired glucose tolerance or even clinical diabetes, but most hyperthyroid patients are euglycemic. Conversely, hypothyroidism results in decreased absorption of glucose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake. Glucose metabolism generally is not affected in a clinically significant manner in nondiabetic patients, although insulin requirements decrease in the hypothyroid
DISORDERS OF THYROID FUNCTION

THYROID HYPOFUNCTION. Hypothyroidism, known as myxedema when severe, is the most common disorder of thyroid function.

Worldwide, hypothyroidism resulting from iodine deficiency remains a common problem. In nonendemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto thyroiditis) accounts for most cases; this disorder is characterized by high levels of circulating antibodies directed against thyroid peroxidase and, sometimes, against thyroglobulin; antibodies directed at the TSH receptor may be present. The conditions are examples of primary hypothyroidism, failure of the thyroid gland itself. Central hypothyroidism occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (secondary hypothyroidism) or hypothalamic failure (tertiary hypothyroidism). Hypothyroidism present at birth (congenital hypothyroidism) is the most common preventable cause of mental retardation in the world.

Common symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, mental slowness, depression, dry skin, constipation, mild weight gain, fluid retention, muscle aches and stiffness, irregular menses, and infertility. Common signs include goiter (primary hypothyroidism only), bradycardia, delayed relaxation phase of the deep tendon reflexes, cool and dry skin, hypertension, nonpitting edema, and facial puffiness. Deficiency of thyroid hormone during the first few months of life causes feeding problems, failure to thrive, constipation, and sleepiness. Retardation of mental development is irreversible if not treated promptly. Childhood hypothyroidism impairs linear growth and bone maturation. Diagnosis requires the finding of an elevated serum TSH or, in cases of central hypothyroidism, a decreased serum free T₄.

THYROID HYPERFUNCTION. Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Increased thyroid hormone production is the most common cause, with the common link of TSH receptor stimulation and increased iodine uptake by the thyroid gland as shown.
by the measurement of the percentage uptake of $^{123}$I or $^{131}$I in a 24-h radioactive iodine uptake (RAIU) test.

TSH receptor stimulation is either the result of TSH receptor stimulating antibody in Graves disease or somatic activating TSH receptor mutations in autonomously functioning nodules or a toxic goiter. In contrast, thyroid inflammation or destruction resulting in excess “leak” of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-h RAIU. The term subclinical hyperthyroidism is defined as those with a subnormal serum TSH and normal concentrations of T$_4$ and T$_3$. Atrial arrhythmias, excess cardiac mortality, and excessive bone loss have been associated with this profile of thyroid function tests.

Graves disease is the most common cause of high RAIU thyrotoxicosis. Graves disease is an autoimmune disorder characterized by increased thyroid hormone production, diffuse goiter, and IgG antibodies that bind to and activate the TSH receptor. As with most types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1-7:1. Graves disease is more common between the ages of 20 and 50, but it may occur at any age. Graves disease is commonly associated with other autoimmune diseases. The characteristic exophthalmos associated with Graves disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extraocular muscles. Toxic uninodular/multinodular goiter accounts for 10-40% of cases of hyperthyroidism and is more common in older patients. A low RAIU is seen in the destructive thyroiditides and in thyrotoxicosis in patients taking excessive doses of thyroid hormone.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat, increased motor activity, and increased sensitivity to catecholamines produced by the sympathetic nervous system. The skin is flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite and, if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Older patients may experience less manifestations of
sympathetic nervous system stimulation. Some individuals may show extensive muscular wasting as a result of thyroid myopathy. The most severe form of hyperthyroidism is thyroid storm (see section below on therapeutic uses of anti-thyroid drugs).

THYROID FUNCTION TESTS. Measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland; total hormone concentration changes with alterations in amount and affinity of TBG in plasma.

Although equilibrium dialysis of undiluted serum and radioimmunoassay for free thyroxine (FT$_4$) in the dialysate represent the gold standard for determining FT$_4$ concentrations, this assay is typically not available in routine clinical laboratories. The most common assays used for estimating the free T$_4$ and free T$_3$ concentrations employ labeled analogs of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays are subject to influences of altered serum binding proteins, nonthyroid disease, and other drugs. In individuals with normal pituitary function, serum measurement of TSH is the thyroid function test of choice because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones. The TSH assay can differentiate between normal and thyrotoxic patients, who should exhibit suppressed TSH values. Recombinant human TSH (thyrotropin alfa [THYROGEN]) is available as an injectable preparation to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and release thyroglobulin.

THERAPEUTIC USES OF THYROID HORMONE

The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism and for TSH suppression therapy in patients with thyroid cancer.

THYROID HORMONE PREPARATIONS. Synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are available and widely used for thyroid hormone therapy.

Levothyroxine. Levothyroxine sodium (L-T$_4$, LEVOTHROID, LEVOXYL,
S synthroid, Unithroid, others) is available in tablets and as a lyophilized powder for injection. Table 39–2 lists drugs and other factors that may influence levothyroxine dosage requirements. Absorption of thyroxine occurs in the stomach and small intestine and is incomplete (~80% of the dose is absorbed). Absorption is slightly increased when the hormone is taken on an empty stomach, and it is associated with less variability in the TSH when taken this way regularly. The serum T4 peaks 2–4 h after oral ingestion, with plasma $t_{1/2}$ ~7-days. For any given serum TSH, the serum T4/T3 ratio is higher in patients taking levothyroxine than in patients with endogenous thyroid function, due to the fact that ~20% of circulating T3 normally is supplied by direct thyroidal secretion. Follow-up blood tests typically are done ~6 weeks after any dosage change due to the 1-week plasma $t_{1/2}$ of T4. In situations where patients cannot take oral medications or where intestinal absorption is in question, levothyroxine may be given intravenously once daily at a dose ~80% of the patient’s daily oral requirement.

Liothyronine. Liothyronine sodium (L-T3) is the salt of triiodothyronine and is available in tablets (Cytomel) and in an injectable form (Triostat, others). Liothyronine absorption is nearly 100% with peak serum levels 2–4 h following oral ingestion. Liothyronine may be used occasionally when a more rapid onset of action is desired such as in the rare presentation of myxedema coma or if rapid termination of action is desired such as when preparing a thyroid cancer patient for 131I therapy. Liothyronine is less desirable for chronic replacement therapy due to the requirement for more frequent dosing (plasma $t_{1/2} = 0.75$ days), higher cost, and transient elevations of serum T3 concentrations above the normal range. In addition, organs that express the type 2 deiodinase use the locally generated T3 in addition to plasma T3, and hence, there is theoretical concern that these organs will not maintain physiological intracellular T3 levels in the absence of plasma T4. Ten to 15 μg of liothyronine sodium 3 times per day typically yields a normal serum free T3 in an athyreotic individual.

Other Preparations. A mixture of thyroxine and triiodothyronine 4:1 by weight is marketed as liotrix (Thyrolar). Desiccated thyroid preparations such as (Armour Thyroid, others), with a similar T4:T3 ratio, also are available. A 60-mg (1 grain) desiccated thyroid tablet is approximately equivalent in activity to 80 μg of thyroxine.
THYROID HORMONE REPLACEMENT THERAPY IN HYPOTHYROIDISM. Thyroxine (L-T4, levothyroxine sodium) is the hormone of choice for thyroid hormone replacement therapy due to its consistent potency and prolonged duration of action. With this therapy, one relies on the types 1 and 2 deiodinases to convert T4 to T3 to maintain a steady serum level of free T3.

The average daily adult replacement dose of levothyroxine sodium is 1.7 μg/kg body weight (0.8 μg/lb). Dosing should generally be based on lean body mass. The goal of therapy is to normalize the serum TSH (in primary hypothyroidism) or free T4 (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism. In primary hypothyroidism, generally it is sufficient to follow TSH without free T4. In individuals >60 years of age and those with known or suspected cardiac disease or with areas of autonomous thyroid function, institution of therapy at a lower daily dose of levothyroxine sodium (12.5-50 μg per day) is appropriate. The dose can be increased at a rate of 25 μg per day every 6-8 weeks until the TSH is normalized. Controlled trials give no evidence that combination therapy with T4 T3 provides a better therapeutic response than does T4 alone. Monotherapy with levothyroxine most closely mimics normal physiology and generally is preferred.

Hypothyroidism During Pregnancy. Due to the increased serum concentration of TBG induced by estrogen, the expression of type 3 deiodinase by the placenta, and the small amount of transplacental passage of L-T4 from mother to fetus, a higher dose of L-T4 is often required in pregnant patients. Overt hypothyroidism during pregnancy is associated with fetal distress, impaired psychoneural development in the progeny, and mildly impaired psychomotor development in the children and preterm delivery. Women should increase their levothyroxine dosage by ~30% as soon as pregnancy is confirmed. Most measure a serum TSH in the first trimester and then adjust the thyroxine dose based on this result. Subsequent dosage adjustments based on serum TSH, measured 4-6 weeks after each adjustment, should be made to bring the TSH into the lower portion of the reference range.

MYXEDEMA COMA. Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism. Myxedema coma occurs most often in elderly patients during the winter months. Cardinal features of myxedema coma are: hypothermia, respiratory depression, and decreased
consciousness.

Intravenous administration of thyroid hormone is advised. Therapy with levothyroxine is begun with a loading dose of 250-500 μg followed by a daily full replacement dose.

**CONGENITAL HYPOTHYROIDISM.** Success in the treatment of congenital hypothyroidism depends on the age at which therapy is started. If therapy is instituted within the first 2 weeks of life, normal physical and mental development can be achieved.

To rapidly normalize the serum thyroxine concentration in the congenitally hypothyroid infant, an initial daily dose of levothyroxine of 10-15 μg/kg is recommended. Laboratory evaluations of TSH and FT₄ are performed 2 and 4 weeks after treatment is initiated, every 1-2 months in the first 6 months, every 3-4 months between 6 months and 3 years of age, and every 6-12 months from age 3 years until the end of growth.

**THYROID CANCER.** The mainstays of therapy for well-differentiated thyroid cancer (papillary, follicular) are surgical thyroidectomy, radioiodine, and levothyroxine to suppress TSH. For most low-risk patients with stage 1 or 2 disease, maintaining the TSH just below the reference range for not more than 5 years is one reasonable approach.

**Thyroid Nodules.** Thyroid nodules usually are asymptomatic, although they can cause neck discomfort, dysphagia, and a choking sensation. The use of levothyroxine to suppress TSH in euthyroid individuals with thyroid nodules cannot be recommended as a general practice. However, if the TSH is elevated, it is appropriate to administer levothyroxine to bring the TSH into the lower portion of the reference range.

**ADVERSE EFFECTS OF THYROID HORMONE.** Adverse effects of thyroid hormone generally occur only upon overtreatment and are similar to the consequences of hyperthyroidism.

**ANTI-THYROID DRUGS AND OTHER THYROID INHIBITORS**
Myriad compounds are capable of interfering, directly or indirectly,
with the synthesis, release, or action of thyroid hormones (Tables 39-2 and 39–3). Several types are clinically useful:

**Table 39–3**

**Anti-thyroid Compounds**

- Anti-thyroid drugs, which interfere directly with the synthesis of thyroid
hormones
- Ionic inhibitors, which block the iodide transport mechanism
- High concentrations of iodine, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis
- Radioactive iodine, which damages the thyroid gland with ionizing radiation

Adjuvant therapy with drugs that have no specific effects on thyroid hormone synthesis is useful in controlling the peripheral manifestations of thyrotoxicosis, including inhibitors of the peripheral deiodination of T₄ to T₃, β adrenergic receptor antagonists, and Ca²⁺ channel blockers.

ANTI-THYROID DRUGS
The anti-thyroid drugs with clinical utility are the thioureylenes, which belong to the family of thioamides. Propylthiouracil is the prototype (Figure 39–5).

Figure 39–5 Anti-thyroid drugs of the thiamide type.

Mechanism of Action. Anti-thyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines. The drugs are thought to inhibit the peroxidase enzyme. Inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of T₄ to T₃. Methimazole does not have this effect; this provides a rationale for the choice of propylthiouracil over other anti-thyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm.
**ADME.** The anti-thyroid compounds currently used in the U.S. are propylthiouracil (6-n-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole; Tapazole, others). In Europe, carbimazole (Neomercazol), a carbethoxy derivative of methimazole, is available, and its anti-thyroid action is due to its conversion to methimazole after absorption. Pharmacological properties of propylthiouracil and methimazole are shown in Table 39–4.

**Untoward Reactions.** The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. Agranulocytosis is the most serious reaction, usually occurring in the first few weeks or months of therapy but sometimes later. Patients should be instructed to immediately report the development of sore throat or fever, and should discontinue their anti-thyroid drug and obtain a granulocyte count. Agranulocytosis is reversible upon discontinuation of the offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery. Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction; frequent leukocyte counts are then required.

The most common reaction is a mild urticarial papular rash that often subsides spontaneously without interrupting treatment, but it sometimes calls for the administration of an antihistamine, corticosteroids, and changing to another. Other less frequent complications are pain and stiffness in the joints, paresthesias, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not
infrequent with higher doses of propylthiouracil. Although vasculitis was previously thought to be a rare complication, antineutrophilic cytoplasmic antibodies (ANCAs) have been reported to occur in ~50% of patients receiving propylthiouracil and rarely with methimazole.

**THERAPEUTIC USES.** The anti-thyroid drugs are used in the treatment of hyperthyroidism:

- As definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves disease
- In conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation
- To control the disorder in preparation for surgical treatment

Methimazole is the drug of choice for Graves disease; it is effective when given as a single daily dose, has improved adherence, and is less toxic than propylthiouracil. Methimazole has a relatively long plasma and intrathyroidal $t_{1/2}$, as well as a long duration of action. The usual starting dose for methimazole is 15–40 mg per day. The usual starting dose of propylthiouracil is 100 mg every 8 h. When doses >300 mg daily are needed, further subdivision of the time of administration to every 4-6 h is occasionally helpful. Once euthyroidism is achieved, usually within 12 weeks, the dose of anti-thyroid drug can be reduced, but not stopped, lest an exacerbation of Graves disease occur.

**Response to Treatment.** The thyrotoxic state usually improves within 3-6 weeks after the initiation of anti-thyroid drugs. The clinical response is related to the dose of anti-thyroid drug, the size of the goiter, and pretreatment serum $T_3$ concentrations. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the $t_{1/2}$ of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. Hypothyroidism may develop as a result of overtreatment. After treatment is initiated, patients should be examined and thyroid function tests (serum $FT_4$ and total or free triiodothyronine concentrations) measured every 2-4 months. Once euthyroidism is established, follow-up every 4-6 months is reasonable. Control of the hyperthyroidism usually is associated with a decrease
in goiter size. When this occurs, the dose of the anti-thyroid drug should be significantly decreased and/or levothyroxine can be added once hypothyroidism is confirmed by laboratory testing.

**Thyrotoxicosis in Pregnancy.** Thyrotoxicosis occurs in ~0.2% of pregnancies and is caused most frequently by Graves disease. Anti-thyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Both propylthiouracil and methimazole cross the placenta equally, and either may be used safely in the pregnant patient, although the concern for propylthiouracil-associated liver failure in pregnancy may favor the use of methimazole. Carbimazole is used in the EU during pregnancy and is rarely associated with congenital gut abnormalities. The anti-thyroid drug dosage should be minimized to keep the serum FT$_4$ index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves disease often improves. Relapse or worsening of Graves disease is common after delivery, and patients should be monitored closely. Methimazole up to 20 mg daily in nursing mothers reportedly has no effect on thyroid function in the infant, and propylthiouracil is thought to cross into breast milk even less than methimazole.

**Adjuvant Therapy.** Several drugs that have no intrinsic anti-thyroid activity are useful in the symptomatic treatment of thyrotoxicosis. ~ Adrenergic receptor antagonists (see Chapter 12) are effective in antagonizing the sympathetic/adrenergic effects of thyrotoxicosis, thereby reducing the tachycardia, tremor, and stare, and relieving palpitations, anxiety, and tension. Either propranolol, 20-40 mg 4 times daily, or atenolol, 50-100 mg daily, is usually given initially. Ca$^{2+}$ channel blockers (diltiazem, 60-120 mg 4 times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias. Usually only short-term treatment with β adrenergic receptor antagonists or Ca$^{2+}$ channel blockers is required, 2-6 weeks, and it should be discontinued once the patient is euthyroid. Immunotherapy has been used for Graves hyperthyroidism and ophthalmopathy. The B-lymphocyte depleting agent rituximab, when used with methimazole, prolongs remission of Graves disease.

**IONIC INHIBITORS**

The ionic inhibitors are substances that interfere with the
concentration of iodide by the thyroid gland. These agents are anions that resemble iodide: *thiocyanate*, *perchlorate*, and *fluoroborate*, all monovalent hydrated anions of a size similar to that of iodide.

*Thiocyanate* differs from the rest qualitatively; it is not concentrated by the thyroid gland but in large amounts may inhibit the organification of iodine. Perchlorate is 10 times as active as thiocyanate. Perchlorate blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS. Perchlorate can be used to control hyperthyroidism; however, when given in excessive amounts (2-3 g daily), it has caused fatal aplastic anemia. Perchlorate in doses of 750 mg daily has been used in the treatment of Graves disease. The various NIS inhibitors (perchlorate, thiocyanate, and nitrate) are additive in inhibiting iodine uptake. Lithium decreases secretion of $T_4$ and $T_3$, which can cause overt hypothyroidism in some patients taking Li$^+$ for the treatment of mania (see Chapter 16).

**IODIDE**

*Iodide* is the oldest remedy for disorders of the thyroid gland. In high concentration, iodide can influence several of the important functions of the thyroid gland. Iodide limits its own transport and acutely and transiently inhibits the synthesis of iodotyrosines and iodothyronines (the *Wolff-Chaikoff effect*). An important clinical effect of high [I–]$_{plasma}$ is inhibition of the release of thyroid hormone.

**RESPONSE TO IODIDE IN HYPERTHYROIDISM.** The response to iodides in patients with hyperthyroidism is often striking and rapid: Release of thyroid hormone into the circulation is rapidly blocked, and its synthesis also is mildly decreased. In the thyroid gland, vascularity is reduced, the gland becomes much firmer, the cells become smaller, colloid reaccumulates in the follicles, and the quantity of bound iodine increases. The maximal effect occurs after 10-15 days of continuous therapy. Iodide therapy usually does not completely control the manifestations of hyperthyroidism, and the beneficial effect disappears. The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy, and in conjunction with anti-thyroid drugs and propranolol, in the treatment of thyrotoxic crisis.
Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident or military exposure. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30-100 mg of iodide daily will markedly decrease the thyroid uptake of radioisotopes. Strong iodine solution (Lugol solution) consists of 5% iodine and 10% potassium iodide, which yield a dose of 8 mg of iodine per drop. Potassium iodide–saturated solution (KISS) also is available, containing 50 mg per drop. Typical doses include 16-36 mg (2-6 drops) of Lugol solution or 50-100 mg (1-2 drops) of KISS 3 times a day. A potassium iodide product (THYROSHIELD) is available over the counter to take in the event of a radiation emergency and block the uptake of radioiodide into the thyroid gland. The adult dose is 2 mL (130 mg) every 24 h, as directed by public health officials. Euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 39–5), and these patients do not escape from the acute Wolff-Chaikoff effect.

Table 39–5

Commonly Used Iodine-Containing Drugs
**UNTOWARD REACTIONS.** Occasional individuals show a marked sensitivity to iodide. Angioedema is the prominent symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present; manifestations of the serum-sickness type of hypersensitivity (e.g., fever, arthralgia, lymph node enlargement, and eosinophilia) may appear. Thrombotic thrombocytopenic purpura and fatal periarteritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (*iodism*) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased

salivation, coryza, sneezing, and irritation of the eyes with swelling of the eyelids commonly occur. Mild iodism simulates a “head cold.” Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. Skin lesions are common and vary in type and intensity. Rarely, severe and sometimes fatal eruptions (ioderma) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism, a rare problem, and generally involute quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever, anorexia, and depression may be present. The symptoms of iodism disappear within a few days after stopping the administration of iodide. Renal excretion of I⁻ can be increased by procedures that promote Cl⁻ excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

**RADIOACTIVE IODINE**

The primary isotopes used for the diagnosis and treatment of thyroid disease are \(^{123}\text{I}\) and \(^{131}\text{I}\). \(^{123}\text{I}\) is primarily a short-lived \(\gamma\)-emitter with a \(t_{1/2}\) of 13 h and is used in diagnostic studies. \(^{131}\text{I}\) has a \(t_{1/2}\) of 8 days and emits both \(\gamma\) rays and \(\beta\) particles. More than 99% of its radiation is expended within 56 days. \(^{131}\text{I}\) is used therapeutically for thyroid destruction of an overactive or enlarged thyroid and in thyroid cancer for thyroid ablation and treatment of metastatic disease.

The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, \(^{127}\text{I}\). \(^{131}\text{I}\) is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus, the destructive \(\beta\) particles originate within the follicle and act almost exclusively on the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The \(\gamma\) radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. With properly selected doses of \(^{131}\text{I}\), it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues.
THERAPEUTIC USES. Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. The clearest indication for radioactive iodine treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is the best form of treatment when Graves disease has persisted or recurred after subtotal thyroidectomy and when prolonged treatment with antithyroid drugs has not led to remission. Finally, radioactive iodine is indicated in patients with toxic nodular goiter. Sodium iodide $^{131}$I (HiCON, others) is available as a solution or in capsules containing carrier-free $^{131}$I suitable for oral administration. Sodium iodide $^{123}$I is available for scanning procedures.

HYPERTHYROIDISM. Radioactive iodine is a valuable alternative or adjunctive treatment of hyperthyroidism. Stable iodide (nonradioactive) may preclude treatment and imaging with radioactive iodine for weeks after the stable iodide has been discontinued. In those patients exposed to stable iodide, a 24-h radioiodine measurement of a tracer dose of $^{123}$I should be performed before $^{131}$I administration to ensure there is sufficient uptake to accomplish the desired ablation. The optimal dose of $^{131}$I, expressed in terms of microcuries taken up per gram of thyroid tissue, varies in different laboratories from 80-150 μCi. The usual total dose is 4-15 mCi.

Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2-3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6-12 months. It is not uncommon, however, for the serum TSH to remain low for several months after $^{131}$I therapy. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free $T_4$ and usually serum $T_3$ concentrations. Depending to some extent on the dosage schedule adopted, 80% of patients are cured by a single dose, ~20% require 2 doses, and a very small fraction require 3 or more doses before the disorder is controlled. $\beta$ Adrenergic antagonists, anti-thyroid drugs, or both, or stable iodide, can be used to hasten the control of hyperthyroidism.

Advantages. With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the U.S., and patients can participate in their customary activities during the entire
procedure, although there are recommendations to limit exposure in young children.

**Disadvantages.** The chief consequence of the use of radioactive iodine is the high incidence of delayed hypothyroidism. Although cancer death rate is not increased after radioiodine therapy, there is a small but significant increase shown in specific types of cancer, including stomach, kidney, and breast. This finding is especially significant because these tissues all express the iodine transporter NIS and may be especially susceptible to radiation effects. Radioactive iodine treatment can induce a radiation thyroiditis, with release of preformed thyroxine and triiodothyronine into the circulation. In most patients, this is asymptomatic, but in some there can be worsening of symptoms of hyperthyroidism and rarely cardiac manifestations, such as atrial fibrillation or ischemic heart disease and very rarely thyroid storm. Pretreatment with anti-thyroid drugs should reduce or eliminate this complication.

*The main contraindication for the use of $^{131}$I therapy is pregnancy.* After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. The risk of causing neoplastic changes in the thyroid gland has been an ongoing; only small numbers of children have been treated in this way. Many clinics decline to treat younger patients and reserve radioactive iodine for patients older than 25-30 years.

**Thyroid Carcinoma.** Because most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH is required to treat metastases effectively. Currently, endogenous TSH stimulation is evoked by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total thyroidectomy with or without radioactive ablation of residual thyroid tissue. An ablative dose of $^{131}$I ranging from 30 mCi to >150 mCi is administered, and a repeat total body scan is obtained 1 week later. Thyrogen (recombinant human TSH) is now available to test the capacity of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin. Thyrogen allows assessment of the presence of metastatic disease, without the necessity for patients to stop their suppressive levothyroxine therapy and become clinically hypothyroid. TSH-suppressive therapy with levothyroxine is indicated in all patients after treatment for thyroid cancer. The goal of therapy usually is to keep serum TSH levels in the subnormal range. A
rise in serum thyroglobulin concentration is often the first indication of recurrent disease.
Estrogens and progestins are hormones that produce myriad physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. The most common uses of these agents are menopausal hormone therapy and contraception in women, but the specific compounds and dosages used in these 2 settings differ substantially. Anti-estrogens are used in the treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are useful to prevent breast cancer and osteoporosis. The main use of antiprogestins has been for medical abortion.

ESTROGENS

Estrogens interact with 2 receptors of the nuclear receptor superfamily, termed estrogen receptors α (Erα) and β (ERβ). The most potent naturally occurring estrogen in humans, for both ERα- and ERβ-mediated actions, is 17β-estradiol, followed by estrone and estriol. Steroidal estrogens arise from androstenedione or testosterone (Figure 40–1) by a reaction catalyzed by aromatase (CYP19).
The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol the main secretory product. Gonadotropins, acting via receptors that couple to the Gs-adenyl cyclase–cyclic AMP pathway, increase the activities of aromatase and facilitate the transport of cholesterol (the precursor of all steroids) into the mitochondria of cells that synthesize steroids. In the ovary, type I 17β-hydroxysteroid dehydrogenase favors the production of testosterone and estradiol from androstenedione and estrone, respectively. In the liver, the type II enzyme favors oxidation of circulating estradiol to estrone, and both of these steroids are then converted to estriol (see Figure 40–1). All 3 of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are

Figure 40–1 The biosynthetic pathway for estrogens.
produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens. Local production of estrogens by aromatization of androgens may play a causal or promotional role in the development of certain diseases such as breast cancer. Estrogens also may be produced from androgens via aromatase in the central nervous system (CNS) and other tissues and exert local effects near their production site (e.g., in bone they affect bone mineral density).

Human urine during pregnancy is an abundant source of natural estrogens. Pregnant mare’s urine is the source of conjugated equine estrogens, which have been widely used therapeutically for many years.

**PHYSIOLOGICAL AND PHARMACOLOGICAL ACTIONS**

**DEVELOPMENTAL ACTIONS.** Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics.

Estrogens cause growth and development of the vagina, uterus, and fallopian tubes, and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (see Chapter 41). Estrogens also play important developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals.

**NEUROENDOCRINE CONTROL OF THE MENSTRUAL CYCLE.**

A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 40–2). A neuronal oscillator, or “clock,” in the hypothalamus fires at intervals that coincide with the release of gonadotropin-releasing hormone (GnRH)
into the hypothalamic-pituitary portal vasculature (see Chapter 38). GnRH interacts with its receptor on pituitary gonadotropes to cause release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle, controls the relative synthesis of FSH and LH.
results in the periodic release of gonadotropin-releasing hormone (GnRH) from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons (NE, norepinephrine). The pulses of GnRH trigger the intermittent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 40–3 for additional details.)

The gonadotropins (LH and FSH) regulate the growth and maturation of follicles in the ovary and the ovarian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus. Because the release of GnRH is intermittent, secretion of LH and FSH is pulsatile. The pulse frequency is determined by the neural “clock” (see Figure 40–2), termed the hypothalamic GnRH pulse generator, but the amount of gonadotropin released in each pulse (i.e., the pulse amplitude) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, pulsatile nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles because constant infusion of GnRH results in a cessation of gonadotropin release and ovarian steroid production (see Chapter 38). Although the precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, hypothalamic cells appear to have an intrinsic ability to release GnRH episodically. Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release. At puberty the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. Although the mechanism of activation is not entirely established, it may involve increases in circulating insulin-like growth factor 1 (IGF)-1 and leptin levels, the latter acting to inhibit neuropeptide Y (NPY) in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 40–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. In the early follicular phase of the cycle: (1) the pulse generator produces bursts of neuronal activity with a frequency of about 1/h that correspond with pulses of GnRH secretion, (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes, and (3) FSH in particular causes the graafian follicle to mature
and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline, so gonadotropin levels gradually fall. Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses and may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus. *Inhibin*, produced by the ovary, exerts negative feedback to selectively decrease serum FSH.

![Hormonal relationships of the human menstrual cycle](image)

**Figure 40–3** Hormonal relationships of the human menstrual cycle. A. Average daily values of LH, FSH, estradiol (E₂), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian
follicle (top) and endometrium (bottom) also are illustrated schematically. Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Redrawn with permission from Thorneycroft et al., 1971. © Elsevier). B. Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) released (i.e., gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at mid-cycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (i.e., the pulse amplitude) during the luteal phase of the cycle.

At mid-cycle, serum estradiol rises above a threshold level of 150-200 pg/mL for ~36 h, exerting a brief positive feedback effect on the pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. Progesterone may contribute to the mid-cycle LH surge. The mid-cycle surge in gonadotropins stimulates follicular rupture and ovulation within 1-2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern, the entire system then resets, and a new ovarian cycle occurs.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release but then have a brief mid-cycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing progesterone receptors) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator,
lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle, and less frequent pulses of larger amplitude in the luteal phase.

In males, testosterone regulates the hypothalamic-pituitary-gonadal axis at both the hypothalamic and pituitary levels, and its negative feedback effect is mediated to a substantial degree by estrogen formed via aromatization.

**EFFECTS OF CYCLICAL GONADAL STEROIDS ON THE REPRODUCTIVE TRACT**

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge (see Figure 40–3).

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. An important response to estrogen in the endometrium and other tissues is induction of the progesterone receptor (PR), which enables cells to respond to this hormone during the second half of the cycle. In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models. Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow “window of implantation,” spanning days 19-24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. If implantation occurs, human chorionic gonadotropin (hCG), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. Later the placenta becomes the major site of estrogen and progesterone synthesis.
**METABOLIC EFFECTS.** Estrogens affect myriad tissues. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, the GI tract, and heart, express low levels of both estrogen receptors (ERs), and the ratio of ERe to ERβ varies in a cell-specific manner. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

Long-term administration of estrogen is associated with decreased plasma renin, angiotensin-converting enzyme, and endothelin-1; expression of the AT1 receptor for AngII is also decreased. Estrogen actions on the vascular wall include increased production of NO and prostacyclin. All of these changes promote vasodilation and retard atherogenesis. Estrogens alter a number of metabolic pathways that affect the clotting cascade. Systemic effects include changes in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and they decrease the anticoagulation factors protein C, protein S, and antithrombin III (see Chapter 30). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of plasminogen-activator inhibitor 1 (PAI-1) protein with a concomitant increase in fibrinolysis. Thus, estrogens increase both coagulation and fibrinolytic pathways, and imbalance in these 2 opposing activities may cause adverse effects.

Estrogens increase bone mass. Bone is continuously remodeled by the resorptive action of osteoclasts and the bone-forming action of osteoblasts. Estrogens directly regulate osteoblasts and increase osteocyte survival by inhibiting apoptosis. The major effect of estrogens is to decrease the number and activity of osteoclasts.

Estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. They increase high-density lipoprotein (HDL) levels and decrease the levels of low-density lipoprotein (LDL) and lipoprotein A (LPA) (see Chapter 31). The presence of ERs in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism may be due partly to direct hepatic actions. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with
cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and sex hormone-binding globulin (SHBG), which binds both androgens and estrogens.

**ESTROGEN RECEPTORS**

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The 2 estrogen receptor genes are located on separate chromosomes: ESR1 encodes ERα, and ESR2 encodes ERβ. Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes. Both ERα and ERβ exist as multiple mRNA isoforms due to differential promoter use and alternative splicing. There are significant differences between the 2 receptor isoforms in the ligand-binding domains and in both transactivation domains. Human ERβ does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds. However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

ERα is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. ERβ is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Both forms of ER are expressed on breast cancers, although ERβ is believed to be the predominant form responsible for growth regulation (see Chapter 63). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer, bone mass, endometrial cancer, or cardiovascular disease have led to contradictory results.

A cloned G protein-coupled receptor, GPR30, also appears to interact with estrogens in some cell systems, and its participation in the rapid effects of
estrogen is an attractive idea. There may be interaction/cross-talk between membrane-associated ERα and membrane-localized GPR30 in some cancer cells, but in vivo confirmation is lacking.

**MECHANISM OF ACTION**

Both ERs are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 40–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to heat-shock protein 90 (HSP90), and upon binding estrogen, a change in ER conformation dissociates the heat-shock proteins and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA. Homodimers of ERα or ERβ and ERα/ERβ heterodimers can be produced depending on the receptor complement in a given cell. The ER dimer binds to estrogen response elements (EREs), typically located in the promoter region of target genes. The ER/DNA complex recruits a cascade of coactivator and other proteins to the promoter region of target genes (Figure 40–4B and legend) and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.
Figure 40–4 Molecular mechanism of action of nuclear estrogen receptor. A. Unliganded estrogen receptor (ER) exists as a monomer within the nucleus. B. Agonists such as 17β-estradiol (E) bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific estrogen response elements in DNA. The ER-DNA complex recruits coactivators such as SWI/SNF that modify chromatin structure, and coactivators such as steroid-receptor coactivator-1 (SRC-1) that has histone acetyltransferase (HAT) activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other coactivators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. C. Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced
conformation also facilitates dimerization and interaction with DNA, but a
different set of proteins called corepressors, such as nuclear-hormone receptor
corepressor (NcoR), are recruited to the complex. NcoR further recruits proteins
such as histone deacetylase I (HDAC1) that act on histones to stabilize
nucleosome structure and prevent interaction with the GTA.

Some ERs are located on the plasma membrane of cells. These ERs are encoded
by the same genes that encode ERα and ERβ but are transported to the plasma
membrane and reside mainly in caveolae. Translocation to the membrane by all
sex steroid receptors is mediated by palmitoylation of a 9–amino acid motif
common to these receptors. Membrane-localized ERs mediate the rapid
activation of some proteins such as MAPK (phosphorylated in several cell types)
and the rapid increase in cyclic AMP caused by the hormone. These membrane
interactions and sequelae provide additional levels of cross-talk and complexity
in estrogen signaling.

**ADME.** Various estrogens are available for oral, parenteral,
transdermal, or topical administration. Given the lipophilic nature of
estrogens, absorption generally is good with the appropriate
preparation. Aqueous or oil-based esters of estradiol are available for
intramuscular injection, ranging in frequency from every week to once
per month. Conjugated estrogens are available for IV or IM
administration. Transdermal patches that are changed once or twice
weekly deliver estradiol continuously through the skin. Preparations
are available for topical use in the vagina or for application to the
skin. Estrogen preparations also are available in combination with a
progestin. All estrogens are labeled with precautionary statements
urging the prescribing of the lowest effective dose and for the shortest
duration consistent with the treatment goals and risks for each
individual patient.

Oral administration is common and may use estradiol, conjugated estrogens,
esters of estrone and other estrogens, and ethinyl estradiol (*in combination with
a progestin*). Estradiol is available in nonmicronized (*FEMTRACE*) and micronized
preparations (*ESTRACE*, others). The micronized formulations yield a large
surface for rapid absorption to partially overcome low absolute oral
bioavailability due to first-pass metabolism. Addition of the ethinyl substituent at C17 (ethinyl estradiol) inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens (PREMARIN), which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; esterified esters (MENEST); or mixtures of synthetic conjugated estrogens prepared from plant-derived sources (CENESTIN;ENJUVIA). These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, estropipate (ORTHO-EST, OGEN, others), estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; e.g., ethinyl estradiol is much more potent than conjugated estrogens.

Administration of estradiol via transdermal patches (ALORA, CLIMARA, ESTRADERM, VIVELLE, others) provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical emulsion (ESTRASORB) or as a gel (ESTROGEL). The transdermal route does not lead to the high level of the drug in the portal circulation after oral administration, and thus should minimize hepatic effects of estrogens. Preparations available for intramuscular injection include compounds such as estradiol valerate (DELESTROGEN, others) or estradiol cypionate (DEP-OESTRADIOL, others), which may be absorbed over several weeks following a single intramuscular injection. Preparations of estradiol (ESTRACE) and conjugated estrogen (PREMARIN) creams are available for topical administration to the vagina. A 3-month vaginal ring (ESTRING, FEMRING) may be used for slow release of estradiol, and tablets are also available for vaginal use (VAGIFEM).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG; ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively. Estrogens undergo rapid hepatic biotransformation, with a plasma $t_{1/2}$ measured in minutes. Estrogens also undergo enterohepatic recirculation via (1) sulfate and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption. Estradiol is converted primarily by 17β-hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16α-
hydroxylation and 17-keto reduction to estriol, the major urinary metabolite; myriad sulfate and glucuronide conjugates appear in the urine. Ethinyl estradiol is cleared much more slowly than estradiol due to decreased hepatic metabolism with $t_{1/2}$ of 13-27 h. *Mestranol*, a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol.

Many drugs, environmental agents (e.g., cigarette smoke), and nutraceuticals (e.g., St. John’s wort) act as inducers or inhibitors of the various enzymes that metabolize estrogens, and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is important with the decreased doses of estrogens currently employed for both menopausal hormone therapy and contraception. A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein, which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol; their efficacy at relevant doses has not been established in human trials.

**UNTOWARD RESPONSES.** Oral contraceptives now contain much lower amounts of both estrogen and progestins, and this has significantly diminished the risks associated with their use.

**CONCERN ABOUT CARCINOGENIC ACTIONS.** Early studies established that the use of estrogens is associated with the risk of developing breast, endometrial, cervical, and vaginal cancer. Estrogen use during pregnancy also can increase the incidence of cancer and nonmalignant genital abnormalities in both male and female offspring. The use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5- to 15-fold. This increased risk can be prevented if a progestin is coadministered with the estrogen, and this is now standard practice.

The association between estrogen and/or estrogen-progestin use and breast cancer is of great concern. The results of 2 large randomized clinical studies (the Women’s Health Initiative study [WHI], and the Million Women Study [MWS]) of estrogen/progestin and estrogen-only in postmenopausal women clearly established a small but significant increase in the risk of breast cancer,
apparently due to the medroxyprogesterone. In the WHI study, an estrogen-progestin combination increased the total risk of breast cancer by 25%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received estrogen alone, the relative risk of breast cancer was actually decreased. Thus, the data suggest that the progestin component in combined hormone-replacement therapy plays a major role in this increased risk of breast cancer. Importantly, the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy. Thus, hormone replacement therapy for ≥5 years is often prescribed to mitigate hot flashes and likely has a minimal effect on the risk of breast cancer.

METABOLIC AND CARDIOVASCULAR EFFECTS. Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, addition of progestins may reduce the favorable actions of estrogens. Estrogens do increase cholesterol levels in bile and cause a relative 2- to 3-fold increase in gallbladder disease. Many studies and clinical trials suggest that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease. However, 2 recent randomized clinical trials have not found such protection. In women with established coronary heart disease (CHD), estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, but there was no overall change in 5 years. In women without existing CHD, treated with an estrogen plus progestin, protective effects were seen but only when hormone replacement was initiated within 10 years of menopause. It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with preexisting cardiovascular disease.

EFFECTS ON COGNITION. Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer disease. However, in more recent studies, estrogen-progestin therapy was associated with increased incidence of dementia, and no benefit of hormone treatment on global cognitive function was observed.

OTHER POTENTIAL UNTOWARD EFFECTS. Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just
before sleep. Fullness and tenderness of the breasts and edema may occur but sometimes can be diminished by lowering the dose. A more serious concern is that estrogens may cause severe migraine in some women. Estrogens also may reactivate or exacerbate endometriosis.

**THERAPEUTIC USES.** The 2 major uses of estrogens are for menopausal hormone therapy (MHT) and as components of combination oral contraceptives, The “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. The doses of estrogens employed in both settings have decreased substantially, thereby reducing the incidence of untoward effects.

**MENOPAUSAL HORMONE THERAPY.** The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

**Vasomotor Symptoms.** The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy. Medroxyprogesterone acetate (discussed in the section on progestins) may provide some relief of vasomotor symptoms; the \( \alpha_2 \) adrenergic agonist clonidine diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

**Osteoporosis.** Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (see Chapter 44). The result is thinning and weakening of the bones and an increased incidence of fractures. Osteoporosis is an indication for estrogen therapy. Most fractures in the postmenopausal period occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women. Estrogens act primarily to decrease bone resorption; consequently, estrogens are more
effective at preventing rather than restoring bone loss and are most effective if treatment is initiated before significant bone loss occurs. Maximal benefit requires continuous use; bone loss resumes when treatment is discontinued. An appropriate diet with adequate intake of \( \text{Ca}^{2+} \) and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment. The bisphosphonates (see Chapter 44) can also be considered.

**Vaginal Dryness and Urogenital Atrophy.** Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women, including vaginal dryness and itching, painful intercourse, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. For relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

**Cardiovascular Disease.** The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause; epidemiological studies show an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. However, estrogens also promote coagulation and thromboembolic events. Randomized prospective studies unexpectedly indicated that the incidence of heart disease and stroke in older postmenopausal women, treated with conjugated estrogens and a progestin, was initially increased, although the trend reversed with time. Combined estrogen-progestin therapy is associated with a decrease in heart attacks in younger women.

**MENOPAUSAL HORMONE REGIMENS.** The use of hormone-replacement therapy, or HRT, that includes a progestin in addition to estrogen, limits estrogen-related endometrial hyperplasia. Postmenopausal HRT, when indicated, should include both an estrogen and progestin for women with a uterus. For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins. Menopausal hormone therapy with estrogens should use the lowest dose and shortest duration necessary to achieve an
appropriate therapeutic goal.

Conjugated estrogens and *medroxyprogesterone acetate* (MPA) have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and *norethindrone, norgestimate, levonorgestrel, norethisterone*, and *progesterone* also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12-14 days of estrogen treatment; and (3) 5-6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. PREMPRO (conjugated estrogens plus MPA given as a fixed dose daily) and PREMFASE (conjugated estrogens given for 28 days plus MPA given for 14 of 28 days) are widely used combination formulations. Other combination products available in the U.S. are FEMHRT (ethinyl estradiol plus norethindrone acetate), ACTIVELLA (estradiol plus norethindrone), PREFEST (estradiol and norgestimate), and ANGELIQ (estradiol and drospirenone). Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, and/or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than does transdermal administration and may increase SHBG, other binding globulins, angiotensinogen; and possibly the cholesterol content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (~50% of those seen with the oral route).

Tibolone (LIVIAL) is widely used in the E.U. for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the U.S. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to 3 metabolites that have predominantly estrogenic, progestogenic, and androgenic activities.
ESTROGEN TREATMENT IN THE FAILURE OF OVARIAN DEVELOPMENT. In several conditions (e.g., Turner syndrome), the ovaries do not develop and puberty does not occur. Therapy with estrogen at the appropriate time replicates the events of puberty, and androgens (see Chapter 41) and/or growth hormone (see Chapter 38) may be used concomitantly to promote normal growth. Although estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus result in a shorter ultimate height.

SELECTIVE ESTROGEN RECEPTOR MODULATORS AND ANTI-ESTROGENS

SELECTIVE ESTROGEN RECEPTOR MODULATORS: TAMOXIFEN, RALOXIFENE, AND TOREMIFENE. Selective estrogen receptor modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) but antagonist activity in tissues such as breast and endometrium. Currently approved drugs in the U.S. in this class are tamoxifen citrate, raloxifene hydrochloride (EVISTA), and toremifene (FARESTON).

ANTI-ESTROGENS: CLOMIPHENE AND FULVESTRANT. These compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene (CLOMID, SEROPHENE, others) is approved for the treatment of infertility in anovulatory women, and fulvestrant (FASLODEX) is used for the treatment of breast cancer in women with disease progression after tamoxifen.

PHARMACOLOGICAL EFFECTS. All of these agents bind to the ligand-binding pocket of both ERα and ER and competitively block estradiol binding. However, the conformation of ligand-bound ERs is different with different ligands, and this has 2 important mechanistic consequences. The distinct ER-ligand conformations recruit different coactivators and corepressors onto the promoter of a target gene. The
tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different coactivator and corepressor levels in different cell types.

**Tamoxifen** exhibits anti-estrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug’s activity depends on the tissue and end point measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women, and yet it stimulates proliferation of endometrial cells and causes endometrial thickening. The drug has an antiresorptive effect on bone, and in humans it decreases total cholesterol, LDL, and LPA but does not increase HDL and triglycerides. Tamoxifen treatment increases the relative risk of deep vein thrombosis, pulmonary embolism, and endometrial carcinoma. Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting. Whereas 17α estradiol induces a conformation that recruits coactivators to the receptor, tamoxifen induces a conformation that permits the recruitment of the corepressor to both ERα and ERβ. The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ER α; because ERβ does not contain a functional AF-1 domain, tamoxifen does not activate ERβ.

**Raloxifene** is an estrogen agonist in bone, where it exerts an antiresorptive effect. The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL. Raloxifene does not cause proliferation or thickening of the endometrium. Studies indicate that raloxifene significantly reduces the risk of ER-positive but not ER-negative breast cancer. Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes, leg cramps, and a 3-fold increase in deep vein thrombosis and pulmonary embolism.

**Clomiphene** increases gonadotropin secretion and stimulates ovulation. Clomiphene’s major pharmacological use is to induce ovulation in women with amenorrhea, polycystic ovarian syndrome, or dysfunctional bleeding with anovulatory cycles, but who have a functional hypothalamic-hypophysial-
ovarian system and adequate endogenous estrogen production.

**Fulvestrant** is anti-estrogenic. In clinical trials it is efficacious in treating tamoxifen-resistant breast cancers. Fulvestrant binds to ERα and ERβ with a high affinity comparable to estradiol but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ERα while apparently protecting ERβ from degradation. This effect on ERα protein levels may explain fulvestrant’s efficacy in tamoxifen-resistant breast cancer.

**ADME.** Tamoxifen is given orally, and peak plasma levels are reached within 4-7 h. It has 2 elimination phases with half-lives of 7-14 h and 4-11 days; thus, 3-4 weeks of treatment are required to reach steady-state plasma levels. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces. In humans, the more potent anti-estrogen metabolite 4-hydroxytamoxifen is produced in the liver. The major route of elimination from the body involves N-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite.

Oral **Raloxifene** is absorbed rapidly with a bioavailability of ~2%. The drug has a $t_{1/2}$ of ~28 h and is eliminated primarily in the feces after hepatic glucuronidation. **Clomiphene** is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces. The long plasma $t_{1/2}$ (5-7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues. **Fulvestrant** is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. The drug is eliminated primarily (90%) via the feces in humans.

**THERAPEUTIC USES**

**BREAST CANCER.** Tamoxifen is highly efficacious in the palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages. Response rates are ~50% in women with ER-
positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years is more efficacious than shorter 1- to 2-year treatment periods in reducing cancer recurrence and death. Prophylactic treatment should be limited to 5 years because effectiveness decreases thereafter. The most frequent side effect is hot flushes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by 2- to 3-fold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy and women with a history of deep vein thrombosis or stroke. Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

**OSTEOPOROSIS.** Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; HDL is not increased. Adverse effects include hot flushes, deep vein thrombosis, and leg cramps.

**INFERTILITY.** Clomiphene is used primarily for treatment of female infertility due to anovulation. By increasing gonadotropin levels, primarily FSH, it enhances follicular recruitment. It is relatively inexpensive, orally active, and requires less extensive monitoring than other treatment protocols. Untoward effects include ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. Prolonged use (e.g., ≥12 cycles) may increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when used to induce ovulation.

**ESTROGEN SYNTHESIS INHIBITORS**

Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (see Chapter 38). The recognition that locally produced as well as circulating estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (see Chapter 63). Both steroidal (e.g., formestane and exemestane [AROMASIN]) and
nonsteroidal agents (e.g., anastrozole [Arimidex], letrozole [Femara], and vorozole) are available. Steroidal, or type I, agents are substrate analogs that act as suicide inhibitors to irreversibly inactivate aromatase, whereas the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs. Exemestane, letrozole, and anastrozole are currently approved in the U.S. for the treatment of breast cancer. These agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen (see Chapter 62). They are highly efficacious and actually superior to tamoxifen in adjuvant use for postmenopausal women, and are indicated either following tamoxifen for 2-5 years or as initial agents. They have the added advantage of not increasing the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. They lack the beneficial effect of tamoxifen to maintain bone density.

**PROGESTINS**

Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (see Figure 40–3). LH, acting via its G protein-coupled receptor, stimulates progesterone secretion during the normal cycle.

![PROGESTERONE](image)

After fertilization, the trophoblast secretes hCG into the maternal circulation, which then stimulates the LH receptor to sustain the corpus luteum and maintain progesterone production. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration with the fetal adrenal glands, and thereafter the corpus luteum is not essential to
continued gestation. Estrogen and progesterone continue to be secreted in large amounts by the placenta up to the time of delivery.

The progestins are widely used with estrogens for MHT. Depot MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives (estranes) were developed for use as progestins in oral contraceptives, but they also exhibit androgenic and other activities. The gonanes are the “19-nor” compounds that have diminished androgenic activity relative to the estranes. These 2 classes of 19-nortestosterone derivatives are the progestational components of most oral and some long-acting injectable contraceptives. The remaining oral contraceptives contain a class of progestins derived from spironolactone (e.g., drospirenone) that have anti-mineralocorticoid and anti-androgenic properties. Other steroidal progestins include the gonane dienogest; 19-nor-progestin derivatives (e.g., nomegestrol, Nestorone, and trimegestone), which have increased selectivity for the progesterone receptor and less androgenic activity than estranes; and the spironolactone derivative drospirenone, which is used in combination with oral contraceptives. Like spironolactone, drospirenone is also a mineralocorticoid and androgen receptor antagonist.

**PHYSIOLOGICAL AND PHARMACOLOGICAL ACTIONS**

**NEUROENDOCRINE ACTIONS.** Progesterone produced in the luteal phase of the cycle decreases the frequency of GnRH pulses. This progesterone-mediated decrease in GnRH pulse frequency is critical for suppressing gonadotropin release and resetting the hypothalamic-pituitary-gonadal axis to transition from the luteal back to the follicular phase. Furthermore, GnRH suppression is the major mechanism of action of progestin-containing contraceptives.

**Reproductive Tract.** Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (see Figure 40–3); the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action on the endometrium and is essential to the development of the normal menstrual pattern. Progesterone also
influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant viscid material. These and other effects of progestins decrease penetration of the cervix by sperm. The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone. Progesterone is very important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility.

Mammary Gland. Development of the mammary gland requires both estrogen and progesterone. During pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin. During the luteal phase of the menstrual cycle, progesterone triggers a single round of mitotic activity in the mammary epithelium. This effect is transient; continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells.

CNS. During a normal menstrual cycle, an increase in basal body temperature of ~0.6°C (1°F) may be noted at mid-cycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar PCO₂ in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may help some patients sleep.

Metabolic Effects. Progesterone itself increases basal insulin levels and the rise in insulin after carbohydrate ingestion but does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogs such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. MPA decreases the favorable HDL
increase caused by conjugated estrogens during postmenopausal hormone replacement, but not the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly alter beneficial estrogen effects on either HDL or LDL profiles; the spironolactone derivative drospirenone may actually have advantageous effects on the cardiovascular system due to its anti-androgenic and anti-mineralocorticoid activities. Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

**CELLULAR MECHANISM OF ACTION.** A single gene encodes 2 isoforms of the progesterone receptor, PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A. Because the ligand-binding domains of the 2 PR isoforms are identical, their ligand-binding properties are also the same. However, the structural differences outside the ligand-binding region contribute to different interactions with coactivators and corepressors and thus differential activities of PR-A and PR-B. The biological activities of PR-A and PR-B are distinct and depend on the target gene. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B and is also a transcriptional inhibitor of other steroid receptors. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin, and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium. In contrast, PR-B may be responsible for mediating progesterone’s effects in the mammary gland.

In the absence of ligand, PR is present primarily in the nucleus in an inactive monomeric state bound to heat-shock proteins. When receptors bind progesterone, the heat-shock proteins dissociate and the receptors are phosphorylated and form dimers (homo- and hetero-) that bind to PREs (progesterone response elements) located on target genes. Transcriptional activation by PR occurs primarily via recruitment of coactivators. The receptor/coactivator complex then favors further interactions that mediate processes such as histone acetylase activity. Histone acetylation causes a remodeling of chromatin that increases the accessibility of general transcriptional proteins, including PolII, to the target promoter. Progesterone antagonists also facilitate receptor dimerization and DNA binding, but, as with ER, the conformation of antagonist-bound PR is different from that of agonist-
bound PR. This different conformation favors PR interaction with corepressors that recruit histone deacetylases, reducing accessibility of a target promoter to the transcriptional apparatus. In general mechanistic terms, the PR functions similarly to the ER (see Figure 40–4).

Certain effects of progesterone, such as increased Ca$^{2+}$ mobilization in sperm, can be seen in as little as 3 min and are therefore considered transcription-independent. Similarly, progesterone can promote oocyte maturation (meiotic resumption) independently of transcription.

ADME. The $t_{1/2}$ of progesterone is ~5 min, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3α, 20α-diol; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer half-lives (e.g., ~7 h for norethindrone, 16 h for norgestrel, 12 h for gestodene, and 24 h for MPA). The metabolism of synthetic progestins is primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites.

Even though progesterone undergoes rapid first-pass metabolism, high-dose (e.g., 100-200 mg) preparations of micronized progesterone (PROMETRIUM) are available for oral use. The absolute bioavailability of these preparations is low but efficacious plasma levels can be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel (CRINONE, PROCHIEVE), as a slow-release intrauterine device (PROGESTASERT) for contraception, and as a vaginal insert (ENDOMETRIN) for assisted reproductive technology. Esters such as MPA (DEPO-PROVERA) are available for intramuscular administration, and MPA (PROVERA, others) and megestrol acetate (MEGACE, others) may be used orally. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time.

THERAPEUTIC USES. Progestins are mainly used for contraception, either alone or with an estrogen, and in combination with estrogen for hormone therapy of postmenopausal women. Progestins also are used diagnostically for secondary amenorrhea. Combinations of estrogens and progestins can also be given to test
for endometrial responsiveness in patients with amenorrhea. Progestins are highly efficacious in decreasing the occurrence of endometrial hyperplasia and carcinoma caused by unopposed estrogens. Local intrauterine application via a hormone-releasing intrauterine device (IUD) containing levonorgestrel can be used to decrease estrogen-induced endometrial hyperplasia while reducing untoward effects of systemically administered progestins. Finally, levonorgestrel is used as so-called emergency contraception after known or suspected unprotected intercourse. The medication is given orally within 72 h after intercourse as either a single 1.5-mg dose (PLAN B ONE-STEP) or as 2 0.75-mg doses (PLAN B) separated by 12 h. The mechanism of action may involve several factors, including the prevention of ovulation, fertilization, and implantation.

ANTIPROGESTINS AND PROGESTERONE-RECEPTOR MODULATORS

The antiprogestin, RU 38486 (often referred to as RU-486) or mifepristone is available for the termination of pregnancy. Ulipristal acetate [ELLA (U.S.), ELLA ONE (E.U.)], a partial agonist at the progesterone receptor, is used for emergency contraception.

MIFEPRISTONE

Mifepristone is a derivative of the 19-norprogestin norethindrone containing a dimethyl-aminophenol substituent at the 11 β-position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone is considered a progesterone-receptor modulator (PRM) due to its context-dependent activity. Onapristone (or ZK 98299) is a pure progesterone antagonist, similar in structure to mifepristone but with a methyl substituent in the 13α rather than 13β orientation.
PHARMACOLOGICAL ACTIONS. Mifepristone acts primarily as a competitive receptor antagonist for both progesterone receptors, although it may have some agonist activity in certain contexts. When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uterine progesterone receptors. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of progesterone receptors in the uterus increases uterine prostaglandin levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst. Mifepristone can delay or prevent ovulation depending on the timing and manner of administration. If administered for 1 or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. Mifepristone also binds glucocorticoid and androgen receptors and exerts anti-glucocorticoid and anti-androgenic actions. Thus, mifepristone blocks the feedback inhibition by cortisol of ACTH secretion from the pituitary, thereby increasing plasma levels of corticotropin and adrenal steroids.

ADME. Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours. In plasma, it is bound by $\alpha_1$ acid glycoprotein, which contributes to the drug’s long $t_{1/2}$ (20-40 h). Metabolites are primarily the mono- and di-demethylated products (thought to have pharmacological activity) formed via CYP3A4. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces.

THERAPEUTIC USES. Mifepristone (MIFEPRISTONE), in combination with
misoprostol or other prostaglandins, is available for the termination of early pregnancy. When mifepristone is used to produce a medical abortion, a prostaglandin is given 48 h after the antiprogesterin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular sulprostone, intravaginal gemeprost, and oral misoprostol have been used. The most severe untoward effect is vaginal bleeding, which most often lasts 8-17 days but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the prostaglandin. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its antiglucocorticoid activity. In fact, due to its high affinity for the glucocorticoid receptor, high doses of mifepristone can result in adrenal insufficiency.

**ULIPRISTAL**

Ulipristal, a derivative of 19-norprogesterone, functions as a selective progesterone receptor modulator (SPRM), acting as a partial agonist at progesterone receptors. Unlike mifepristone, ulipristal appears to be a relatively weak glucocorticoid antagonist.

**PHARMACOLOGICAL ACTIONS.** In high doses, ulipristal has antiproliferative effects in the uterus; however, its most relevant actions to date involve its capacity to inhibit ovulation. Ulipristal’s anti-ovulatory actions likely occur due to progesterone regulation at many levels, including inhibition of LH release through the hypothalamus and pituitary, and inhibition of LH-induced follicular rupture within the ovary. A 30-mg dose of ulipristal can inhibit ovulation when taken up to 5 days after intercourse. Ulipristal can block ovarian rupture at or even just after the time of the LH surge. Ulipristal may also block endometrial implantation of the fertilized egg, although whether this contributes to its effects as an emergency contraceptive is not clear.

**THERAPEUTIC USES.** Ulipristal acetate [Ella, Ella One] has recently been licensed in the E.U. and the U.S. as an emergency contraceptive. Studies comparing ulipristal to levonorgestrel (progesterone-only emergency contraception, or POEC) demonstrate that ulipristal is at least as effective when taken up to 72 h after unprotected sexual intercourse. In addition, ulipristal
remains effective up to 120 h (5 days) after intercourse, making ulipristal a more versatile emergency contraceptive than levonorgestrel, which does not work well beyond 72 h after unprotected intercourse. The most severe side effect in clinical trials has been a headache and abdominal pain.

HORMONAL CONTRACEPTIVES

The incredible growth of the earth’s human population stands out as one of the fundamental events of the last 2 centuries. The Old Testament dictum “Be fruitful and multiply” (Genesis 9:1) has been followed too religiously by readers and nonreaders of the Bible alike. In 1798, Malthus started a great controversy by opposing the prevailing view of unlimited progress for humankind by making 2 postulates and a conclusion. Malthus postulated “that food is necessary for the existence of man” and that sexual attraction between female and male is necessary and likely to persist, since “toward the extinction of the passion between the sexes, no progress whatever has hitherto been made,” barring “individual exceptions.” Malthus concluded that “the power of populations is infinitely greater than the power of the earth to produce subsistence for man,” producing a “natural inequality” that would someday loom “insurmountable in the way to perfectibility of society.”

Malthus was right: passion between the sexes persists and the power of populations is very great indeed, so much so that our sheer numbers have increased to the point that they are straining the earth’s capacity to supply food, energy, and raw materials, and to absorb the detritus of its human burden. Marine fisheries are being depleted, forests and aquifers are disappearing, and the atmosphere is accumulating greenhouse gases from combustion of the fossil fuels that provide the energy needs of 7 billion people, up from 1 billion in Malthus’ day. Perhaps some of the blame can be laid at the feet of medical science: advances in public health and medicine have led to a significant decline in mortality and an increased life expectancy. However, medical science has also begun to assume a portion of the responsibility for overpopulation and its adverse effects. To this end, drugs in the form of hormones and their analogs have been developed to control human fertility.

COMBINATION ORAL CONTRACEPTIVES. The most frequently used agents in the U.S. are combination oral contraceptives containing
both an estrogen and a progestin. Their theoretical efficacy is 99.9%. Combination oral contraceptives are available in many formulations. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. (Virtually all preparations come as 28-day packs, with the pills for the last 7 days containing only inert ingredients.) For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “pill-free” period. The biphasic and triphasic preparations provide 2 or 3 different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day “off” period each month. However, several oral contraceptions are now available whereby progestin withdrawal is only induced every 3 months.

The estrogen content of current preparations ranges from 20-50 µg; most contain 30-35 µg. Preparations containing ≥35 µg of an estrogen are generally referred to as “low-dose” or “modern” pills. The dose of progestin is more variable because of differences in potency of the compounds used. A transdermal preparation of norelgestromin and ethinyl estradiol (Ortho Evra) is marketed for weekly application to the buttock, abdomen, upper arm, or torso for the first 3 consecutive weeks followed by a patch-free week for each 28-day cycle. A similar 3-week on/1-week off cycle is employed for the intravaginal ring containing ethinyl estradiol and etonogestrel (Nuvaring).

**PROGESTIN-ONLY CONTRACEPTIVES.** Several agents are available with theoretical efficacies of 99%. Specific preparations include the “minipill”; low doses of progestins (e.g., 350 µg of norethindrone [NOR-QD, Ortho Micronor, others]) taken daily without interruption; subdermal implants of 216 mg of norgestrel (NORPLANT II, JADELLE) for long-term contraceptive action (e.g., up to 5 years) or 68 mg of etonogestrel (IMPLANON) for contraception.
lasting 3 years; and crystalline suspensions of medroxyprogesterone acetate for intramuscular injection of 104 mg (DEPO-SUBQ PROVERA 104) or 150 mg (DEPO-PROVERA, others) of drug; each provides effective contraception for 3 months. An IUD (PROGESTASERT) that releases low amounts of progesterone locally is available for insertion on a yearly basis. Its effectiveness is considered to be 97-98%, and contraceptive action probably is due to local effects on the endometrium. An IUD (MIRENA) releases levonorgestrel for up to 5 years.

MECHANISM OF ACTION

COMBINATION ORAL CONTRACEPTIVES. Combination oral contraceptives act by preventing ovulation. Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a mid-cycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone diminishes the frequency of GnRH pulses. Because the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents.

Multiple pituitary effects of both estrogen and progestin components are likely to contribute to oral contraceptive action. Oral contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. The progestin component may also inhibit the estrogen-induced LH surge at mid-cycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation.

PROGESTIN-ONLY CONTRACEPTIVES. Progestin-only pills and
levonorgestrel implants are highly efficacious but block ovulation in only 60-80% of cycles. Their effectiveness is thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of IUDs that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation, presumably by decreasing the frequency of GnRH pulses.

**UNTOWARD EFFECTS**

**COMBINATION ORAL CONTRACEPTIVES.** Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors.

*Cardiovascular Effects.* For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). The risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism. Postmarketing studies indicate that women using transdermal contraceptives have a higher than expected exposure to estrogen and are at increased risk for the development of venous thromboembolism.

Early high-dose combination oral contraceptives caused hypertension in 4-5% of normotensive women and increased blood pressure in 10-15% of those with preexisting hypertension. This incidence is much lower with newer low-dose preparations, and most reported changes in blood pressure are not significant. The cardiovascular risk associated with oral contraceptive use does not appear to persist after use is discontinued. Estrogens increase serum HDL and decrease LDL levels; progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant changes in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have
been reported.

Cancer. Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. There is not a widespread association between oral contraceptive use and cancer. Epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about 2-fold but only in long-term users (>5 years) with persistent human papilloma virus infection. There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma. Current estimates indicate there is about a doubling in the risk of liver cancer after 4-8 years of use; these are rare cancers, and the absolute increases are small.

The effects of oral contraceptives on breast cancer are a concern. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1-1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose, or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. Combination oral contraceptives decrease the incidence of endometrial cancer by 50%, an effect that lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer.

Metabolic and Endocrine Effects. The effects of sex steroids on glucose metabolism and insulin sensitivity are complex and may differ among agents in the same class. Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance; these effects have decreased as steroid dosages have been lowered; current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives raised LDL and reduced HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles. There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and associated with very long-
The estrogentic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including those that bind thyroid hormones, glucocorticoids, and sex steroids. Although physiological feedback mechanisms generally adjust hormone synthesis to maintain normal “free” hormone levels, these changes can affect the interpretation of endocrine function tests that measure total plasma hormone levels, and may necessitate dose adjustment in patients receiving thyroid-hormone replacement. The ethinyl estradiol present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity that exerts a counter effect so that overall there is a minimal effect on hemostatic balance. This compensatory effect is diminished in smokers.

**Miscellaneous Effects.** Nausea, edema, and mild headache occur in some individuals; migraine headaches may be precipitated in a smaller fraction of women. Breakthrough bleeding may occur during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day “off” period, thus causing confusion about a possible pregnancy. Acne and hirsutism may be due to the androgenic activity of the 19-nor progestins.

**PROGESTIN-ONLY CONTRACEPTIVES.** Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases. No evidence indicates that the progestin-only minipill preparations increase thromboembolic events. Acne may be a problem because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation.

Headache is a commonly reported untoward effect of depot MPA. Mood changes and weight gain also have been reported. Many studies have found decreases in HDL levels and increases in LDL levels, and there have been reports of decreased bone density. These effects may be due to reduced endogenous estrogens because depot MPA lowers gonadotropin levels. Because of the time required to completely eliminate the drug, the contraceptive effect of this agent
may remain for 6-12 months after the last injection. Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and, rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported. Acne is seen in some patients. Ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

CONTRAINDICATIONS. Modern oral contraceptives are considered generally safe in most healthy women; however, these agents can contribute to the incidence and severity of cardiovascular, thromboembolic, or malignant disease, particularly if other risk factors are present. Contraindications for combination oral contraceptive use include: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. The risk of serious cardiovascular side effects is particularly marked in women >35 years of age who smoke heavily (e.g., >15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Other relative contraindications include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, discontinuation of oral contraceptives for several weeks to a month is recommended to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose forms should generally be used in such cases. Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer. Depot MPA and levonorgestrel inserts are contraindicated in women with a history or predisposition to thrombophlebitis or thromboembolic disorders.

CHOICE OF CONTRACEPTIVE PREPARATIONS
Treatment should generally begin with preparations containing the minimum dose of steroids that provides effective contraceptive coverage. This is typically a pill with 30-35 µg of estrogen, but preparations with 20 µg may be adequate for lighter women or >40 years of age with perimenopausal symptoms; a preparation containing 50 µg of estrogen may be required for heavier women. In women for whom estrogens are contraindicated or undesirable, progestin-only contraceptives may be an option. The progestin-only minipill may have enhanced effectiveness in several such types of women (e.g., nursing mothers and women >40 years of age, in whom fertility may be decreased). The choice of a preparation also may be influenced by the specific 19-nor progestin component because this component may have varying degrees of androgenic and other activities. The androgenic activity of this component may contribute to untoward effects such as weight gain, acne due to increased sebaceous gland secretions, and unfavorable lipoprotein profiles. These side effects are greatly reduced in newer low-dose contraceptives that contain progestins with little to no androgenic activity.

NONCONTRACEPTIVE HEALTH BENEFITS

Combination oral contraceptives have substantial health benefits unrelated to their contraceptive use. Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use. Depot MPA injections reduce substantially the incidence of uterine cancer. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease. Oral contraceptives have major benefits related to menstruation in many women, including more regular menstruation, reduced menstrual blood loss, less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated.
TESTOSTERONE AND OTHER ANDROGENS

In men, testosterone is the principal secreted androgen. Leydig cells synthesize the majority of testosterone by the pathways shown in Figure 41–1. In women, testosterone also is the principal androgen and is synthesized in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors androstenedione and dehydroepiandrosterone are weak androgens that can be converted peripherally to testosterone.

Figure 41–1 Pathway of synthesis of testosterone in the Leydig cells of the testes. In Leydig cells, the 11 and 21 hydroxylases (present in adrenal cortex) are absent but CYP17 (17 α-hydroxylase) is present. Thus, androgens and estrogens are synthesized; corticosterone and cortisol are not formed. Bold arrows indicate
favored pathways.

**SECRETION AND TRANSPORT OF TESTOSTERONE.** Testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains many of the other differences between men and women. In the first trimester in utero, the fetal testes begin to secrete testosterone, the principal factor in male sexual differentiation, probably stimulated by human chorionic gonadotropin (hCG) from the placenta. By the beginning of the second trimester, the serum testosterone concentration is close to that of mid-puberty, ~250 ng/dL (Figure 41–2). Testosterone production then falls by the end of the second trimester, but by birth the value is again ~250 ng/dL, possibly due to stimulation of the fetal Leydig cells by luteinizing hormone (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at ~250 ng/dL at 2-3 months after birth and falls to <50 ng/dL by 6 months, where it remains until puberty. During puberty, from ~12 to 17 years of age, the serum testosterone concentration in males increases so that by early adulthood the serum testosterone concentration is 500 ng/dL to 700 ng/dL in men, compared to 30 ng/dL to 50 ng/dL in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.
Figure 41–2 Schematic representation of the serum testosterone concentration from early gestation to old age.

LH, secreted by the pituitary gonadotropes (see Chapter 38), is the principal stimulus of testosterone secretion in men, perhaps potentiated by follicle-stimulating hormone (FSH), also secreted by gonadotropes. The secretion of LH by gonadotropes is positively regulated by hypothalamic gonadotropin-releasing hormone (GnRH); testosterone directly inhibits LH secretion in a negative feedback loop. LH is secreted in pulses, which occur approximately every 2 h and are greater in magnitude in the morning. The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Testosterone secretion is likewise pulsatile and diurnal, the highest plasma concentrations occurring at ~8 A.M. and the lowest at ~8 P.M. The morning peaks diminish as men age. Sex hormone-binding globulin (SHBG) binds ~40% of circulating testosterone with high affinity, rendering the bound hormone unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving ~2% unbound or free. In women, LH stimulates the corpus luteum (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, estradiol and progesterone, not testosterone, are the principal inhibitors of LH secretion in women.
METABOLISM OF TESTOSTERONE TO ACTIVE AND INACTIVE COMPOUNDS. Testosterone has many different effects in tissues, both directly and through its metabolism to dihydrotestosterone and estradiol (Figure 41–3). The enzyme 5α-reductase catalyzes the conversion of testosterone to dihydrotestosterone. Dihydrotestosterone binds the androgen receptor (AR) with higher affinity than testosterone and activates gene expression more efficiently. Two forms of 5α-reductase have been identified: type I, which is found predominantly in nongenital skin, liver, and bone; and type II, which is found predominantly in urogenital tissue in men and genital skin in men and women. The enzyme complex aromatase, present in many tissues, catalyzes the conversion of testosterone to estradiol. This conversion accounts for ~85% of circulating estradiol in men; the remainder is secreted directly by the testes. Hepatic metabolism converts testosterone to the biologically inactive compounds androsterone and etiocholanolone (see Figure 41–3). Dihydrotestosterone is metabolized to androsterone, androstenedione, and androstenediol.

![Figure 41–3 Metabolism of testosterone to its major active and inactive metabolites.](image-url)
PHYSIOLOGICAL AND PHARMACOLOGICAL EFFECTS OF ANDROGENS

Testosterone is the principal circulating androgen in men. The varied effects of testosterone are due to its ability to act by at least 3 mechanisms: by binding to the AR; by conversion in certain tissues to dihydrotestosterone, which also binds to the AR; and by conversion to estradiol, which binds to the estrogen receptor (Figure 41–4).

![Diagram of testosterone metabolism and effects](image)

Figure 41–4 Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.

EFFECTS THAT OCCUR VIA THE ANDROGEN RECEPTOR.
Testosterone and dihydrotestosterone act as androgens via a single AR, a member of the nuclear receptor superfamily and is designated as NR3A.

In the absence of a ligand, the AR is located in the cytoplasm associated with a
heat-shock protein complex. When testosterone or dihydrotestosterone binds to the ligand-binding domain, the AR dissociates from the heat-shock protein complex, dimerizes, and translocates to the nucleus. The dimer then binds via the DNA-binding domains to androgen response elements on certain responsive genes. The ligand-receptor complex recruits coactivators and acts as a transcription factor complex, stimulating or repressing expression of those genes.

Mutations in the hormone or DNA-binding regions of AR result in resistance to the action of testosterone, beginning in utero. Male sexual differentiation therefore is incomplete, as is pubertal development. Other AR mutations occur in patients with spinal and bulbar muscular atrophy, known as Kennedy disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the molecule. The result is very mild androgen resistance, manifest principally by gynecomastia, and progressively severe motor neuron atrophy. The mechanism by which the neuronal atrophy occurs is unknown. Other mutations in AR may explain why metastatic prostate cancer often regresses initially in response to androgen deprivation treatment, but then becomes unresponsive to continued deprivation. AR continues to be expressed in androgen-independent prostate cancer, and its signaling remains active. The ligand-independent signaling may result from mutations in the AR gene or changes in AR coregulatory proteins. In some patients resistant to standard androgen deprivation therapy, the tumor responds to further depletion of androgens by inhibitors of adrenal androgen synthesis, such as abiraterone.

**EFFECTS THAT OCCUR VIA THE ESTROGEN RECEPTOR.** Certain effects of testosterone are mediated by its conversion to estradiol, catalyzed by CYP19.

In the rare males deficient in CYP19 or the estrogen receptor, the epiphyses do not fuse and long-bone growth continues indefinitely; moreover, such patients are osteoporotic. Estradiol corrects the bone abnormalities in patients with
aromatase deficiency but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone expresses the AR, testosterone also may have an effect on bone via the AR. Administration of estradiol to a male with CYP19 deficiency can increase libido, suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol.

**EFFECTS OF ANDROGENS AT DIFFERENT STAGES OF LIFE**

*In Utero.* When the fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby Wolffian ducts to differentiate into the male internal genitalia. In the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia. The increase in testosterone at the end of gestation may result in further phallic growth.

*Infancy.* The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

*Puberty.* Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes. The increase in testosterone production by Leydig cells and the effect of FSH on the Sertoli cells stimulate the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously, and the changes in most of them occur gradually during the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Muscle mass and strength, especially of the shoulder girdle, increase, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to a slowing and then cessation of growth. Bone also becomes thicker. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin
concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops. Other changes may result from the increase in testosterone during puberty. Men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

**Adulthood.** The serum testosterone concentration and the characteristics of the adult man are maintained largely during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples and/or at the vertex. Two other conditions are of great medical significance. One is benign *prostatic hyperplasia*, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5α-reductase II within prostatic cells. The other change is the development of *prostate cancer*. Although no direct evidence suggests that testosterone causes the disease, prostate cancer depends on androgen stimulation. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action at the receptor.

**Senescence.** As men age, the serum testosterone concentration gradually declines (see Figure 41–2), and the SHBG concentration gradually increases, so that by age 80, the total testosterone concentration is ~80% and the free testosterone is ~40% of those at age 20. This fall in serum testosterone could contribute to several other changes that occur with increasing age in men, including decreases in energy, libido, muscle mass and strength, and bone mineral density. Androgen deprivation also leads to insulin resistance, truncal obesity, and abnormal serum lipids, as observed in patients with metastatic prostate cancer receiving this treatment (see also Chapter 63).

**CONSEQUENCES OF ANDROGEN DEFICIENCY**

The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.
**DURING FETAL DEVELOPMENT.** Testosterone deficiency in a male fetus during the first trimester in utero causes incomplete sexual differentiation. Complete deficiency of testosterone secretion results in entirely female external genitalia. Testosterone deficiency at this stage of development also leads to failure of the Wolffian ducts to differentiate into the male internal genitalia, but the Müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete Müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally but its action is diminished because of an abnormality of the AR or of the 5α-reductase. Abnormalities of the AR can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization in utero and result only in impaired spermatogenesis in adulthood. Abnormal 5α-reductase results in incomplete virilization of the external genitalia in utero but normal development of the male internal genitalia, which requires only testosterone. Testosterone deficiency during the third trimester impairs phallus growth. The result, microphallus, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH synthesis. In addition, with testosterone deficiency, the testes fail to descend into the scrotum; this condition, cryptorchidism, occurs commonly in boys whose LH secretion is subnormal (see Chapter 38).

**BEFORE COMPLETION OF PUBERTY.** When a boy can secrete testosterone normally in utero but loses the ability to do so before the anticipated age of puberty, the result is failure to complete puberty. All of the pubertal changes previously described, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue, called *gynecomastia*.

**AFTER COMPLETION OF PUBERTY.** When testosterone secretion becomes impaired after puberty (e.g., castration or anti-androgen treatment), regression of the pubertal effects of testosterone depends on both the degree and the duration
of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or 2, but other testosterone-dependent characteristics decline more slowly. A clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably can be detected by dual energy absorptiometry within 2 years. A loss of sexual hair takes many years.

IN WOMEN. Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. The loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) may result in the loss of effects associated with libido, energy, muscle mass and strength, and bone mineral density.

THERAPEUTIC ANDROGEN PREPARATIONS

Ingestion of testosterone is not an effective means of replacing testosterone deficiency due to the rapid hepatic catabolism. Most pharmaceutical preparations of androgens, therefore, are designed to bypass hepatic catabolism of testosterone.

TESTOSTERONE ESTERS. Esterifying a fatty acid to the 17α-hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthate (heptanoate) or cypionate (cyclopentylpropionate) (Table 41–1), is dissolved in oil and administered intramuscularly every 2-4 weeks to hypogonadal men, the ester hydrolyzes in vivo and results in serum testosterone concentrations that range from higher than normal in the first few days after the injection to low normal just before the next injection (Figure 41–5). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone, when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic catabolism. Testosterone undecanoate in oil also can be injected and produces stable serum testosterone concentrations for 2 months. The undecanoate ester of testosterone is not currently marketed in the U.S.

**ALKYLATED ANDROGENS.** Several decades ago, chemists found that adding an alkyl group to the 17α position of testosterone retards its hepatic catabolism. Consequently, 17α-alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone and cause hepatotoxicity, whereas native testosterone does not. Some 17α-alkylated androgens show greater anabolic effects than androgenic effects compared to native testosterone in laboratory tests in rats; however, these “anabolic” steroids, so favored by athletes to illicitly improve performance, have not been convincingly demonstrated to have such a differential effect in human beings. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances.

**TRANSDERMAL DELIVERY SYSTEMS.** Chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. The first such preparations were patches, 1 of which (*Androderm*) is still available. Newer preparations include gels (*Androgel*, *Testim*, *Bio-T-Gel*) and a buccal tablet (*Striant*) (see Figure 41–5).

**SELECTIVE ANDROGEN RECEPTOR MODULATORS.** Selective estrogen receptor modulators (SERMs) have been developed (see Chapter 40). Are selective AR modulators possible that exhibit desirable effects of testosterone in some tissues, such as muscle and bone, without the undesirable effects in other tissues, such as prostate? Nonsteroidal molecules with these properties have been developed and are being tested in humans.

**THERAPEUTIC USES OF ANDROGENS**

**MALE HYPOGONADISM.** The best established indication for
administration of androgens is testosterone deficiency in men. Any of the testosterone preparations or testosterone esters described can be used to treat testosterone deficiency.

**Monitoring for Efficacy.** The goal of administering testosterone to a hypogonadal man is to mimic as closely as possible the normal serum concentration (see Figure 41–5). Therefore, measuring the serum testosterone concentration during treatment is the most important aspect of monitoring testosterone treatment for efficacy. When the enanthate or cypionate ester of testosterone is administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation. Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in adult men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years.

**Monitoring for Deleterious Effects.** Testosterone administered by itself as a the transdermal preparation has no “side effects” (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17α-alkylated androgens, do have undesirable effects even when dosages are targeted at physiological replacement. Some of these undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins. Replacement of physiological levels of testosterone occasionally may have undesirable effects in the presence of concomitant illnesses. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these
conditions. When a man is >40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer. The principal adverse effects of the 17α-alkylated androgens are hepatic, including cholestasis and, uncommonly, peliosis hepatis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. The 17α-alkylated androgens, especially in large amounts, may lower serum high-density lipoprotein cholesterol.

**Monitoring at the Anticipated Time of Puberty.** Testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth-hormone status of the boy being treated, must be considered. Boys who are short because of growth-hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

**MALE SENESCENCE.** Preliminary evidence suggests that increasing the serum testosterone concentration of men whose serum levels are subnormal for no reason other than their age will increase their bone mineral density and lean mass and decrease their fat mass. It is uncertain, however, if such treatment will worsen benign prostatic hyperplasia or increase the incidence of prostate cancer.

**FEMALE HYPOGONADISM.** In a study of women with low serum testosterone concentrations due to panhypopituitarism, increasing the testosterone concentration to normal was associated with small increases in bone mineral density, fat-free mass, and sexual function compared to placebo.

**ENHANCEMENT OF ATHLETIC PERFORMANCE.** Some athletes take drugs, including androgens, to attempt to improve their performance. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances.

**Kinds of Androgens Used.** Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When such use by athletes began more than 25 years ago, 17α-alkylated androgens and other compounds that were thought to have greater anabolic effects than androgen effects relative to testosterone (so-called anabolic steroids) were used most commonly. Because
these compounds can be detected readily by organizations that govern athletic competitions, other agents that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone (DHEA), also have increased in popularity recently because they are treated as nutritional supplements and thus are not regulated by athletic organizations. A new development in use of androgens by athletes is tetrahydrogestrinone (THG), a potent androgen that appears to have been designed and synthesized in order to avoid detection by antidoping laboratories on the basis of its novel structure (see Table 41–1) and rapid catabolism.

**Efficacy.** The few controlled studies of the effects of pharmacological doses of androgens do suggest a dose-dependent effect of testosterone on muscle strength that acts synergistically with exercise. In another trial, androstenedione did not produce an increase in muscle strength in men compared to placebo; the treatment also did not increase the mean serum testosterone concentration.

**Side Effects.** All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis. When administered in high doses, androgens that can be converted to estrogens, such as testosterone itself, cause gynecomastia. Androgens whose A ring has been modified so that it cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia even in high doses. The 17α-alkylated androgens are the only androgens that cause hepatotoxicity. These androgens, when administered in high doses, affect serum lipid concentrations, specifically to decrease high-density lipoprotein (HDL) cholesterol and increase low-density lipoprotein (LDL) cholesterol. Women and children experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

**CATABOLIC AND WASTING STATES.** Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting
states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with acquired immunodeficiency syndrome (AIDS), which often is accompanied by hypogonadism.

**ANGIOEDEMA.** Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it. The 17α-alkylated androgens (e.g., stanozolol, danazol) stimulate hepatic synthesis of the esterase inhibitor. Alternatively, concentrated C1-esterase inhibitor derived from human plasma (CINRYZE) may be used for protection in patients with hereditary angioedema.

**BLOOD DYSCRASIAS.** Androgens, such as danazol, still are used occasionally as adjunctive treatment for hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

**ANTI-ANDROGENS**

Some antifungal drugs of the imidazole family, such as ketoconazole (see Chapter 57), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis but sometimes are employed in cases of glucocorticoid excess (see Chapter 42).

**INHIBITORS OF ANDROGEN ACTION.** These drugs inhibit the binding of androgens to the AR or inhibit 5α-reductase.

**ANDROGEN RECEPTOR ANTAGONISTS.**

*Flutamide, Bicalutamide, Nilutamide, and Enzalutamide.* These relatively potent AR antagonists have limited efficacy when used
alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analog in the treatment of metastatic prostate cancer (see Chapter 63). Flutamide also has been used to treat hirsutism in women; however, its association with hepatotoxicity warrants caution against its use for this cosmetic purpose.

![Flutamide](image)

Spironolactone (Aldactone; see Chapter 25) is an inhibitor of aldosterone that also is a weak inhibitor of the AR and a weak inhibitor of testosterone synthesis. When the agent is used to treat fluid retention or hypertension in men, gynecomastia is a common side effect. In part because of this adverse effect, the selective mineralocorticoid receptor antagonist eplerenone (Inspra) was developed. Spironolactone can be used in women to treat hirsutism. Cyproterone acetate is a progestin and a weak anti-androgen by virtue of binding to the AR. It is effective in reducing hirsutism but is not approved for use in the U.S.

5α-REDUCTASE INHIBITORS. Finasteride (Proscar) and dutasteride (Avodart) are antagonists of 5α-reductase. They block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These drugs are approved to treat benign prostatic hyperplasia.

Impotence is a documented, albeit infrequent, side effect of this use. Gynecomastia is a rare side effect. Finasteride also is approved for use in the treatment of male pattern baldness under the trade name Propecia, and is effective in the treatment of hirsutism.
Finasteride
The major physiological and pharmacological effects of \textit{adrenocorticotropic hormone} (ACTH, corticotropin) result from its action to increase the circulating levels of \textit{adrenocortical steroids}. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because corticosteroids mimic the therapeutic effects of ACTH, synthetic steroids generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are employed at physiological doses for replacement therapy when endogenous production is impaired. Glucocorticoids potently suppress inflammation, and their use in inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because glucocorticoids exert effects on almost every organ system, the clinical use of and withdrawal from corticosteroids are complicated by a number of serious side effects. Therefore, the decision to institute therapy with systemic corticosteroids always requires careful consideration of the relative risks and benefits in each patient.

\textbf{ACTH}

Human ACTH, a peptide of 39 amino acids, is synthesized as part of a larger precursor protein, proopiomelanocortin (POMC), and is liberated from the precursor through proteolytic cleavage at dibasic residues by the \textit{serine endoprotease, prohormone convertase 1} (also known as prohormone convertase 3) (\textit{Figure 42–1}). Other biologically important peptides, including \textit{endorphins, lipotropins, and the melanocyte-stimulating hormones} (MSHs), also are produced by proteolytic processing of the same POMC precursor (\textit{see Chapter 18}).
Figure 42–1 Processing of proopiomelanocortin POMC to ACTH.
Proopiomelanocortin (POMC) is converted to adrenocorticotropic hormone (ACTH) and other peptides in the anterior pituitary. The boxes within the ACTH structure indicate regions important for steroidogenic activity (residues 6-10) and binding to the ACTH receptor (15-18). α-Melanocyte-stimulating hormone also derives from the POMC precursor and contains the first 13 residues of ACTH. LPH, lipotropin; MSH, melanocyte-stimulating hormone.

The actions of ACTH and the other melanocortins liberated from POMC are mediated by their specific interactions with 5 melanocortin receptor (MCR) subtypes (MC1R-MC5R) comprising a subfamily of G protein-coupled receptors (GPCRs). The well-known effects of MSH on pigmentation result from interactions with the MC1R on melanocytes. ACTH, which is identical to α-MSH in its first 13 amino acids, exerts its effects on the adrenal cortex through the MC2R. The affinity of ACTH for the MC1R is much lower than for the MC2R; however, under pathological conditions in which ACTH levels are persistently elevated, such as primary adrenal insufficiency, ACTH also can signal through the MC1R and cause hyperpigmentation. β-MSH and possibly other melanocortins, acting via the MC4R and MC3R in the hypothalamus, play a role in regulating appetite and body weight. The role of MC5R is less well defined.
ACTIONS ON THE ADRENAL CORTEX. Acting via MC2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor dehydroepiandrosterone (DHEA). The adrenal cortex histologically and functionally can be separated into 3 zones (Figure 42–2) that produce different steroid products under different regulatory influences:

- The outer zona glomerulosa secretes the mineralocorticoid aldosterone.

Figure 42–2 The three anatomically and functionally distinct compartments of the adrenal cortex. The major functional compartments of the adrenal cortex are shown, along with the steroidogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiological regulators of steroid production: angiotensin II (AngII) and K⁺ for the zona glomerulosa and ACTH for the zona fasciculata. The physiological regulator(s) of dehydroepiandrosterone (DHEA) production by the zona reticularis are not known, although ACTH acutely increases DHEA biosynthesis.
• The middle zona fasciculata secretes the glucocorticoid cortisol.
• The inner zona reticularis secretes DHEA and its sulfated derivative DHEAS (plasma concentration 1000× that of DHEA). DHEA sulfatase converts DHEAS to DHEA in the periphery.

Cells of the outer zone have receptors for angiotensin II (AngII) and express aldosterone synthase (CYP11B2), an enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by AngII and extracellular K+ (see Chapter 25) and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. With persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed ACTH escape). Cells of the zona fasciculata have fewer receptors for AngII and express steroid 17α-hydroxylase (CYP17) and 11β-hydroxylase (CYP11B1) enzymes that catalyze the production of glucocorticoids. In the zona reticularis, CYP17 carries out an additional C17-20 lyase reaction that converts C21 corticosteroids to C19 androgen precursors.

In the absence of the anterior pituitary and ACTH stimulation, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired. Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hypertrophy and hyperplasia of the inner zones of the adrenal cortex, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis.

**MECHANISM OF ACTION.** ACTH stimulates the synthesis and release of adrenocortical hormones by increasing de novo biosynthesis. ACTH, binding to MC2R, activates the Gs-adenylyl cyclase-cyclic AMP-PKA pathway. Cyclic AMP is the second messenger for most effects of ACTH on steroidogenesis. Temporally, the response of adrenocortical cells to ACTH has 2 phases. The acute phase, which occurs within seconds to minutes, largely reflects increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes. Pathways of adrenal steroid biosynthesis and the
structures of the major steroid intermediates and products of the human adrenal
cortex are shown in Figure 42–3. The rate-limiting step in steroid hormone
production is the conversion of cholesterol to pregnenolone, a reaction catalyzed
by CYP11A1, the cholesterol side-chain cleavage enzyme. Most of the enzymes
required for steroid hormone biosynthesis, including CYP11A1, are members of
the cytochrome P450 superfamily (see Chapter 6).

Figure 42–3 Pathways of corticosteroid biosynthesis. The steroidogenic
pathways used in the biosynthesis of the corticosteroids are shown, along with
the structures of the intermediates and products. The pathways unique to the
zona glomerulosa are shown in the orange box; those that occur in the inner zona
fasciculata and zona reticularis are shown in the *gray box*. The zona reticularis does not express 3β-HSD and thus preferentially synthesizes DHEA; see Figure 42–2. CYP11A1, cholesterol side-chain cleavage enzyme; 3β-HSD, 3β-hydroxysteroid dehydrogenase; CYP17, steroid 17α-hydroxylase; CYP21, steroid 21-hydroxylase; CYP11B2, aldosterone synthase; CYP11B1, steroid 11β-hydroxylase.

**REGULATION OF ACTH SECRETION**

**HYPOTHALAMIC-PITUITARY-ADRENAL AXIS.** The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes are regulated by corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP), peptide hormones released by specialized neurons of the endocrine hypothalamus. This hypothalamic-pituitary-adrenal (HPA) axis forms an integrated system that maintains appropriate levels of glucocorticoids (Figure 42–4). The 3 characteristic modes of regulation of the HPA axis are *diurnal rhythm* in basal steroidogenesis, *negative feedback regulation* by adrenal corticosteroids, and marked *increases in steroidogenesis in response to stress.*
The diurnal rhythm is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at ~8 A.M. Negative feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

ARGININE VASOPRESSIN. AVP also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. AVP is produced in the paraventricular nucleus and secreted into the pituitary plexus from the median eminence. AVP binds to V₁b receptor and activates the Gq-PLC-IP₃-Ca²⁺ pathway to enhance the release of ACTH. In contrast to CRH, AVP does not increase ACTH synthesis.
NEGATIVE FEEDBACK OF GLUCOCORTICOIDS. Glucocorticoids inhibit ACTH secretion via direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and via direct effects on corticotropes. The indirect inhibitory effects on CRH neurons appear to be mediated by specific corticosteroid receptors in the hippocampus. At lower cortisol levels, the mineralocorticoid receptor (MR), which has a higher affinity for glucocorticoids than classical glucocorticoid receptors (GRs), is the major receptor species occupied. As glucocorticoid concentrations rise and saturate the MR, the GR becomes increasingly occupied. Both the MR and GR apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves the GR. In the pituitary, glucocorticoids act through the GR to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes) and delayed (requiring hours and involving changes in gene transcription mediated through the GR).

THE STRESS RESPONSE. Stress overcomes negative feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, increased corticosteroid secretion is vital to maintain homeostasis in these stressful settings. As discussed later, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response.

ASSAYS FOR ACTH. Immunochemiluminescent assays that use 2 separate antibodies directed at distinct epitopes on the ACTH molecule now are widely available. These assays increase the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism, due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemiluminescent ACTH assays also are useful in differentiating between ACTH-dependent and ACTH-independent forms of hypercorticism: High ACTH levels are seen when the hypercorticism results from pituitary adenomas (e.g., Cushing disease) or nonpituitary tumors that secrete ACTH (e.g., the syndrome of ectopic ACTH),
whereas low ACTH levels are seen in patients with excessive glucocorticoid production due to primary adrenal disorders. One problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

**THERAPEUTIC USES AND DIAGNOSTIC APPLICATIONS OF ACTH.** ACTH has limited utility therapeutically. All proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects. Moreover, therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. Cosyntropin (CORTROSYN, SYNACTHEN), a synthetic peptide that corresponds to residues 1-24 of human ACTH, is used testing the integrity of the HPA axis. At the considerably supraphysiological dose of 250 μg, cosyntropin maximally stimulates adrenocortical steroidogenesis. An increase in the circulating cortisol to a level greater than 18-20 μg/dL indicates a normal response.

**CRH Stimulation Test.** Ovine CRH (corticorelin [ACTHREL]) and human CRH are available for diagnostic testing of the HPA axis, with the former used in the U.S. and the latter preferred in Europe. In patients with documented ACTH-dependent hypercorticism, CRH testing may help differentiate between a pituitary source (i.e., Cushing disease) and an ectopic source of ACTH.

**ABSORPTION AND FATE TOXICITY.** ACTH is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the $t_{1/2}$ in plasma is ~15 min, primarily due to rapid enzymatic hydrolysis. Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyntropin generally is less antigenic than native ACTH.

**ADRENOCORTICAL STEROIDS**

The adrenal cortex synthesizes 2 classes of steroids: the *corticosteroids* (glucocorticoids and mineralocorticoids; see Figure
42–3), which have 21 carbon atoms, and the androgens, which have 19 carbons (see Figures 41–1 and 41–3). The actions of corticosteroids historically were described as glucocorticoid (reflecting their carbohydrate metabolism–regulating activity) and mineralocorticoid (reflecting their electrolyte balance–regulating activity). In humans, cortisol (hydrocortisone) is the main glucocorticoid and aldosterone is the main mineralocorticoid (Table 42–1).

Although the adrenal cortex is an important source of androgen precursors in women, patients with adrenal insufficiency can be restored to normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Adrenal androgens are not essential for survival. The levels of DHEA and DHEA-S peak in the third decade of life and decline progressively thereafter. Moreover, patients with a number of chronic diseases have very low DHEA levels, leading some to propose that DHEA treatment might at least partly alleviate the loss of libido, the decline in cognitive function, the decreased sense of well-being, and other adverse physiological consequences of aging. However, studies on the benefits of addition of DHEA to the standard replacement regimen in women with adrenal insufficiency have been inconclusive.

PHYSIOLOGICAL FUNCTIONS AND PHARMACOLOGICAL EFFECTS

PHYSIOLOGICAL ACTIONS. Corticosteroids have numerous effects, which include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and
preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist stressful and noxious stimuli and environmental changes. In the absence of the adrenal cortex, survival is made possible only by maintaining an optimal environment, including adequate and regular feeding, ingestion of relatively large amounts of NaCl, and maintenance of an appropriate environmental temperature; stresses such as infection, trauma, and extremes in temperature in this setting can be life threatening.

The actions of corticosteroids are related to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Conversely, in the absence of glucocorticoids, EPI and NE have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed permissive and most likely reflect steroid-induced changes in protein synthesis that, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are termed mineralocorticoids and glucocorticoids, according to their relative potencies in Na\(^+\) retention, effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis), and anti-inflammatory effects. In general, potencies of steroids as judged by their ability to sustain life in adrenalectomized animals closely parallel those determined for Na\(^+\) retention, whereas potencies based on effects on glucose metabolism closely parallel those for anti-inflammatory effects. The effects on Na\(^+\) retention and the carbohydrate/anti-inflammatory actions are not closely related and reflect selective actions at distinct receptors. As noted below (see structure-activity relationships and Table 42–3), some steroid derivatives provide relative selectivity for effects on Na\(^+\) retention or anti-inflammatory effects.

**GENERAL MECHANISMS FOR CORTICOSTEROID EFFECTS.**
Corticosteroids bind to specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby
changing the levels and array of proteins synthesized by the various target tissues (Figure 38–5). Most effects of corticosteroids are not immediate but become apparent after several hours; clinically, one generally sees a delay before beneficial effects of corticosteroid therapy become manifest. Although corticosteroids predominantly act by increasing gene transcription, there are examples in which glucocorticoids decrease gene transcription. In addition, corticosteroids may exert some of their immediate effects by nongenomic mechanisms.

Glucocorticoid Receptors (GRs). The receptors for corticosteroids are members of the nuclear receptor family of transcription factors. The GR resides predominantly in the cytoplasm in an inactive form complexed with other proteins. Steroid binding results in receptor activation and translocation to the nucleus (see Figure 38–5). Several GR isoforms result from alternative RNA splicing. Of these, GRα is the prototypical glucocorticoid-responsive isoform. A second major GR isoform, GRβ, is a truncated dominant negative variant that lacks 35 amino acids at the C-terminus and is unable to bind glucocorticoids or activate gene expression. Polymorphisms have been identified in the human GR that are associated with differences in GR function and have been linked to glucocorticoid insensitivity.

Regulation of Gene Expression by Glucocorticoids. After ligand binding, the GR dissociates from its associated proteins and translocates to the nucleus. There, it interacts with specific DNA sequences called glucocorticoid responsive elements (GREs), which provide specificity to the induction of gene transcription by glucocorticoids. Genes can be activated or inhibited by GR-GRE interactions. The mechanisms by which GR activates transcription are complex and not completely understood, but they involve the interaction of the GR with transcriptional coactivators and with proteins that make up the basal transcription apparatus. In a case of transcriptional inhibition by GR, GR inhibits transcription of POMC by a direct interaction with a GRE in the POMC promoter, thereby contributing to the negative feedback regulation of the HPA axis. Other genes negatively regulated by glucocorticoids include genes for cyclooxygenase-2 (COX-2), inducible NO synthase (NOS2), and inflammatory cytokines. Some inhibitory effects of glucocorticoids such as downregulation of
expression of genes encoding a number of cytokines, collagenase, and stromelysin, have been linked to protein–protein interactions between the GR and other transcription factors (e.g., NF-κB and AP-1) rather than to negative effects of the GR at specific GREs. Such protein–protein interactions and their consequent negative effects on gene expression appear to contribute significantly to the anti-inflammatory and immunosuppressive effects of the glucocorticoids.

Regulation of Gene Expression by Mineralocorticoids. Like the GR, the mineralocorticoid receptor (MR) also is a ligand-activated transcription factor and binds to a very similar hormone-responsive element. The MR also associates with HSP90 and activates the transcription of discrete sets of genes within target tissues. The selective actions of GR and MR result from differences in their ability to inhibit AP-1–mediated gene activation and differential interactions with other transcription factors. In addition, the MR has restricted expression: It is expressed in epithelial tissues involved in electrolyte transport (i.e., the kidney, colon, salivary glands, and sweat glands) and in nonepithelial tissues (e.g., hippocampus, heart, vasculature and adipose tissue).

Aldosterone exerts its effects on Na\(^+\) and K\(^+\) homeostasis primarily via its actions on the principal cells of the distal renal tubules and collecting ducts, whereas the effects on H\(^+\) secretion largely are exerted in the intercalated cells. The binding of aldosterone to the MR in the kidney initiates a sequence of events that includes the rapid induction of serum- and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na\(^+\) channels in the apical membrane. Thereafter, increased Na\(^+\) influx stimulates the Na\(^+\), K\(^+\)-ATPase in the basolateral membrane. In addition to these rapid genomic actions, aldosterone also increases the synthesis of the individual components of these membrane proteins as part of a more delayed effect.

Receptor-Independent Mechanism for Corticosteroid Specificity. Aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) bind the MR with equal affinity. The apparent specificity of the MR for aldosterone is maintained in the face of much higher circulating levels of glucocorticoids by the type 2 isozyme of 11β-hydroxysteroid dehydrogenase (11βHSD2). This enzyme metabolizes glucocorticoids such as cortisol to receptor-inactive 11-keto derivatives such as cortisone (Figure 42–5). Because its predominant physiological form is the hemiacetal derivative that is resistant to 11βHSD action, aldosterone escapes this inactivation and maintains
mineralocorticoid activity.

**Figure 42–5** *11β-hydroxysteroid dehydrogenase confers specificity of corticosteroid action*. Type 2 *11β*-hydroxysteroid dehydrogenase (11β-HSD2) converts cortisol, which binds to both the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), to cortisone, which binds to neither MR nor GR, thereby protecting the MR from the high circulating concentrations of cortisol. This inactivation allows specific responses to aldosterone in sites such as the distal nephron. Aldosterone hemiacetal is resistant to 11βHSD. The type 1 isozyme of 11βHSD (11βHSD1) catalyzes the reverse reaction, which converts inactive cortisone to active cortisol in such tissues as liver and fat. Only ring C of the corticosteroid is depicted; see text figures for structures of cortisone and aldosterone hemiacetal.

**CARBOHYDRATE AND PROTEIN METABOLISM**. Corticosteroids profoundly affect carbohydrate and protein metabolism, which can be viewed as protecting glucose-dependent tissues (e.g., the brain and heart) from starvation. They stimulate the liver to form glucose from amino acids and glycerol and to store glucose as liver glycogen. In the
periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Because of their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in susceptible patients.

**LIPID METABOLISM.** Two effects of corticosteroids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in hypercorticism, such as Cushing syndrome. In this setting, there is increased fat in the back of the neck (“buffalo hump”), face (“moon facies”), and supraclavicular area, coupled with a loss of fat in the extremities. The other is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration.

**ELECTROLYTE AND WATER BALANCE.** Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na\(^+\) from the tubular fluid; they also increase the urinary excretion of K\(^+\) and H\(^+\). These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na\(^+\) balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na\(^+\) concentration, normal or low plasma K\(^+\), and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na\(^+\) wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Chronically, hyperaldosteronism causes hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water. In part, the inability of patients with glucocorticoid deficiency to
excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney. In addition to their effects on monovalent cations and water, glucocorticoids also exert multiple effects on Ca\(^{2+}\) metabolism. Steroids lower Ca\(^{2+}\) uptake from the gut and increase Ca\(^{2+}\) excretion by the kidney. These effects collectively lead to decreased total body Ca\(^{2+}\) stores.

CARDIOVASCULAR SYSTEM. The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na\(^{+}\), as is evident in primary aldosteronism. MR activation has direct effects on the heart and vessel walls; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis appears to result from direct mineralocorticoid actions in the heart rather than from the effect of hypertension because treatment with spironolactone, an MR antagonist, blocks the development of fibrosis without altering blood pressure. The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced responsiveness to vasoconstrictors such as NE and AngII, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

SKELETAL MUSCLE. Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, either secondary to glucocorticoid therapy or endogenous hypercorticism, causes skeletal muscle wasting. This effect, *steroid myopathy*, accounts in part for weakness and fatigue in patients with glucocorticoid excess.

CNS. Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte
concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability. Patients with adrenal insufficiency exhibit a diverse array of neurological manifestations, including apathy, depression, and irritability, even psychosis. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as mania, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing syndrome.

FORMED ELEMENTS OF BLOOD. Glucocorticoids exert minor effects on hemoglobin and erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing syndrome and of normochromic, normocytic anemia in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish erythrocytes destruction. Corticosteroids also affect circulating white blood cells. Addison disease is associated with an increased mass of lymphoid tissue and lymphocytosis. In contrast, Cushing syndrome is characterized by lymphocytopenia and decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4-6 h; this effect persists for 24 h and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and decreased adherence to vascular walls. Finally, certain lymphoid malignancies are destroyed by glucocorticoid treatment, an effect that may relate to the capacity of glucocorticoids to activate apoptosis.

ANTI-INFLAMMATORY AND IMMUNOSUPPRESSIVE ACTIONS. In addition to their effects on lymphocyte number, corticosteroids
profoundly alter the immune responses of lymphocytes. These effects are an important facet of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Although the use of glucocorticoids as anti-inflammatory agents does not address the underlying cause of the disease, the suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense valuable in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (see Chapter 65), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (see Chapter 35). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. Glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of pro-inflammatory cytokines, as well as COX-2 and NOS2. Some of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 42–2.

Table 42–2

Inhibitory Effects of Glucocorticoids on Inflammatory/Immune Responses
ADME

ABSORPTION. Hydrocortisone and numerous congeners, including the synthetic analogs, are orally effective. Certain water-soluble esters of hydrocortisone and its synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action. Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

TRANSPORT, METABOLISM, AND EXCRETION. After absorption, ≥90% of cortisol in plasma is reversibly bound to protein under normal circumstances. Only the fraction of corticosteroid that is unbound is active and can enter cells. Two plasma proteins account for almost all of the steroid-binding capacity: corticosteroid-binding globulin (CBG; also called transcortin), and albumin.
CBG is an α-globulin secreted by the liver that has high affinity for steroids (estimated dissociation constant of \(~1.3 \times 10^{-9}\) M) but relatively low total binding capacity, whereas albumin, also produced by the liver, has a relatively large binding capacity but low affinity (estimated dissociation constant of \(1 \times 10^{-3}\) M). At normal or low concentrations of corticosteroids, most of the hormone is protein bound. At higher steroid concentrations, the capacity of protein binding is exceeded, and a greater fraction of the steroid exists in the free state. CBG has relatively high affinity for cortisol and some of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these latter steroids are found in the free form. A special state of physiological hypercorticism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase severalfold. The physiological significance of these changes remains to be established.

Synthetic steroids with an 11-keto group, such as cortisone and prednisone, must be enzymatically reduced to the corresponding 11β-hydroxy derivative before they are biologically active. The type 1 isozyme of 11β-hydroxysteroid dehydrogenase (11βHSD1) catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., hydrocortisone or prednisolone rather than cortisone or prednisone). Such settings include severe hepatic failure and patients with the rare condition of cortisone reductase deficiency.

**STRUCTURE-ACTIVITY RELATIONSHIPS.** Chemical modifications to the cortisol molecule have generated derivatives with greater separations of glucocorticoid and mineralocorticoid activity (Table 42–3); for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used. In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. None of these currently available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism, or from suppressive effects on the HPA axis.

*Biological t½: S, short (8-12 h); I, intermediate (12-36 h); L, long (36-72 h).

*Dose relationships apply only to oral or IV administration; potencies may differ greatly following IM or intra-articular administration.

*This agent is not used for glucocorticoid effects.

Estimates of Na⁺-retaining and anti-inflammatory potencies of representative steroids are listed in Table 42–3. Some steroids that are classified predominantly as glucocorticoids (e.g., cortisol), also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency, the mineralocorticoid effects of these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na⁺ retention but has only modest potency for effects on carbohydrate metabolism. At normal rates of secretion by the adrenal cortex or in doses that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

**TOXICITY OF ADRENOCORTICAL STEROIDS**

Two categories of toxic effects result from the therapeutic use of corticosteroids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life threatening and require a careful assessment of the risks and benefits in each patient.
WITHDRAWAL OF THERAPY. The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. Several other complications are associated with steroid withdrawal. The most severe complication of steroid cessation, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to recovery can be a year or longer. Protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment with corticosteroids have been proposed. Patients who have received supraphysiological doses of glucocorticoids for a period of 2-4 weeks within the preceding year should be considered to have some degree of HPA impairment. A characteristic glucocorticoid withdrawal syndrome consists of fever, myalgia, arthralgia, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted. Finally, *pseudotumor cerebri*, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

CONTINUED USE OF SUPRAPHYSIOLOGICAL GLUCOCORTICOID DOSES. Besides the consequences that result from the suppression of the HPA axis, a number of other complications result from prolonged therapy with corticosteroids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, possible peptic ulcers, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

THERAPEUTIC USES

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the appropriate dose to achieve a given therapeutic effect must be determined by trial and error and must be reevaluated periodically as
the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond 1 week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.

When glucocorticoids are to be given over long periods, the dose must be determined by trial and error and must be the lowest that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate tapering the glucocorticoid dose once the initial benefit of therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent accurate observations of the patient.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis to be made. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient. Long courses of therapy at high doses should be reserved for life-threatening disease. To
diminish HPA axis suppression, the intermediate-acting steroid preparations (e.g., prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoids also has been employed because certain patients obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1-1.5 g/day of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders such as acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis.

REPLACEMENT THERAPY FOR ADRENAL INSUFFICIENCY. Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in developing countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, acquired immunodeficiency syndrome, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy. Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

ACUTE ADRENAL INSUFFICIENCY. This life-threatening disease is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus and sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic sodium chloride solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiac function often is reduced in the setting of adrenocortical insufficiency, the patient should be
monitored for evidence of volume overload such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone (cortisol) should be given by continuous infusion at a rate of 50-100 mg every 8 h, a dose that confers sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6-8 h. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency. For the treatment of unconfirmed acute adrenal insufficiency, 4 mg of dexamethasone sodium phosphate can be substituted for hydrocortisone because dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin stimulation test). A failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency.

**CHRONIC ADRENAL INSUFFICIENCY.** Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis but with lesser severity. These patients require daily treatment with corticosteroids.

Traditional replacement regimens have used hydrocortisone in doses of 20-30 mg/day. *Cortisone acetate*, which is inactive until converted to cortisol by 11βHSD1, also has been used in doses ranging from 25-37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; fludrocortisone acetate generally is used in doses of 0.05-0.2 mg/day. For patients with secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate because the zona glomerulosa, which makes mineralocorticoids, is intact. When initiating treatment in patients with panhypopituitarism, it is important to administer glucocorticoids before initiating treatment with thyroid hormone because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol.

The adequacy of corticosteroid replacement therapy is judged by clinical criteria
and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed but should be <100 pg/mL (22 pmol/L).

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., phenytoin, barbiturates, or rifampin) or who suffer the stress of intercurrent illness. *All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen.* During minor illness, the glucocorticoid dose should be doubled. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg subcutaneously or intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo surgery. In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is hydrocortisone, 100 mg parenterally every 8 h. Following surgery, the dose is halved each day until it is reduced to routine maintenance levels.

**CONGENITAL ADRENAL HYPERPLASIA (CAH).** This is a group of genetic disorders in which the activity of 1 of the several enzymes required for the biosynthesis of glucocorticoids is deficient. The impaired production of cortisol and the consequent lack of negative feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. CAH includes a spectrum of disorders for which precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient. In ~90% of patients, CAH results
from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (see Figure 42–3).

Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH, if not treated in utero with glucocorticoids, frequently are born with virilized external genitalia (female pseudohermaphroditism) that results from elevated production of adrenal androgen precursors at critical stages of sexual differentiation in utero. Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses. Some patients with classical CAH are unable to conserve Na\(^+\) normally and thus are called “salt wasters.” All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is \(~0.6\) mg/kg daily in 2 or 3 divided doses. The mineralocorticoid used is fludrocortisone acetate (0.05-0.2 mg/day). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

**THERAPEUTIC USES IN NONENDOCRINE DISEASES.** There are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed below illustrate the principles governing glucocorticoid use in selected diseases for which glucocorticoids are more frequently employed. The dosage of glucocorticoids varies considerably depending on the nature and
severity of the underlying disorder. Approximate doses of a representative glucocorticoid (e.g., prednisone) are provided.

**Rheumatic Disorders.** Glucocorticoids are used widely in the treatment of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg/day in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by the clinical picture.

Glucocorticoids are often used in conjunction with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Intermediate-acting glucocorticoids such as prednisone and methylprednisolone are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with chronic use, glucocorticoids are used as stabilizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory agents. In this case, glucocorticoids provide relief until other, slower-acting antirheumatic drugs (e.g., methotrexate or agents targeted at tumor necrosis factor) take effect. A typical starting dose is 5-10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20-40 mg/day of prednisone or equivalent), with rapid taper thereafter. Alternatively, patients with major symptomatology confined to 1 or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5-20 mg of triamcinolone acetonide or its equivalent.
In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to use a glucocorticoid that does not require bioactivation (e.g., prednisolone rather than prednisone) and to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

**Renal Diseases.** Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1-2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6-8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2-3 weeks in 85% of patients, and >95% of patients have remission within 3 months. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8-10 weeks (e.g., prednisone, 120 mg every other day), followed by a 1- to 2-month period of tapering.

**Allergic Disease.** The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine. The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone, 125 mg intravenously every 6 h, or equivalent) are appropriate. In allergic rhinitis, intranasal steroids are viewed as the drug of choice by many experts.

**Pulmonary Diseases.** The use of glucocorticoids in bronchial asthma and other pulmonary diseases is discussed in Chapter 36. Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of
respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely. Betamethasone (12 mg intramuscularly every 24 h for 2 doses) or dexamethasone (6 mg intramuscularly every 12 h for 4 doses) is administered to women with definitive signs of premature labor between 26 and 34 weeks of gestation.

**Infectious Diseases.** Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One example of beneficial effects is seen in AIDS patients with *Pneumocystis carinii* pneumonia and moderate to severe hypoxia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children ≥2 months of age.

**Ocular Diseases.** Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival sac. For diseases of the posterior segment, intraocular injection or systemic administration is required. These uses of glucocorticoids are discussed in Chapter 64.

**Skin Diseases.** Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatological disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/day of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Chapter 65 presents the dermatologic uses of glucocorticoids.

**GI Diseases.** Patients with inflammatory bowel disease (chronic ulcerative
colitis and Crohn disease) who fail to respond to more conservative management (i.e., rest, diet, and sulfasalazine) may benefit from glucocorticoids; steroids are most useful for acute exacerbations (see Chapter 47).

**Hepatic Diseases.** The use of corticosteroids in hepatic disease has been highly controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis; as many as 80% of patients show histological remission when treated with prednisone (40-60 mg daily initially, with tapering to a maintenance dose of 7.5-10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent meta-analyses do not support a beneficial role of corticosteroids. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

**Malignancies.** Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects, most commonly as a component of combination therapy (see Chapters 46 and 63).

**Cerebral Edema.** Corticosteroids are of value in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic.

**MISCELLANEOUS USES**

**Sarcoidosis.** Corticosteroids are indicated therapy for patients with debilitating symptoms or life-threatening forms of sarcoidosis. Patients with severe pulmonary involvement are treated with 10-20 mg/day of prednisone, or an equivalent dose of alternative steroids, to induce remission. Higher doses may be required for other forms of this disease. Maintenance doses may be as low as 5 mg/day of prednisone. All patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate are at increased risk of secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should receive prophylactic antituberculosis therapy.

**Thrombocytopenia.** In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1-1.5
mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed high-dose glucocorticoid therapy.

**Autoimmune Destruction of Erythrocytes.** Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive Coombs test) are treated with prednisone (1 mg/kg/day). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

**Organ Transplantation.** In organ transplantation, high doses of prednisone (50-100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (see Chapter 35). For some solid organ transplants (e.g., pancreas), protocols that either withdraw corticosteroids early after transplantation or that avoid them completely are becoming more common.

**Spinal Cord Injury.** Multicenter-controlled trials have demonstrated significant decreases in neurological defects in patients with acute spinal cord injury treated within 8 h of injury with large doses of methylprednisolone sodium succinate (30 mg/kg initially followed by an infusion of 5.4 mg/kg/h for 23 h).

**DIAGNOSTIC APPLICATIONS OF DEXAMETHASONE.** In addition to its therapeutic uses, dexamethasone is used as a first-line agent to diagnose hypercortisolism and to differentiate among the different causes of Cushing syndrome. The rationale and procedure are described in detail on page 1233 of the 12th edition of the parent text.

**INHIBITORS OF THE BIOSYNTHESIS AND ACTION OF ADRENOCORTICAL STEROIDS**

Hypercortisolism with its attendant morbidity and mortality is most frequently caused by corticotroph adenomas that overproduce ACTH (Cushing disease) or by adrenocortical tumors or bilateral hyperplasias that overproduce cortisol (Cushing syndrome). Less frequently, hypercortisolism may result from adrenocortical carcinomas or ectopic ACTH- or CRH-producing tumors. Although
surgery is the treatment of choice, it is not always effective, and adjuvant therapy with inhibitors of steroidogenesis becomes necessary. In these settings, ketoconazole, metyrapone, etomidate, and mitotane are clinically useful. Ketoconazole, etomidate, and mitotane are discussed in more detail in other chapters. All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient’s HPA axis must be carefully monitored. Agents that act as glucocorticoid receptor antagonists (antiglucocorticoids) are discussed later in this chapter; mineralocorticoid antagonists are discussed in Chapter 25.

**Ketoconazole.** Ketoconazole (NIZORAL) is an antifungal agent (see Chapter 57). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because of its inhibition of the activity of CYP17 (17α-hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is the best tolerated and most effective inhibitor of steroid hormone biosynthesis in patients with hypercortisolism (although the FDA has not approved this indication for ketoconazole). In most cases, a dosage regimen of 600-800 mg/day (in 2 divided doses) is required, and some patients may require up to 1200 mg/day (in 2-3 doses). Side effects include hepatic dysfunction. The potential of ketoconazole to interact with CYP isoforms can lead to serious drug interactions (see Chapter 6).

**Metyrapone.** Metyrapone (METOPIRONE) is a relatively selective inhibitor of CYP11B1 (11β-hydroxylase), which converts 11-deoxycortisol to cortisol, thereby reducing cortisol production and elevating precursor levels (e.g., 11-deoxycortisol). Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycortisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol and 11-deoxycortisol are measured at 8 A.M. the next morning. A plasma cortisol <8 μg/dL validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycortisol level <7 μg/dL is highly suggestive of impaired hypothalamic-pituitary-adrenal function.
Metyrapone has been used to treat the hypercorticism resulting from either adrenal neoplasms or tumors producing ACTH ectopically. Maximal suppression of steroidogenesis requires doses of 4 g/day. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500-750 mg 3 or 4 times daily is employed. The use of metyrapone in the treatment of Cushing syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycortisol. Other side effects include nausea, headache, sedation, and rash.

**Etomidate.** Etomidate (AMIDATE), a substituted imidazole used primarily as an anesthetic agent and sedative, inhibits cortisol secretion at subhypnotic doses primarily by inhibiting CYP11B1 activity. Etomidate has been used off-label to treat hypercortisolism when rapid control is required in a patient who cannot take medication by the oral route. Etomidate is administered as a bolus of 0.03 mg/kg intravenously, followed by an infusion of 0.1 mg/kg/h to a maximum of 0.3 mg/kg/h.

**Mitotane.** Mitotane (LYSODREN) is an adrenocorticolytic agent used to treat inoperable adrenocortical carcinoma. Its cytolytic action is due to its metabolic conversion to a reactive acyl chloride by adrenal mitochondrial CYPs and subsequent reactivity with cellular proteins. Doses range from 0.5-3 g administered 3 times daily. Its onset of action takes weeks to months, and GI disturbances and ataxia are its major toxicities.

**Aminogluthethimide.** Aminogluthethimide (CYTADREN) primarily inhibits CYP11A1 (the initial and rate-limiting step in the biosynthesis of all physiological steroids) and also inhibits CYP11B1 and CYP19 (aromatase). Aminogluthethimide recently has been withdrawn from the market by the manufacturer and is no longer available.

**ANTIGLUCOCORTICOIDS**

The progesterone receptor antagonist mifepristone (MIFEPREX; RU-486) has received considerable attention because of its use as an
antiprogestogen that can terminate early pregnancy (see Chapter 66). At higher doses, mifepristone also inhibits the GR, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its capacity to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in a small number of patients with hypercortisolism. Currently, its use for this purpose is restricted to patients with inoperable causes of cortisol excess that have not responded to other agents.
Diabetes mellitus is a spectrum of metabolic disorders arising from myriad pathogenic mechanisms, all resulting in hyperglycemia. Both genetic and environmental factors contribute to its pathogenesis, which involves insufficient insulin secretion, reduced responsiveness to endogenous or exogenous insulin, increased glucose production, and/or abnormalities in fat and protein metabolism. The resulting hyperglycemia may lead to both acute symptoms and metabolic abnormalities. Major sources of the morbidity of diabetes are the chronic complications that arise from prolonged hyperglycemia, including retinopathy, neuropathy, nephropathy, and cardiovascular disease. These chronic complications can be mitigated in many patients by sustained control of the blood glucose. There are now a wide variety of treatment options for hyperglycemia that target different processes involved in glucose regulation or dysregulation.

**PHYSIOLOGY OF GLUCOSE HOMEOSTASIS**

**REGULATION OF BLOOD GLUCOSE.** The maintenance of glucose homeostasis, termed *glucose tolerance*, is a highly developed systemic process involving the integration of several major organs ([Figure 43–1](#)). Although the actions of insulin are of central importance, webs of inter-organ communication via other hormones, nerves, local factors and substrates, also play a vital role. The pancreatic β cell is central in this homeostatic process, adjusting the amount of insulin secreted very precisely to promote glucose uptake after meals and to regulate glucose output from the liver during fasting.
Figure 43–1 Insulin, glucagon, and glucose homeostasis. **A. Fasting State**—In healthy humans plasma glucose is maintained in a range from 4.4-5 mM, and fatty acids near 400 µM. In the absence of nutrient absorption from the GI tract, glucose is supplied primarily from the liver and fatty acids from adipose tissue. With fasting, plasma insulin levels are low, and plasma glucagon is elevated, contributing to increased hepatic glycogenolysis and gluconeogenesis; low insulin also releases adipocytes from inhibition, permitting increased lipogenesis. Most tissues oxidize primarily fatty acids during fasting, sparing glucose for use by the CNS. **B. Prandial State**—During feeding, nutrient absorption causes an increase in plasma glucose, resulting in release of incretins from the gut and neural stimuli that promote insulin secretion. Under the control of insulin, the liver, skeletal muscle, and adipose tissue actively take up glucose. Hepatic glucose production and lipolysis are inhibited, and total body glucose oxidation increases. The brain senses plasma glucose concentrations and provides regulatory inputs contributing to fuel homeostasis. The *boldness of the arrows* reflects relative intensity of action; a *dashed line* indicates little or no activity.

In the *fasting state* (Figure 43–1A), the fuel demands of the body are met by the oxidation of fatty acids. The brain does not effectively use fatty acids to meet energy needs and in the fasting state requires glucose for normal function; glucose requirements are ~2 mg/kg/min in adult humans, largely to supply the
central nervous system (CNS) with an energy source. Fasting glucose requirements are primarily provided by the liver. Liver glycogen stores provide some of this glucose; conversion of lactate, alanine, and glycerol into glucose accounts for the remainder. The dominant regulation of hepatic glycogenolysis and gluconeogenesis are the pancreatic islet hormones insulin and glucagon. Insulin inhibits hepatic glucose production, and the decline of circulating insulin concentrations in the post-absorptive state (fasting) is permissive for higher rates of glucose output. Glucagon maintains blood glucose concentrations at physiological levels in the absence of exogenous carbohydrate (overnight and in between meals) by stimulating gluconeogenesis and glycogenolysis by the liver. Insulin secretion is stimulated by food ingestion, nutrient absorption, and elevated blood glucose, and insulin promotes glucose, lipid, and protein anabolism (Figure 43–1B). The centrality of insulin in glucose metabolism is emphasized by the fact that all the forms of human diabetes have as a root cause some abnormality of insulin secretion or action.

Pancreatic β cell function is primarily controlled by plasma glucose concentrations. Elevations of blood glucose are necessary for insulin release above basal levels, and other stimuli are relatively ineffective when plasma glucose is in the fasting range (4.4-5.5 mM or 80-100 mg %). These other stimuli include nutrient substrates, insulinotropic hormones released from the GI tract, and autonomic neural pathways. Neural stimuli cause some increase of insulin secretion prior to food consumption. Neural stimulation of insulin secretion occurs throughout the meal and contributes significantly to glucose tolerance. Arrival of nutrient chyme to the intestine leads to the release of insulinotropic peptides from specialized endocrine cells in the intestinal mucosa. Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), together termed incretins, are the essential gut hormones contributing to glucose tolerance. They are secreted in proportion to the nutrient load ingested and relay this information to the islet as part of a feed-forward mechanism that allows an insulin response appropriate to meal size. Insulin secretion rates in healthy humans are highest in the early digestive phase of meals, preceding and limiting the peak in blood glucose. This pattern of premonitory insulin secretion is an essential feature of normal glucose tolerance. How to mimic this pattern is one of the key challenges for successful insulin therapy in diabetic patients.
Elevated circulating insulin concentrations lower glucose in blood by inhibiting hepatic glucose production and stimulating the uptake and metabolism of glucose by muscle and adipose tissue. Production of glucose is inhibited half-maximally by an insulin concentration of ~120 pmol/L, whereas glucose utilization is stimulated half-maximally at ~300 pmol/L. Some of the effects of insulin on the liver occur rapidly, within the first 20 min of meal ingestion, whereas stimulation of peripheral glucose uptake may require up to an hour to reach significant rates. Insulin has potent effects to reduce lipolysis from adipocytes, primarily through the inhibition of hormone-sensitive lipase, and increases lipid storage by promoting lipoprotein–lipase synthesis and adipocyte glucose uptake. Insulin also stimulates amino acid uptake and protein synthesis and inhibits protein degradation in muscle and other tissues.

The limited glycogen stores in skeletal muscle are mobilized at the onset of activity but most of the glucose support for exercise comes from hepatic gluconeogenesis. The dominant regulation of hepatic glucose production during exercise comes from EPI and NE. The catecholamines stimulate glycogenolysis and gluconeogenesis, inhibit insulin secretion, and enhance release of glucagon, all contributing to increased hepatic glucose output. In addition, catecholamines promote lipolysis, freeing fatty acids for oxidation in exercising muscle and glycerol for hepatic gluconeogenesis.

PANCREATIC ISLET PHYSIOLOGY AND INSULIN SECRETION. The pancreatic islets comprise 1-2% of the pancreatic volume. The pancreatic islet is a highly vascularized, highly innervated mini-organ containing 5 endocrine cell types: α cells that secrete glucagon, cells that secrete insulin, δ cells that secrete somatostatin, cells that secrete pancreatic polypeptide, and ε cells that secrete ghrelin.

Insulin is initially synthesized as a single polypeptide chain, preproinsulin (110 amino acid), which is processed first to proinsulin and then to insulin and C-peptide (Figure 43–2). This complex and highly regulated process involves the Golgi complex, the endoplasmic reticulum, and the secretory granules of the β cell. Secretory granules are critical in bringing insulin to the cell surface for exocytosis, and in the cleavage and processing of the prohormone to the final secretion products, insulin and C-peptide. Equimolar quantities of insulin and C-peptide (31 amino acids) are co-secreted. Insulin has a t_{1/2} of 5-6 min due to
extensive hepatic clearance. C-peptide, in contrast, with no known physiological function or receptor, has a $t_{1/2}$ of $\sim 30$ min. The C-peptide is useful in assessment of $\beta$ cell secretion, and to distinguish endogenous and exogenous hyperinsulinemia (for example in the evaluation of insulin-induced hypoglycemia). The $\beta$ cell also synthesizes and secretes *islet amyloid polypeptide* (IAPP) or *amylin*, a 37–amino acid peptide. IAPP influences GI motility and the speed of glucose absorption. Pramlintide is an agent used in the treatment of diabetes that mimics the action of IAPP.

**Figure 43–2** *Synthesis and processing of insulin.* The initial peptide, preproinsulin (110 amino acids) consists of a signal peptide (SP), B chain, C peptide, and A chain. The SP is cleaved and S-S bonds form as the proinsulin folds. Two prohormone convertases, PC1 and PC2, cleave proinsulin into insulin, C peptide, and 2 dipeptides. Insulin and C peptide are stored in granules and co-secreted in equimolar quantities.

Insulin secretion is tightly regulated to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the
coordinated interplay of various nutrients, GI hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids (arginine, etc.), fatty acids, and ketone bodies promote the secretion of insulin. Glucose is the primary insulin secretagogue, and insulin secretion is tightly coupled to the extracellular glucose concentration. Insulin secretion is much greater when the same amount of glucose is delivered orally compared to intravenously (incretin effect). Islets are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α2 adrenergic receptors inhibits insulin secretion, whereas β2 adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α2 adrenergic receptors. Glucagon and somatostatin inhibit insulin secretion.

The molecular events controlling glucose-stimulated insulin secretion begin with the transport of glucose into the β cell via GLUT, a facilitative glucose transporter, primarily GLUT1 in human β cells (Figure 43–3). Upon entry into the β cell, glucose is quickly phosphorylated by glucokinase (GK; hexokinase IV); this phosphorylation is the rate-limiting step in glucose metabolism in the β cell. GK’s distinctive affinity for glucose leads to a marked increase in glucose metabolism over the range of 5-10 mM glucose, where glucose-stimulated insulin secretion is most pronounced. The glucose-6-phosphate produced by GK activity enters the glycolytic pathway, producing changes in NADPH and the ratio of ADP/ATP. Elevated ATP inhibits an ATP-sensitive K+ channel (K_{ATP} channel), leading to cell membrane depolarization. This heteromeric K_{ATP} channel consists of an inward rectifying K+ channel (Kir6.2) and a closely associated protein known as the sulfonylurea receptor (SUR). Mutations in the K_{ATP} channel are responsible for some types of neonatal diabetes or hypoglycemia. Membrane depolarization then leads to opening of a voltage-dependent Ca^{2+} channel and increased intracellular Ca^{2+}, resulting in exocytotic release of insulin from storage vesicles. These intracellular events are modulated by changes in cAMP production, amino acid metabolism, and the level of transcription factors. GPCRs for glucagon, GIP, and GLP-1 couple to G_s to stimulate adenyl cyclase and insulin secretion; receptors for somatostatin and α2 adrenergic agonists couple to G_{i} to reduce cellular cAMP production and secretion.
Figure 43–3 Regulation of insulin secretion from a pancreatic β cell. The pancreatic β cell in a resting state (fasting blood glucose) is hyperpolarized. Glucose, entering via GLUT transporters (primarily GLUT1 in humans, GLUT2 in rodents), is metabolized and elevates cellular ATP, which reduces K⁺ conductance through the K_{ATP} channel; the decreased K⁺ conductance results in depolarization, leading to Ca^{2+}-dependent exocytosis of stored insulin. The K_{ATP} channel, with SUR1 and Kir 6.2 subunits, is the site of action of several classes of drugs: ATP binds to and inhibits Kir 6.2; sulfonylureas and meglitinides bind to and inhibit SUR1; all 3 agents thereby promote insulin secretion. Diazoxide and ADP-Mg^{2+} (low ATP) bind to and activate SUR1, thereby inhibiting insulin secretion. Incretins enhance insulin secretion.

The pancreatic α cell secretes glucagon, primarily in response to hypoglycemia. Glucagon biosynthesis begins with preproglucagon, which is processed in a cell-specific fashion to several biologically active peptides such as glucagon, GLP-1, and glucagon-like peptide 2 (GLP-2) (see Figure 43–9). In general, glucagon and insulin secretion are regulated in a reciprocal fashion; that is, the agents or processes that stimulate insulin secretion inhibit glucagon secretion. Notable exceptions are arginine and somatostatin: arginine stimulates and somatostatin inhibits the secretion of both hormones.
INSULIN ACTION. The insulin receptor is expressed on virtually all mammalian cell types. Tissues that are critical for regulation of blood glucose are liver, skeletal muscle, fat (see Figure 43–1), and specific regions of the brain and the pancreatic islet. The actions of insulin are anabolic, and insulin signaling is critical for promoting the uptake, use, and storage of the major nutrients: glucose, lipids, and amino acids. Insulin stimulates glycogenesis, lipogenesis, and protein synthesis; it also inhibits the catabolism of these compounds. On a cellular level, insulin stimulates transport of substrates and ions into cells, promotes translocation of proteins between cellular compartments, regulates the action of specific enzymes, and controls gene transcription and mRNA translation. Some effects of insulin (e.g., activation of glucose and ion transport systems, phosphorylation or dephosphorylation of specific enzymes) occur within seconds or minutes; other effects (e.g., those promoting protein synthesis and regulating gene transcription and cell proliferation) manifest over minutes to hours to days. The effects of insulin on cell proliferation and differentiation occur over days.

THE INSULIN RECEPTOR. Insulin action is transmitted through a receptor tyrosine kinase that bears functional similarity to the insulin-like growth factor 1 (IGF-1) receptor. The insulin receptor is composed of linked α/β subunit dimers that are products of a single gene; dimers linked by disulfide bonds form a transmembrane heterotetramer glycoprotein composed of 2 extracellular α-subunits and 2 membrane-spanning β-subunits (Figure 43–4). The number of receptors varies from 40/cell on erythrocytes to 300,000/cell on adipocytes and hepatocytes.
Figure 43–4 Pathways of insulin signaling. The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P) of the receptor’s β subunits and a small number of specific substrates (yellow shapes): the insulin receptor substrate (IRS) proteins, Gab-1 and SHC; within the membrane, a caveolar pool of insulin receptor phosphorylates caveolin (Cav), APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects resulting from each pathway. In target tissues such as skeletal muscle and adipocytes, a key event is the translocation of the Glut4 glucose transporter from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and noncaveolar pathways. In the noncaveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP3) and/or an atypical form of PKC is involved. In the caveolar pathway, caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein, TC10. The pathways are inactivated by specific phosphoprotein phosphatases (e.g., PTB1B). In addition to the actions shown, insulin also stimulates the plasma membrane Na+, K+-ATPase by a mechanism that is still being elucidated;
the result is an increase in pump activity and a net accumulation of K+ in the cell. Abbreviations: APS, adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CrkII, chicken tumor virus regulator of kinase II; GLUT4, glucose transporter 4; Gab-1, Grb-2 associated binder; MAP kinase, mitogen-activated protein kinase; PDK, phosphoinositide-dependent kinase; PI3 kinase, phosphatidylinositol-3-kinase; PIP3, phosphatidylinositol trisphosphate; PKB, protein kinase B (also called Akt); aPKC, atypical isoform of protein kinase C; Y, tyrosine residue; Y-P, phosphorylated tyrosine residue.

The α-subunits inhibit the inherent tyrosine kinase activity of the β-subunits. Insulin binding to the α-subunits releases this inhibition and allows transphosphorylation of 1 β-subunit by the other, and autophosphorylation at specific sites from the juxtamembrane region to the intracellular tail of the receptor. Activation of the insulin receptor initiates signaling by phosphorylating a set of intracellular proteins such as the insulin receptor substrates (IRS) and Src-homology-2-containing protein (Shc). These IRS interact with effectors that amplify and extend the signaling cascade.

Insulin action on glucose transport depends on the activation of phosphatidylinositol-3-kinase (PI3K). PI3K is activated by interaction with IRS proteins and generates phosphatidylinositol 3,4,5-trisphosphate (PIP3), which regulates the localization and activity of several downstream kinases, including Akt, atypical isoforms of protein kinase C (PKC ζ and λ/τ), and mammalian target of rapamycin (mTOR). The isoform Akt2 appears to control the downstream steps that are important for glucose uptake in skeletal muscle and adipose tissue, and to regulate glucose production in the liver. Substrates of Akt2 coordinate the translocation of the glucose transporter 4 (GLUT4) to the plasma membrane through processes involving actin remodeling and other membrane trafficking systems. Actions of small G-proteins, such as Rac and TC10, have also been implicated in the actin remodeling necessary for GLUT4 translocation. GLUT4 is expressed in insulin-responsive tissues such as skeletal muscle and adipose tissue. In the basal state, most GLUT4 resides in the intracellular space; following activation of insulin receptors, GLUT4 is shifted rapidly and in abundance to the plasma membrane, where it facilitates inward transport of glucose from the circulation. Insulin signaling also reduces GLUT4 endocytosis, increasing the residence time of the protein in the plasma membrane. Following the facilitated diffusion into cells along a concentration gradient, glucose is
phosphorylated to glucose-6-phosphate (G-6-P) by hexokinases. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin. G-6-P can be isomerized to G-1-P and stored as glycogen (insulin enhances the activity of glycogen synthase); G-6-P can enter the glycolytic pathway (for ATP production) and the pentose phosphate pathway.

PATHOPHYSIOLOGY AND DIAGNOSIS OF DIABETES MELLITUS

GLUCOSE HOMEOSTASIS AND THE DIAGNOSIS OF DIABETES

Broad categories of glucose homeostasis as defined by the fasting blood glucose or the glucose level following an oral glucose challenge include:

- Normal glucose homeostasis: fasting plasma glucose <5.6 mmol/L (100 mg/dL)
- Impaired fasting glucose (IFG): 5.6-6.9 mmol/L (100-125 mg/dL)
- Impaired glucose tolerance (IGT): glucose level between 7.8 and 11.1 mmol/L (140-199 mg/dL) 120 min after ingestion of 75 g liquid glucose solution
- Diabetes mellitus (see Table 43–1)

Table 43–1

Criteria for the Diagnosis of Diabetes

- Symptoms of diabetes plus random blood glucose concentration ≥11.1 mM (200 mg/dL) or
- Fasting plasma glucose ≥7.0 mM (126 mg/dL) or
- Two-hour plasma glucose ≥11.1 mM (200 mg/dL) during an oral glucose tolerance test
- HbA1c ≥6.5%

Notes:
- Random is defined as without regard to time since the last meal.
- Fasting is defined as no caloric intake for at least 8 h.
- The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; this test is not recommended for routine clinical use.

Source: Adapted from Diabetes Care, 2010;33:S62-S69.

The American Diabetes Association (ADA) and the World Health
Organization (WHO) have adopted criteria for the diagnosis of diabetes, based on the fasting blood glucose, the glucose value following an oral glucose challenge, or the level of hemoglobin A₁c (HbA₁c, or more simply, A₁c; exposure of proteins to elevated [glucose] produces nonenzymatic glycation of proteins including Hb. Thus, the level of A₁c represents a measure of the average glucose concentration to which the Hb has been exposed) (see Table 43–1). The diagnostic criteria have recently been changed to also include an A₁c value ≥6.5%. Impaired fasting glucose (IFG) and impaired glucose tolerance (IGT), or an A₁c of 5.7-6.4% portend a markedly increased risk of progressing to type 2 diabetes, and are associated with increased risk of cardiovascular disease.

The 4 categories of diabetes include type 1 diabetes, type 2 diabetes, other forms of diabetes, and gestational diabetes (Table 43–2). Although hyperglycemia is common to all forms of diabetes, the pathogenic mechanisms leading to diabetes are quite distinct.

**Table 43–2**

**Different Forms of Diabetes Mellitus**
Screening for Diabetes and Categories of Increased Risk of Diabetes. Many individuals with type 2 diabetes are asymptomatic at the time of diagnosis, and diabetes is often found on routine blood testing for nonglucose-related reasons. The ADA recommends widespread screening for type 2 diabetes of these individuals with the following features:

- >45 years of age, or
- Body mass index >25 kg/m² with 1 of these additional risk factors: hypertension, low high-density lipoprotein, family history of type 2 diabetes, high-risk ethnic group (African American, Latino, Native American, Asian American, and Pacific Islander), abnormal glucose testing
(IFG, IGT, A1c of 5.7-6.4%), cardiovascular disease, and women with polycystic ovary syndrome or who have previously delivered a large infant

Earlier diagnosis and treatment of type 2 diabetes should delay diabetes-related complications and reduce the burden of the disease. A number of interventions including pharmacological agents and lifestyle modification are effective. Screening for type 1 diabetes is not currently recommended.

**PATHOGENESIS OF TYPE 1 DIABETES.** Type 1 diabetes accounts for 5-10% of diabetes and results from autoimmune-mediated destruction of the β cells of the islet leading to total or near total insulin deficiency. Prior terminology included juvenile-onset diabetes mellitus or insulin-dependent diabetes mellitus. Type 1 diabetes resulting from autoimmune β cell destruction can occur at any age. Individuals with type 1 diabetes and their families have an increased prevalence of autoimmune diseases such as Addison disease, Graves and Hashimoto disease, pernicious anemia, vitiligo, and celiac sprue. The concordance of type 1 diabetes in genetically identical twins is 40-60%, indicating a significant genetic component. The major genetic risk (40-50%) is conferred by HLA class II genes encoding HLA-DR and HLA-DQ (and possibly other genes with the HLA locus). However, there clearly is a critical interaction of genetics and an environmental or infectious agent. Most individuals with type 1 diabetes (-75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population.

Genetically susceptible individuals are thought to have a normal β cell number or mass until β cell–directed autoimmunity develops and β cell loss begins. The initiating or triggering stimulus for the autoimmune process is not known, but most favor exposure to viruses (enterovirus, etc.) or other ubiquitous environmental agents. The β cell destruction is cell mediated, and there is also evidence that infiltrating cells produce local inflammatory agents such as TNF-α, IFN-γ, and IL-1, all of which can lead to β cell death. The β cell destruction occurs over a period of months to years and when >80% of the β cells are destroyed, hyperglycemia ensues and the clinical diagnosis of type 1 diabetes is made. Most patients report several weeks of polyuria and polydipsia, fatigue, and often abrupt and significant weight loss. Some adults with the phenotypic appearance of type 2 diabetes (obese, not insulin-requiring initially) have islet cell autoantibodies suggesting autoimmune-mediated β cell destruction and are
diagnosed as expressing latent-autoimmune diabetes of adults (LADA).

**PATHOGENESIS OF TYPE 2 DIABETES.** The condition is best thought of as a heterogeneous syndrome of dysregulated glucose homeostasis associated with impaired insulin secretion and action. Overweight or obesity is a common correlate of type 2 diabetes that occurs in -80% of affected individuals. For the vast majority of persons developing type 2 diabetes, there is no clear inciting incident; rather, the condition is thought to develop gradually over years with progression through identifiable prediabetic stages. Type 2 diabetes results when there is insufficient insulin action to maintain plasma glucose levels in the normal range. Insulin action is the composite effect of plasma insulin concentrations (determined by islet β cell function) and insulin sensitivity of key target tissues (liver, skeletal muscle, and adipose tissue). These sites of regulation are all impaired to variable extents in patients with type 2 diabetes (Figure 43–5). The etiology of type 2 diabetes has a strong genetic component. It is a heritable condition with a relative 4-fold increased risk of disease for persons having a diabetic parent or sibling, increasing to 6-fold if both parents have type 2 diabetes. Although more than 20 genetic loci with clear associations to type 2 diabetes have been identified through recent genome-wide association studies, the contribution of each is relatively small.

![Pathophysiology of type 2 diabetes mellitus](image)

*Figure 43–5 Pathophysiology of type 2 diabetes mellitus. Graphs show data from diabetic (solid red line) and -nondiabetic (dashed blue line) patients, comparing postprandial*
insulin and glucagon secretion and hepatic glucose production, and the sensitivities of muscle glucose use and adipocyte lipolysis to insulin.

**Impaired β Cell Function.** In persons with type 2 diabetes, the sensitivity of the β cell to glucose is impaired, and there is also a loss of responsiveness to other stimuli such as insulinotropic GI hormones and neural signaling. This results in delayed secretion of insufficient amounts of insulin, allowing the blood glucose to rise dramatically after meals, and failure to restrain liver glucose release during fasting. The absolute mass of β cells also is greatly reduced in type 2 diabetes patients. Progressive reduction of β cell mass and function explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients frequently have elevated levels of fasting insulin, a result of their higher fasting glucose levels and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the diabetic islet. Whereas healthy subjects have only 2-4% of total circulating insulin as proinsulin, type 2 diabetic patients can have 10-20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin.

**Insulin Resistance.** *Insulin sensitivity* is measured as the amount of glucose cleared from the blood in response to a dose of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as *insulin resistance*. There is inherent variability of insulin sensitivity among cells, tissues, and individuals. Insulin sensitivity is affected by many factors including age, body weight, physical activity levels, illness, and medications. Nonetheless, persons with type 2 diabetes or glucose intolerance have reduced responses to insulin and can easily be distinguished from groups with normal glucose tolerance.

*The major insulin-responsive tissues are skeletal muscle, adipose tissue, and liver.* Insulin resistance in muscle and fat is generally marked by a decrease in transport of glucose from the circulation. Hepatic insulin resistance generally refers to a blunted ability of insulin to suppress glucose production. Insulin resistance in adipocytes causes increased rates of lipolysis and release of fatty acids into the circulation, which can contribute to insulin resistance in liver and
muscle, hepatic steatosis, and dyslipidemia. The sensitivity of humans to the
effects of insulin administration is inversely related to the amount of fat stored in
the abdominal cavity; more visceral adiposity leads to more insulin resistance.
Intracellular lipid or its by-products may have direct effects to impede insulin
signaling. Enlarged collections of adipose tissue, visceral or otherwise, are often
infiltrated with macrophages and can become sites of chronic inflammation.
Adipocytokines, secreted from adipocytes and immune cells, including TNF-α,
IL-6, resistin, and retinol-binding protein 4, can also cause systemic insulin
resistance.

Sedentary persons are more insulin resistant than active ones, and physical
training can improve insulin sensitivity. Physical activity can decrease the risk of
developing diabetes and improve glycemic control in persons who have diabetes.
Insulin resistance is more common in the elderly; within populations, insulin
sensitivity decreases linearly with age. At the cellular level, insulin resistance
involves blunted steps in the cascade from the insulin receptor tyrosine kinase to
translocation of GLUT4 transporters, but the molecular mechanisms are
incompletely defined. There have been >75 different mutations in the insulin
receptor discovered, most of which cause significant impairment of insulin
action. These mutations affect insulin receptor number, movement to and from
the plasma membrane, binding, and phosphorylation. Mutations involving the
insulin binding domains of the extracellular α-chain cause the most severe
syndromes. Insulin sensitivity is under genetic control but it is unclear whether
insulin-resistant individuals have mutations in specific components of the insulin
signaling cascade or whether they have a complement of signaling effectors that
operate at the lower range of normal. Regardless, it is apparent that insulin
resistance clusters in families and is a major risk factor for the development of
diabetes.

*Dysregulated Hepatic Glucose Metabolism.* In type 2 diabetes, hepatic glucose
output is excessive in the fasting state and inadequately suppressed after meals.
Abnormal secretion of the islet hormones, both insufficient insulin and excessive
glucagon, accounts for a significant portion of dysregulated hepatic glucose
metabolism in type 2 diabetes. Increased concentrations of glucagon, especially
in conjunction with hepatic insulin resistance, can lead to excessive hepatic
gluconeogenesis and glycogenolysis and abnormally high fasting glucose
concentrations. The liver is resistant to insulin action in type 2 diabetes. This
contributes to the reduced potency of insulin to suppress hepatic glucose production and promote hepatic glucose uptake and glycogen synthesis after meals. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in the liver are maintained and even accentuated by fasting hyperinsulinemia. This contributes to hepatic steatosis and further worsening of insulin resistance.

PATHOGENESIS OF OTHER FORMS OF DIABETES. Mutations in key genes involved in glucose homeostasis cause monogenic diabetes, which is inherited in an autosomal dominant fashion. These fall in 2 broad categories: diabetes onset in the immediate neonatal period (<6 months of age) and diabetes in children or adults. Some forms of neonatal diabetes are caused by mutations in the SUR or its accompanying inward rectifying K+ channel and mutations in the insulin gene. Monogenic diabetes beyond the first year of life may appear clinically similar to type 1 or type 2 diabetes. In other instances, young individuals (adolescence to young adulthood) may have monogenic forms of diabetes known as maturity onset diabetes of the young (MODY). Phenotypically, these individuals are not obese and are not insulin resistant, or they may initially have modest hyperglycemia. The most common causes are mutations in key islet-enriched transcription factors or glucokinase. Most individuals with MODY are treated similarly to those with type 2 diabetes.

Diabetes may also be the result of other pathological processes such as acromegaly and Cushing disease (see Table 43–2). A number of medications promote hyperglycemia or lead to diabetes by either impairing insulin secretion or insulin action (Table 43–3).

Table 43–3

Some Drugs That May Promote Hyperglycemia or Hypoglycemia
DIABETES-RELATED COMPLICATIONS. Diabetes can cause metabolic derangements or acute complications, such as the life-threatening metabolic disorders of diabetic ketoacidosis and hyperglycemic hyperosmolar state. These require hospitalization for insulin administration, rehydration with intravenous fluids, and careful monitoring of electrolytes and metabolic parameters. Chronic complications of diabetes are commonly divided into microvascular and macrovascular complications. Microvascular complications occur only in individuals with diabetes and include retinopathy, nephropathy, and neuropathy. Macrovascular complications occur more frequently in individuals with diabetes but are not diabetes specific (e.g., increased atherosclerosis-related events such as myocardial infarction and stroke). In the U.S., diabetes is the leading cause of blindness in adults, the leading reason for renal failure requiring dialysis or renal transplantation, and the leading cause of nontraumatic lower extremity amputations. Fortunately, most of these diabetes-related complications can be prevented, delayed, or reduced by near normalization of the blood glucose on a consistent basis. How chronic hyperglycemia causes these complications is unclear. For microvascular complications, current hypothesis are that hyperglycemia leads to advanced glycosylation end products (AGEs), increased glucose metabolism via the sorbitol pathway, increased formation of diacylglycerol leading to PKC activation, and increased flux through the hexosamine pathway. Growth factors such as vascular endothelial growth factor α may be involved in diabetic retinopathy and TGF-β in diabetic nephropathy.

THERAPY OF DIABETES

GOALS OF THERAPY. The goals of therapy for diabetes are to alleviate the
symptoms related to hyperglycemia (fatigue, polyuria, etc.) and to prevent or reduce the acute and chronic complications of diabetes.

Glycemic control is assessed using both short-term (blood glucose self-monitoring) and long-term metrics (A1c, fructosamine). Using capillary blood glucose measurements, the patient assesses capillary blood glucose on a regular basis (fasting, before meals, or postprandially) and reports these values to the diabetes management team. A1c reflects glycemic control over the prior 3 months; glycosylated albumin (fructosamine) is a measure of glycemic control over the preceding 2 weeks. The term *comprehensive diabetes care* describes optimal therapy, which involves more than glucose management and includes aggressive treatment of abnormalities in blood pressure and lipids and detection and management of diabetes-related complications (Figure 43–6). Table 43–4 shows the ADA-recommended treatment goals for comprehensive diabetes care, for glucose, blood pressure, and lipids. A summary of available pharmacologic agents for the treatment of diabetes is at the end of this chapter (see Table 43–8).

![Management of diabetes](image)

**Figure 43–6** Components of comprehensive diabetes care.

**Table 43–4**

Goals of Therapy in Diabetes
| INDEX | GOAL$^b$
|---|---
| **Glycemic control$^b$** |  
| A1C | <7.0%$^c$
| Preprandial capillary plasma glucose | 3.9-7.2 mmol/L (70-130 mg/dL)
| Peak postprandial capillary plasma glucose | 10.0 mmol/L (<180 mg/dL)$^d$
| **Blood pressure** | <130/80
| **Lipids$^a$** |  
| Low-density lipoprotein | <2.6 mmol/L (<100 mg/dL)$^f$
| High-density lipoprotein | >1.1 mmol/L (>40 mg/dL)$^e$
| Triglycerides | <1.7 mmol/L (<150 mg/dL)$^e$

$^a$Goals should be individualized for each patient and may be different for certain patient populations.

$^b$A1C is primary goal.

$^c$While the ADA recommends an A1C <7.0% in general, it recommends an appropriate goal for the individual patient based on age, duration of diabetes, life expectancy, other medical conditions, cardiovascular disease).

$^d$One to two hours after beginning of a meal.

$^e$In decreasing order of priority

$^f$In individuals with coronary artery disease, an LDL <1.8 mmol (70 mg/dL) is the goal.

$^g$For women, some suggest a goal that is 0.25 mmol/L (10 mg/dL) higher.

NONPHARMACOLOGIC ASPECTS OF DIABETES THERAPY. The patient with diabetes should be educated about nutrition, exercise, and medications aimed at lowering the plasma glucose. In type 1 diabetes, matching caloric intake and insulin dosing is very important. In type 2 diabetes, the diet is directed at weight loss and reducing blood pressure and atherosclerotic risk. Remarkably, bariatric surgery also rapidly improves glucose tolerance and can prevent or reverse type 2 diabetes.

INSULIN THERAPY

Insulin is the mainstay for treatment of virtually all type 1 and many type 2 diabetes patients. Insulin may be administered intravenously, intramuscularly, or subcutaneously. Long-term treatment relies predominantly on subcutaneous injection. Subcutaneous administration of insulin delivered into the peripheral circulation can lead to near-normal glycemia but differs from physiological secretion of insulin in 2 major ways:

- The absorption kinetics do not reproduce the rapid rise and decline of endogenous insulin in response to glucose following intravenous or oral administration.
- Injected insulin is delivered into the peripheral circulation instead of being released into the portal circulation. Thus, the portal/peripheral insulin concentration is not physiological, and this may alter the influence of insulin on hepatic metabolic processes.
INSULIN PREPARATION AND CHEMISTRY. Human insulin, produced by recombinant DNA technology, is soluble in aqueous solution. Doses and concentration of clinically used insulin preparations are expressed in international units. One unit of insulin is defined as the amount required to reduce the blood glucose concentration in a fasting rabbit to 45 mg/dL (2.5 mM). Commercial preparations of insulin are supplied in solution or suspension at a concentration of 100 units/mL, which is ~3.6 mg insulin per milliliter (0.6 mM) and termed U-100. Insulin also is available in a more concentrated solution (500 units/mL or U-500) for patients who are resistant to the hormone.

INSULIN FORMULATIONS. Preparations of insulin are classified according to their duration of action into short-acting and long-acting (Table 43–5).

*Glarine and detemir have minimal peak activity.
*Dual: two peaks - one at 2-3 h; the second one several hours later.
Within the short-acting acting category, some distinguish the very rapid-acting insulins (aspart, glulisine, lispro) from regular insulin. Likewise, some distinguish formulations with a longer duration of action (detemir, glargine) from NPH insulin. Two approaches are used to modify the absorption and pharmacokinetic profile of insulin. The first approach is based on formulations that slow the absorption following subcutaneous injection. The other approach is to alter the amino acid sequence or protein structure of human insulin so that it retains its ability to bind the insulin receptor, but its behavior in solution or following injection is either accelerated or prolonged in comparison to native or regular insulin (Figure 43–7). There is wide variability in the kinetics of insulin action between and even within individuals. The time to peak hypoglycemic effect and insulin levels can vary by 50%, due in part, by large variations in the rate of subcutaneous absorption.

Figure 43–7 *Insulin analogs.* Modifications of native insulin can alter its pharmacokinetic profile. Reversing amino acids 28 and 29 in the B chain (lispro) or substituting Asp for Pro$^{28B}$ (aspart) gives analogs with reduced tendencies for molecular self-association that are faster acting. Altering Asp$^{3B}$ to Lys and Lys$^{29B}$ to Glu produces an insulin (glulisine) with a more rapid onset and a shorter duration of action. Substituting Gly for Asn$^{21A}$ and lengthening the B chain by adding Arg$^{31}$ and Arg$^{32}$ produces a derivative (glargine) with reduced solubility at pH 7.4 that is, consequently, absorbed more slowly and acts over a longer period of time. Deleting Thr$^{30B}$ and adding a myristoyl group to the ε-amino group of Lys$^{29B}$ (detemir) enhances reversible binding to albumin,
thereby slowing transport across vascular endothelium to tissues and providing prolonged action.

**Short-Acting Regular Insulin.** Native or regular insulin molecules associate as hexamers in aqueous solution at a neutral pH and this aggregation slows absorption following subcutaneous injection. Regular insulin should be injected 30-45 min before a meal. Regular insulin also may be given intravenously or intramuscularly.

**Short-Acting Insulin Analogs.** These analogs are absorbed more rapidly from subcutaneous sites than regular insulin (see Figures 43–7 and 43–8; see Table 43–5). Insulin analogs should be injected <15 min before a meal.

![Figure 43–8](image)

**Figure 43–8** Commonly used insulin regimens. Panel A shows administration of a long-acting insulin like glargine (detemir could also be used but often requires twice-daily administration) to provide basal insulin and a pre-meal short-acting insulin analog (see Table 43–5). Panel B shows a less intensive insulin regimen with BID injection of NPH insulin providing basal insulin and regular insulin or an insulin analog providing meal-time insulin coverage. Only 1 type of short-acting insulin would be used. Panel C shows the insulin level attained following subcutaneous insulin (short-acting insulin analog) by an insulin pump.
programmed to deliver different basal rates. At each meal, an insulin bolus is delivered. B, breakfast; L, lunch; S, supper; HS, bedtime. *Upward arrow* shows insulin administration at mealtime. (Copyright 2008 American Diabetes Association. From Kaufman FR, ed. *Medical Management of Type 1 Diabetes*, 5th ed. Modified with permission from the American Diabetes Association.)

*Insulin lispro* (HUMALOG) is identical to human insulin except at positions B28 and B29. Unlike regular insulin, lispro dissociates into monomers almost instantaneously following injection. This property results in the characteristic rapid absorption and shorter duration of action compared with regular insulin. The prevalence of hypoglycemia is reduced with lispro; and glucose control, as assessed by A1c, is modestly but significantly improved (0.3-0.5%).

*Insulin aspart* (NOVOLOG) is formed by the replacement of proline at B28 with aspartic acid, reducing self-association. Like lispro, insulin aspart dissociates rapidly into monomers following injection. Insulin aspart and insulin lispro have similar effects on glucose control and hypoglycemia frequency, with lower rates of nocturnal hypoglycemia as compared with regular insulin.

*Insulin glulisine* (APIDRA) is formed when glutamic acid replaces lysine at B29, and lysine replaces asparagine at B3; these substitutions result in a reduction in self-association and rapid dissociation into active monomers. The time–action profile of insulin glulisine is similar to that of insulin aspart and insulin lispro.

**Long-Acting Insulins.** *Neutral protamine hagedorn* (NPH; insulin isophane) is a suspension of native insulin complexed with zinc and protamine in a phosphate buffer. This produces a cloudy or whitish solution in contrast to the clear appearance of other insulin solutions. This formulation dissolves more gradually when injected subcutaneously and thus its duration of action is prolonged. NPH insulin is usually given either once a day (at bedtime) or twice a day in combination with short-acting insulin.

*Insulin glargine* (LANTUS) is a long-acting analog of human insulin. Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position 21 on the A chain is replaced with glycine. Insulin glargine is a clear solution with a pH of 4.0, which stabilizes the insulin hexamer. When injected into the neutral pH of
the subcutaneous space, aggregation occurs, resulting in prolonged, but predictable, absorption from the injection site. Owing to insulin glargine’s acidic pH, it cannot be mixed with short-acting insulin preparations that are formulated at a neutral pH. Glargine has a sustained peakless absorption profile, and provides a better once-daily 24-h insulin coverage than NPH insulin. Clinical trial data suggest that glargine has a lower risk of hypoglycemia, particularly overnight compared to NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and does not accumulate after several injections. The site of administration does not influence the time–action profile of glargine.

*Insulin detemir* (LEVEMIR) is an insulin analog modified by the addition of a saturated fatty acid to the ε amino group of LysB29, yielding a myristoylated insulin. When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. Clinical studies in patients with type 1 diabetes have demonstrated that when insulin detemir is administered twice a day, it has a smoother time–action profile and produces a reduced prevalence of hypoglycemia than NPH insulin. The absorption profiles of glargine and detemir insulin are similar, but detemir often requires twice-daily administration.

**Other Insulin Formulations.** Stable combinations of NPH and regular insulin in proportions of 70:30 combinations are available, as are combinations of lispro protamine/lispro (50/50 and 75/25) and aspart protamine/aspart (70/30) (see Table 43–5).

**INSULIN DELIVERY.** Most insulin is injected subcutaneously. Pen devices containing prefilled regular, lispro, NPH, glargine, premixed lispro protamine-lispro, or premixed aspart protamine-aspart have proven to be popular with many diabetic patients. Jet injector systems that enable patients to receive subcutaneous insulin injections without a needle are available. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly, such as during the perioperative period, during labor and delivery, and in intensive care situations.

*Continuous Subcutaneous Insulin Infusion (CSII).* Short-acting insulins are
the only form of the hormone used in subcutaneous infusion pumps. A number of pumps are available for CSII therapy. Insulin pumps provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the dawn phenomenon (rise in blood glucose that occurs just prior to awakening from sleep) and bolus injections that are programmed according to the size and nature of a meal. Selection of the most appropriate patients is extremely important for success with CSII. Pump therapy is capable of producing a more physiological profile of insulin replacement during exercise (where insulin production is decreased) and therefore less hypoglycemia than do traditional subcutaneous insulin injections.

FACTORS THAT AFFECT INSULIN ABSORPTION. Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscularly rather than subcutaneously). Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption. The abdomen currently is the preferred site of injection in the morning because insulin is absorbed 20-30% faster from that site than from the arm. Rotation of insulin injection sites traditionally has been advocated to avoid lipohypertrophy or lipoatrophy. In a small group of patients, subcutaneous degradation of insulin has been observed, and this has necessitated the injection of large amounts of insulin for adequate metabolic control.

INSULIN DOSING AND REGIMENS. A number of commonly used dosage regimens that include mixtures of insulin given in 2 or more daily injections are depicted in Figure 43–8.

In most patients, insulin-replacement therapy includes long-acting insulin (basal) and a short-acting insulin to provide postprandial needs. In a mixed population of type 1 diabetes patients, the average dose of insulin is usually 0.6-0.7 units/kg body weight per day, with a range of 0.2-1 units/kg/day. Obese patients generally and pubertal adolescents require more (~1-2 units/kg/day) because of resistance of peripheral tissues to insulin. Patients who require less insulin than 0.5 units/kg/day may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. The basal dose
is usually 40-50% of the total daily dose with the remainder as prandial or pre-meal insulin. The insulin dose at mealtime should reflect the anticipated carbohydrate intake. A supplemental scale of short-acting insulin is added to the prandial insulin dose to allow correction of the BG. **Insulin administered as a single daily dose of long-acting insulin, alone or in combination with short-acting insulin, is rarely sufficient to achieve euglycemia. More complex regimens that include multiple injections of long-acting or short-acting insulin are needed to reach this goal. In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by self-monitoring of glucose and measurements of A1c.** In patients who have gastroparesis or loss of appetite, injection of a short-acting analog postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

**ADVERSE EVENTS.** Hypoglycemia is the major risk that must be weighed against benefits of efforts to normalize glucose control. Insulin treatment of both type 1 and type 2 diabetes is associated with modest weight gain. Although uncommon, allergic reactions to recombinant human insulin may still occur as a result of reaction to the small amounts of aggregated or denatured insulin in preparations, to minor contaminants, or because of sensitivity to a component added to insulin in its formulation (protamine, Zn\(^{2+}\), etc.). Atrophy of subcutaneous fat at the site of insulin injection (lipoatrophy) was a rare side effect of older insulin preparations. Lipohypertrophy (enlargement of subcutaneous fat depots) has been ascribed to the lipogenic action of high local concentrations of insulin.

**INSULIN TREATMENT OF KETOACIDOSIS AND OTHER SPECIAL SITUATIONS.** Intravenous administration of insulin is most appropriate in patients with ketoacidosis or severe hyperglycemia with a hyperosmolar state. Insulin infusion inhibits lipolysis and gluconeogenesis completely and produces near-maximal stimulation of glucose uptake. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by -10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin to prevent hypoglycemia but to allow clearance of all ketones. Patients with nonketotic hyperglycemic hyperosmolar state may be more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes is an integral part of the therapy in both situations because there is always a major deficit. A long-acting
insulin should be administered subcutaneously before the insulin infusion is discontinued.

TREATMENT OF DIABETES IN CHILDREN OR ADOLESCENTS. Diabetes is one of the most common chronic diseases of childhood, and rates of type 1 diabetes in American youth are estimated at 1 in 300. An unfortunate corollary of the growing rates of obesity over the past 3 decades is an increase in the numbers of children and adolescents with non-autoimmune, or type 2, diabetes. Current estimates are that 15-20% of new cases of pediatric diabetes may be type 2 diabetes; rates vary by ethnicity, with disproportionately high rates in Native Americans, African Americans, and Latinos. Current practice is for more intensive, physiologically based insulin replacement with a goal of tight glucose control achieved with combinations of basal and prandial insulin replacement. The primary limiting factor of more aggressive insulin therapy is hypoglycemia. Diabetic patients <5 years old have increased rates of severe hypoglycemia with seizures and coma, and may suffer permanent cognitive dysfunction as a result of repeated episodes of low blood glucose. Older children and adolescents do not seem to have demonstrable cognitive impairment related to hypoglycemia; good glycemic control is associated with better mental function. The standard for insulin treatment now includes multiple dose regimens with 3-5 injections per day or CSII. Split/mixed regimens using NPH and regular insulin have been increasingly supplanted by regimens using insulin analogs because they offer more flexibility in dosing and meal patterns. Similarly, CSII is used with increasing frequency in the pediatric diabetic population and in older children and adolescents.

Because of the association of type 2 diabetes with obesity in the pediatric age group, lifestyle management is the recommended first step in therapy. Goals of reducing body weight and increasing physical activity are broadly recommended. The only medication currently approved by the FDA specifically for medical treatment of type 2 diabetes is metformin. Metformin is approved for children as young as 10 years of age and is available in a liquid formulation (100 mg/mL). Insulin is the typical second line of therapy after metformin; basal insulin can be added to oral agent therapy or multiple daily injections can be used when simpler regimens are not successful. Weight gain is a more significant problem than hypoglycemia with insulin treatment in pediatric type 2 diabetes.

MANAGEMENT OF DIABETES IN HOSPITALIZED PATIENTS.
Hyperglycemia is common in hospitalized patients. Prevalence estimates of elevated blood glucose among inpatients with and without a prior diagnosis of diabetes range between 20% and 100% for patients treated in intensive care units (ICUs) and 30% and 83% outside the ICU. Stress of illness has been associated with insulin resistance, possibly the result of counterregulatory hormone secretion, cytokines, and other inflammatory mediators. Food intake is often variable due to concurrent illness or preparation for diagnostic testing. Medications used in the hospital, such as glucocorticoids or dextrose-containing intravenous solutions, can exacerbate tendencies toward hyperglycemia. Finally fluid balance and tissue perfusion can affect the absorbance of subcutaneous insulin and the clearance of glucose. Therapy of hyperglycemia in hospitalized patients needs to be adjusted for these variables.

Emerging data indicate that hyperglycemia portends poor outcomes in hospitalized patients. The ADA currently suggests these blood glucose targets: 140-180 m/dL (7.8-10.0 mM) in critically ill patients and random glucose of 180 mg/dL (10 mM) or pre-meal glucose of 140 mg/dL (7.8 mM) in noncritically ill patients. Insulin is the cornerstone of treatment of hyperglycemia in hospitalized patients. For critically ill patients and those with variable blood pressure, edema, and tissue perfusion, intravenous insulin is the treatment of choice. Oral agents have a limited place in treatment of hyperglycemic patients in the hospital because of slow onset of action, insufficient potency, need for intact GI function, and side effects. Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth.

**INSULIN SECRETAGOGUES AND ORAL HYPOGLYCEMIC AGENTS**

A variety of sulfonylureas, meglitinides, GLP-1 agonists, and inhibitors of dipeptidyl peptidase-4 (DPP-4) are used as secretagogues to stimulate insulin release (Table 43–6).

<table>
<thead>
<tr>
<th><strong>Table 43–6</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Properties of Insulin Secretagogues</strong></td>
</tr>
</tbody>
</table>
KATP CHANNEL MODULATORS: SULFONYLUREAS

First-generation sulfonylureas (tolbutamide, tolazamide, and chlorpropamide) are rarely used now in the treatment of type 2 diabetes. The second, more potent generation of hypoglycemic sulfonylureas includes glyburide (glibenclamide; DIABETA, others), glipizide (GLUCOTROL, others), and glimepiride (AMARYL, others). Some are available in an extended-release (glipizide) or a micronized (glyburide) formulation.

MECHANISM OF ACTION. Sulfonylureas stimulate insulin release by binding to a specific site on the β cell KATP channel complex (SUR) and inhibiting its activity. KATP channel inhibition causes cell membrane depolarization and the cascade of events leading to insulin secretion (see Figure 43–3). The acute administration of sulfonylureas to type 2 diabetes patients increases insulin release from the pancreas. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The absence of
acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to downregulation of cell surface receptors for sulfonylureas on the pancreatic β cell.

**ADME.** Sulfonylureas are effectively absorbed from the GI tract. Food and hyperglycemia can reduce absorption. Sulfonylureas in plasma are largely (90-99%) bound to protein, especially albumin. The volumes of distribution of most of the sulfonylureas are ~0.2 L/kg. Although their half-lives are short (3-5 h), their hypoglycemic effects are evident for 12-24 h, and they often can be administered once daily. The liver metabolizes all sulfonylureas, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

**ADVERSE EFFECTS AND DRUG INTERACTIONS.** Sulfonylureas may cause hypoglycemic reactions, including coma. Weight gain of 1-3 kg is a common side effect of improving glycemic control with sulfonylurea treatment. Less frequent side effects include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. Rarely, patients treated with these drugs develop an alcohol-induced flush similar to that caused by disulfiram or hyponatremia.

The hypoglycemic effect of sulfonylureas may be enhanced by various mechanisms (decreased hepatic metabolism or renal excretion, displacement from protein-binding sites). Some drugs (sulfonamides, clofibrate, and salicylates) displace the sulfonylureas from binding proteins, thereby transiently increasing the concentration of free drug. Ethanol may enhance the action of sulfonylureas and cause hypoglycemia. Hypoglycemia may be more frequent in patients taking a sulfonylurea and 1 of these agents: androgens, anticoagulants, azole antifungals, chloramphenicol, fenfluramine, fluconazole, gemfibrozil, H2 antagonists, magnesium salts, methyldopa, MAO inhibitors, probenecid, sulfinpyrazone, sulfonamides, tricyclic antidepressants, and urinary acidifiers. Other drugs may decrease the glucose-lowering effect of sulfonylureas by increased hepatic metabolism, increased renal excretion, or inhibiting insulin secretion (β blockers, Ca2+ channel blockers, cholestyramine, diazoxide, estrogens, hydantoins, isoniazid, nicotinic acid, phenothiazines, rifampin, sympathomimetics, thiazide diuretics, and urinary alkalinizers).
DOSAGE FORMS AVAILABLE. Treatment is initiated at lower end of the dose range and titrated upward based on the patient’s glycemic response. Some have a longer duration of action and can be prescribed in a single daily dose (glimepiride), whereas others are formulated as extended-release or micronized formulations to extend their duration of action (see Table 43–6). Sulfonylureas such as glipizide or glimepiride appear safer in elderly individuals with type 2 diabetes.

THERAPEUTIC USES. Sulfonylureas are used to treat hyperglycemia in type 2 diabetes. Of properly selected patients, 50-80% respond to this class of agents. All members of the class appear be equally efficacious. A significant number of patients who respond initially later cease to respond to the sulfonylurea and develop unacceptable hyperglycemia (secondary failure). This may occur as a result of a change in drug metabolism or more likely from a progression of β cell failure. Some individuals with neonatal diabetes or MODY-3 respond to these agents. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation, and, for the older preparations, significant hepatic or renal insufficiency.

K<sub>ATP</sub> CHANNEL MODULATORS: NONSULFONYLUREAS

REPAGLINIDE. Repaglinide (PRANDIN) is an oral insulin secretagogue of the meglitinide class (see Table 43–6). Like sulfonylureas, it stimulates insulin release by closing K<sub>ATP</sub> channels in pancreatic β cells.

The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 h. The t<sub>1/2</sub> is ~1 h. These features allow for multiple preprandial use. Repaglinide is metabolized primarily by the liver (CYP3A4) to inactive derivatives. Because a small proportion (~10%) is metabolized by the kidney, dosing of the drug in patients with renal insufficiency also should be performed cautiously. The major side effect of repaglinide is hypoglycemia. Repaglinide also is associated with a decline in efficacy (secondary failure) after initially improving glycemic control. Certain drugs may potentiate the action of repaglinide by displacing it from plasma protein binding sites (β blockers, chloramphenicol, coumarins, MAOIs, NSAIDs, probenecid, salicylates, and sulfonamide) or altering its metabolism (gemfibrozil, itraconazole, trimethoprim,
NATEGLINIDE. Nateglinide (STARLIX) is an orally effective insulin secretagogue. Nateglinide stimulates insulin secretion by blocking $K_{ATP}$ channels in pancreatic β cells. Nateglinide promotes a more rapid but less sustained secretion of insulin than other available oral antidiabetic agents. The drug’s major therapeutic effect is reducing postprandial glycemic elevations in type 2 diabetes patients.

Nateglinide is most effective when administered in a dose of 120 mg, 1-10 min before a meal. It is metabolized primarily by hepatic CYPs (2C9, 70%; 3A4, 30%) and should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Some drugs reduce the glucose-lowering effect of nateglinide (corticosteroids, rifamycins, sympathomimetics, thiazide diuretics, thyroid products); others (alcohol, NSAIDs, salicylates, MAOIs, and nonselective β blockers) may increase the risk of hypoglycemia with nateglinide. Nateglinide therapy may produce fewer episodes of hypoglycemia than other currently available oral insulin secretagogues including repaglinide. As with sulfonylureas and repaglinide, secondary failure occurs.

AMPK AND PPARG ACTIVATORS

METFORMIN. Metformin (GLUCOPHAGE, others) is the only member of the biguanide class of oral hypoglycemic drugs available for use today.

Mechanism of Action. Metformin increases the activity of the AMP-dependent protein kinase (AMPK). AMPK is activated by phosphorylation when cellular energy stores are reduced. Activated AMPK stimulates fatty acid oxidation, glucose uptake, and nonoxidative metabolism, and it reduces lipogenesis and gluconeogenesis. The net result of these actions is increased glycogen storage in skeletal muscle, lower rates of hepatic glucose production, increased insulin sensitivity, and lower blood glucose levels.

The molecular mechanism by which metformin activates AMPK is not known; it may be indirect, possibly via reduction of intracellular energy stores. Metformin
has little effect on blood glucose in normoglycemic states, does not affect the release of insulin or other islet hormones, and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, metformin lowers blood glucose by reducing hepatic glucose production and increasing peripheral glucose uptake. This effect is at least partially mediated by reducing insulin resistance at key target tissues. Table 43–7 compares metformin and thiazolidinediones (glitazones).

ADME

Metformin is absorbed primarily from the small intestine. The drug does not bind to plasma proteins, and is excreted unchanged in the urine. It has a t₁/₂ in the circulation of ~2 h. The transport of metformin into cells is mediated in part by organic cation transporters OCT 1 and OCT 2.

THERAPEUTIC USES AND DOSAGE. Metformin, currently the most commonly used oral agent for type 2 diabetes, is generally accepted as the first-line treatment for this condition. Metformin is effective as monotherapy and in combination therapy. Fixed-dose combinations of metformin in conjunction with glipizide, glyburide, pioglitazone, repaglinide, rosiglitazone, and sitagliptin are available. Metformin is available as an immediate-release form. The currently recommended dosing is 0.5-1.0 g twice daily, with a maximum dose of 2550 mg. A sustained-release preparation is available for once-daily dosing; the maximum
dose is 2 g.

Metformin has superior or equivalent efficacy of glucose lowering compared to other oral agents used to treat diabetes, and reduces diabetes-related complications in patients with type 2 diabetes. Metformin does not typically cause weight gain and in some cases causes weight reduction. Metformin is not effective in the treatment of type 1 diabetes. In persons with IGT, treatment with metformin delays the progression to diabetes. Metformin has been used as a treatment for infertility in women with the polycystic ovarian syndrome. Although not formally approved for this purpose, metformin has demonstrable effects to improve ovulation and menstrual cyclicity and reduce circulating androgens and hirsutism.

**ADVERSE EFFECTS; INTERACTIONS.** The most common side effects (10-25%) of metformin are GI: nausea, indigestion, abdominal cramps or bloating, diarrhea, or some combination of these. Metformin has direct effects on GI function including glucose and bile salt absorption. Use of metformin is associated with 20-30% lower blood levels of vitamin B\textsubscript{12}. Most GI adverse effects of metformin abate over time with continued use, and can be minimized by starting at low doses and gradually titrating to a target dose over several weeks, and by having patients take it with meals.

Metformin has been associated with lactic acidosis, mostly reported in patients with concurrent conditions that can cause poor tissue perfusion such as sepsis, myocardial infarction, and congestive heart failure; recent analyses of this association have raised doubts as to whether the association of lactic acidosis with metformin is causal. Renal failure is a comorbidity reported in patients having lactic acidosis associated with metformin use, and decreased glomerular filtration rates are thought to increase plasma metformin levels by reducing clearance of drug from the circulation (e.g., when creatinine clearance drops below 50 mL/min). It is important to assess renal function before starting metformin and to monitor function at least annually. Metformin should be discontinued preemptively in situations where renal function could decline precipitously, such as before radiographic procedures that use contrast dyes and during admission to hospital for severe illness. Metformin should not be used in severe pulmonary disease, decompensated heart failure, severe liver disease, or chronic alcohol abuse. Cationic drugs that are eliminated by renal tubular
secretion have the potential for interaction with metformin by competing for common renal tubular transport systems. Adjustment of metformin is recommended in patients who are taking cationic medications such as cimetidine, furosemide, and nifedipine.

**THIAZOLIDINEDIONES**

Thiazolidinediones are ligands for the PPAR receptor, a pair of nuclear hormone receptors that are involved in the regulation of genes related to glucose and lipid metabolism. Two thiazolidinediones are currently available to treat patients with type 2 diabetes, rosiglitazone (AVANDIA) and pioglitazone (ACTOS). Table 43–7 compares thiazolidinediones and metformin.

**Mechanism of Action; Pharmacological Effects.** Thiazolidinediones activate PPAR receptors. PPAR is expressed primarily in adipose tissue with lesser expression in cardiac, skeletal, and smooth muscle cells, islet β cells, macrophages, and vascular endothelial cells. The endogenous ligands for PPAR include small lipophilic molecules such as oxidized linoleic acid, arachidonic acid, and the prostaglandin metabolite 15d-PGJ2; rosiglitazone and pioglitazone are synthetic ligands for PPAR. Ligand binding to PPAR causes heterodimer formation with the retinoid X receptor and interaction with PPAR response elements on specific genes. The principal response to PPAR activation is adipocyte differentiation. PPAR activity also promotes uptake of circulating fatty acids into fat cells and shifts of lipid stores from extra-adipose to adipose tissue. One consequence of the cellular responses to PPAR activation is increased tissue sensitivity to insulin.

Pioglitazone and rosiglitazone are insulin sensitizers and increase insulin-mediated glucose uptake by 30-50% in patients with type 2 diabetes. Although adipose tissue seems to be the primary target for PPAR agonists, both clinical and preclinical models support a role for skeletal muscle, the major site for insulin-mediated glucose disposal, in the response to thiazolidinediones. In addition to promoting glucose uptake into muscle and adipose tissue, the thiazolidinediones reduce hepatic glucose production and increase hepatic glucose uptake. It is not clear whether thiazolidinedione-induced improvement of insulin resistance is due to direct effects on key target tissues (skeletal muscle
and liver), indirect effects mediated by secreted products of adipocytes (e.g., adiponectin), or some combination of these.

Thiazolidinediones also affect lipid metabolism. Treatment with rosiglitazone or pioglitazone reduces plasma levels of fatty acids by increasing clearance and reducing lipolysis. These drugs also cause a shift of triglyceride stores from nonadipose to adipose tissues, and from visceral to subcutaneous fat depots. In clinical trials, pioglitazone reduces plasma triglycerides by 10-15%, and raises HDL cholesterol levels. However, randomized clinical trials demonstrated a questionable benefit of pioglitazone, and no effect of rosiglitazone on major events related to atherosclerosis.

**ADME.** Both agents are absorbed within 2-3 h, and bioavailability is unaffected by food. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency, but should not be used if there is active hepatic disease. Rifampin induces hepatic CYPs and causes a significant decrease in plasma concentrations of rosiglitazone and pioglitazone; gemfibrozil impedes metabolism of the thiazolidinediones and can increase plasma levels by γ2-fold. Prudence suggests reducing the doses of the thiazolidinediones when they are used in conjunction with gemfibrozil.

**Therapeutic Uses and Dosage.** Rosiglitazone and pioglitazone are dosed once daily. The starting dose of rosiglitazone is 4 mg and should not exceed 8 mg daily. The starting dose of pioglitazone is 15-30 mg, up to a maximum of 45 mg daily. Thiazolidinediones enhance insulin action on liver, adipose tissue, and skeletal muscle, confer improvements in glycemic control in persons with type 2 diabetes, and cause average reductions in A1c of 0.5-1.4%. Thiazolidinediones require the presence of insulin for pharmacological activity and are not indicated to treat type 1 diabetes. Both pioglitazone and rosiglitazone are effective as monotherapy and as additive therapy to metformin, sulfonylureas, or insulin. The onset of action of thiazolidinediones is relatively slow; maximal effects on glucose homeostasis develop gradually over the course of 1-3 months.

**ADVERSE EFFECTS AND DRUG INTERACTIONS.** The most common adverse effects of the thiazolidinediones are weight gain and edema. Thiazolidinediones cause an increase in body adiposity and an average weight gain of 2-4 kg over the first year of treatment. The use of insulin with thiazolidinedione treatment roughly doubles the incidence of edema and amount
of weight gain, compared with either drug alone. Macular edema has been reported in patients using both rosiglitazone and pioglitazone, usually in association with more general fluid retention. Beyond regular retinal exams, diabetic patients taking thiazolidinediones should be observed for visual changes.

Exposure to these drugs over several years in clinical trials has been associated with an increased incidence of heart failure (up to 2-fold). This has generally been attributed to the effect of the drugs to cause plasma volume expansion in type 2 diabetic patients who have significantly increased risk for heart failure. There does not appear to be an acute effect of pioglitazone or rosiglitazone to reduce myocardial contractility or ejection fraction. The use of thiazolidinediones in diabetic patients without a history of heart failure, or with compensated heart failure, can be initiated, but monitoring for signs and symptoms of congestive heart failure is important, especially when insulin is also used. Thiazolidinediones should not be used in patients with moderate to severe heart failure. Recent evidence suggests that rosiglitazone, but not pioglitazone, increases the risk of cardiovascular events (myocardial infarction, stroke). The FDA requires that new prescriptions for rosiglitazone be issued under a risk evaluation and mitigation strategy and be limited to patients whose diabetes could not be adequately controlled by other medications (including pioglitazone).

Treatment with thiazolidinediones has been associated with increased risk of bone fracture in women and with a small but consistent reduction in the hematocrit. Pioglitazone and rosiglitazone are associated with a lowering of transaminases, probably reflective of reductions in hepatic steatosis; thus, thiazolidinediones should be withheld from patients with clinically apparent liver disease and liver function be monitored intermittently during treatment.

**GLP-1-BASED AGENTS**

Incretins are GI hormones that are released after meals and stimulate insulin secretion. The best known incretins are GLP-1 and GIP. GIP is not effective for stimulating insulin release and lowering blood glucose in persons with type 2 diabetes, whereas GLP-1 is effective. Consequently, the GLP-1 signaling system has been a successful drug
Both GLP-1 and glucagon are products derived from preproglucagon, a 180–amino acid precursor with 5 separately processed domains (Figure 43–9). Given intravenously to diabetic subjects in supraphysiologic amounts, GLP-1 stimulates insulin secretion, inhibits glucagon release, delays gastric emptying, reduces food intake, and normalizes fasting and postprandial insulin secretion. The insulinotropic effect of GLP-1 is glucose-dependent in that insulin secretion at fasting glucose concentrations, even with high levels of circulating GLP-1, is minimal. GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase IV (DPP-4), with a plasma $t_{1/2}$ of 1-2 min; thus, the natural peptide, itself, is not a useful therapeutic agent. Two broad strategies have been taken to applying GLP-1 to therapeutics, the development of injectable, DPP-4 resistant peptide agonists of the GLP-1 receptor, and the creation of small molecule inhibitors of DPP-4 (Figure 43–10; see Table 43–6).

Figure 43–9 Processing of proglucagon to glucagon, GLP-1, GLP-2, and GRPP. Proglucagon is synthesized in islet α cells, intestinal enteroendocrine cells (L cells), and a subset of neurons in the hindbrain. In α cells, prohormone processing is primarily by proconvertase 2, releasing glucagon, glicentin-related pancreatic polypeptide (GRPP), and a major proglucagon fragment, containing the 2 glucagon-like peptides (GLPs). In L cells and neurons, proglucagon cleavage is mostly through proconvertase 1/3, giving glicentin, oxyntomodulin, GLP-1, and GLP-2. STN, solitary tract nucleus.
Figure 43–10 Pharmacological effects of DDP-4 inhibition. DPP-4, an ectoenzyme located on the luminal side of capillary endothelial cells metabolizes the incretins, glucagon-like peptide 1 (GLP-1), and glucose-dependent insulino tropic polypeptide (GIP), by removing the 2 N-terminal amino acids. The target for DPP-4 cleavage is a proline or alanine residue in the second position of the primary peptide sequence. The truncated metabolites GLP-1[9-36] and GIP[3-42] are the major forms of the incretins in plasma and are inactive as insulin secretagogues. Treatment with a DPP-4 inhibitor increases the concentrations of intact GLP-1 and GIP.

GLP-1 RECEPTOR AGONISTS. Two GLP-1 receptor agonists that have been approved for treatment diabetic patients in the U.S. Exendin-4, a naturally occurring 39-amino acid reptilian peptide and GLP-1 homolog, is a potent GLP-1 receptor agonist that shares many of the physiological and pharmacological effects of GLP-1. It is not metabolized by DPP-4 and so has a plasma $t_{1/2}$ of 2-3 h following subcutaneous injection. Exendin-4 causes glucose-dependent insulin secretion, delayed gastric emptying, lower glucagon levels, and
reduced food intake.

**Exenatide** (BYETTA), synthetic exendin-4, is approved for use as monotherapy and as adjunctive therapy for type 2 diabetes patients not achieving glycemic targets with other drugs.

In clinical trials, exenatide, alone or in combination with metformin, sulfonylurea, or thiazolidinedione, was associated with improved glycemic control, as reflected in an ~1% decrease in A1c, and weight loss that averaged 2.5-4 kg.

**Liraglutide** is also a GLP-1 receptor agonist. Structurally, liraglutide is nearly identical to native GLP-1, with Lys\(^{34}\) to Arg substitution and addition of a α-glutamic acid spacer coupled to a C16 fatty acyl group.

The fatty acid side chain permits binding to albumin and other plasma proteins and accounts for an extended \(t_{1/2}\) permitting once-daily administration. The pharmacodynamic profile of liraglutide mimics GLP-1 and exenatide, and in clinical trials liraglutide caused both improvement in glycemic control and weight loss. In a single comparative trial, liraglutide reduced A1c -30% more than exenatide. Liraglutide is indicated for adjunctive therapy in patients not achieving glycemic control with metformin, sulfonylurea, their combination, or metformin/thiazolidinedione.

**MECHANISM OF ACTION.** All GLP-1 receptor agonists share a common mechanism, activation of the GLP-1 receptor. GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous systems, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cyclic AMP-PKA pathway and several GEFs (guanine nucleotide exchange factors). GLP-1 receptor activation also initiates signaling via PKC and PI3K and alters the activity of several ion channels. In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (see Figure 43–3).

**ABSORPTION, DISTRIBUTION, METABOLISM, EXCRETION, AND DOSING.** Exenatide is given as a subcutaneous injection twice daily, typically before meals. Exenatide is rapidly absorbed, reaches peak concentrations in ~2
h, undergoes little metabolism in the circulation, and has a volume of distribution of nearly 30 L. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. Exenatide is marketed as a pen that delivers 5 or 10 µg; dosing is typically started at the lower amount and increased as needed.

Liraglutide is given as a subcutaneous injection once daily. Peak levels occur in 8-12 h and the elimination $t_{1/2}$ is 12-14 h. There is little renal or intestinal excretion of liraglutide, and clearance is primarily through the metabolic pathways of large plasma proteins. Liraglutide is supplied in a pen injector that delivers 0.6, 1.2, or 1.8 mg of drug; the low dose is for treatment initiation, with elevation to the higher doses based on clinical response.

**ADVERSE EFFECTS AND DRUG INTERACTIONS.** Intravenous or subcutaneous administration of GLP-1 causes nausea and vomiting; the doses above which GLP-1 causes GI side effects are higher than those needed to regulate blood glucose. Nonetheless, up to 40-50% of subjects report nausea at the initiation of therapy. The GI side effects of these drugs wane over time. Activation of the GLP-1 receptor can delay gastric emptying, and GLP-1 agonists may alter the pharmacokinetics of drugs that require rapid GI absorption, such as oral contraceptives and antibiotics. In the absence of other diabetes drugs that cause low blood glucose, hypoglycemia associated with GLP-1 agonist treatment is rare. The combination of exenatide or liraglutide with sulfonylurea drugs causes an increased rate of hypoglycemia compared to sulfonylurea treatment alone. Because of its reliance on renal clearance, exenatide should not be given to persons with moderate to severe renal failure (creatinine clearance <30 mL/min). Based on surveillance data, there is a possible association of exenatide treatment with pancreatitis, including fatal and nonfatal hemorrhagic or necrotizing pancreatitis.

**DPP-4 INHIBITORS**

DPP-4 is a serine protease that is widely distributed throughout the body, expressed as an ectoenzyme on endothelial cells, on the surface of T-lymphocytes, and in a circulating form. DPP-4 cleaves the two N-terminal amino acids from peptides with a proline or alanine in the second position. It seems to be especially critical for the inactivation
of GLP-1 and GIP. DPP-4 inhibitors increase the AUC of GLP-1 and GIP when their secretion is by a meal (see Figure 43–10). Several agents provide nearly complete and long-lasting inhibition of DPP-4, thereby increasing the proportion of active GLP-1 from 10-20% of total circulating GLP-1 immunoreactivity to nearly 100%. **Sitagliptin** (JANUVIA), **saxagliptin** (ONGLYZA), **linagliptin** (TRADJENTA), and **alogliptin** (NESINA) are available in the U.S.; **vildagliptin**, is available in the E.U.

**MECHANISMS OF ACTION; EFFECTS.** Sitagliptin and alogliptin are competitive inhibitors of DPP-4; vildagliptin and saxagliptin bind the enzyme covalently. All 4 drugs can be given in doses that lower measurable activity of DPP-4 by >95% for 12 h. This causes a greater than 2-fold elevation of plasma concentrations of active GIP and GLP-1 and is associated with increased insulin secretion, reduced glucagon levels, and improvements in both fasting and postprandial hyperglycemia. Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety, nor does chronic treatment with DPP-4 inhibitors affect body weight. DPP-4 inhibitors, used as monotherapy in type 2 diabetic patients, reduced A1c levels by an average ~0.8%. These compounds are also effective for chronic glucose control when added to the treatment of diabetic patients receiving metformin, thiazolidinediones, sulfonylureas, and insulin. The effects of DPP-4 inhibitors in combination regimens appear to be additive. The recommended dose of sitagliptin is 100 mg once daily. The recommended dose of saxagliptin is 5 mg once daily.

**ADME.** DPP-4 inhibitors are absorbed effectively from the small intestine. They circulate in primarily in unbound form and are excreted largely unchanged in the urine. Both sitagliptin and saxagliptin are excreted renally, and lower doses should be used in patients with reduced renal function. Sitagliptin has minimal metabolism by hepatic microsomal enzymes. Saxagliptin is metabolized by CYP3A4/5 to an active metabolite. The dose saxagliptin should be lowered to 2.5 mg daily when coadministered with strong CYP3A4 inhibitors (e.g., ketoconazole, atazanavir, clarithromycin, indinavir,itraconazole, nefazodone, nelfinavir, ritonavir, saquinavir, and telithromycin).

**ADVERSE EFFECTS; DRUG INTERACTIONS.** There are no consistent
adverse effects that have been noted in clinical trials with any of the DPP-4 inhibitors. DPP-4 is expressed on lymphocytes; in the immunology literature, the enzyme is referred to as CD26. This area bears scrutiny as more patients are treated with these compounds.

OTHER HYPOGLYCEMIC AGENTS

ALPHA GLUCOSIDASE INHIBITORS

α-Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α-glucosidase in the intestinal brush border. These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects. The drugs in this class are acarbose (PRECOSE, others), miglitol (GLYSET), and voglibose.

DOsing; ADME. Dosing of acarbose and miglitol are similar. Both are provided as 25, 50, or 100 mg tablets that are taken before meals. Treatment should start with lower doses and be titrated as indicated by balancing postprandial glucose, A1c, and GI symptoms. Acarbose is minimally absorbed; the small amount of drug reaching the systemic circulation is cleared by the kidney. Miglitol absorption is saturable, with 50-100% of any dose entering the circulation. Miglitol is cleared almost entirely by the kidney, and dose reductions are recommended for patients with creatinine clearance <30 mL/min.

ADVERSE EFFECTS AND DRUG INTERACTIONS. The most prominent adverse effects are malabsorption, flatulence, diarrhea, and abdominal bloating. Mild to moderate elevations of hepatic transaminases have been reported with acarbose, but symptomatic liver disease is very rare. Cutaneous hypersensitivity has been described but is also rare. Hypoglycemia has been described when α-glucosidase inhibitors are added to insulin or an insulin secretagogue. Acarbose can decrease the absorption of digoxin and miglitol can decrease the absorption of propranolol and ranitidine. Alpha glucosidase inhibitors are contraindicated in patients with stage 4 renal failure.

THERAPEUTIC USES. α-Glucosidase inhibitors are indicated as adjuncts to diet and exercise in type 2 diabetic patients not reaching glycemic targets. They
can also be used in combination with other oral antidiabetic agents and/or insulin. In clinical studies α-glucosidase inhibitors reduce A1c by 0.5-0.8%, fasting glucose by ~1 mM and postprandial glucose by 2.0-2.5 mM. These agents do not cause weight gain or have significant effects on plasma lipids.

**PRAMLIINTIDE**

Islet amyloid polypeptide (IAPP, amylin), is a 37–amino acid peptide produced in the pancreatic β cell and secreted with insulin. A synthetic form of amylin with several amino acid modifications to improve bioavailability, pramlintide (SYMLIN), has been developed as a drug for the treatment of diabetes; pramlintide may affect its actions via the amylin receptor in specific regions of the hindbrain. Activation of the amylin receptor causes reductions in glucagon release, delayed gastric emptying, and satiety.

**ADME; DOSING.** Pramlintide is administered as a subcutaneous injection prior to meals. Pramlintide is not extensively bound by plasma proteins and has a $t_{1/2}$ of 50 min. Metabolism and clearance is primarily by the kidney. The doses in patients with type 1 diabetes start at 15 µg and are titrated upward to a maximum of 60 µg; in type 2 diabetes the starting dose is 60 µg and the maximum is 120 µg. Because of differences in the pH of the solutions, pramlintide should not be administered in the same syringe as insulin.

**ADVERSE EFFECTS; DRUG INTERACTIONS.** The most common adverse effects are nausea and hypoglycemia. Although pramlintide alone does not lower blood glucose, addition to insulin at mealtimes has been noted to cause increased rates of hypoglycemia, occasionally severe. It is currently recommended that prandial insulin doses be reduced 30-50% at the time of pramlintide initiation and then retitrated. Because of its effects on GI motility, pramlintide is contraindicated in patients with gastroparesis or other disorders of motility. Pramlintide is a pregnancy Category C drug. Pramlintide can be used in persons with moderate renal disease (creatinine clearance >20 mL/min).

**THERAPEUTIC USES.** Pramlintide is approved for treatment of types 1 and 2 diabetes as an adjunct in patients who take insulin with meals. Pramlintide is now being evaluated as a drug for weight loss in nondiabetic persons.
BILE ACID BINDING RESINS

The only bile acid sequestrant specifically approved for the treatment of type 2 diabetes is *colesevelam* (WELCHOL).

MECHANISM OF ACTION. The mechanism by which bile acid binding and removal from enterohepatic circulation lowers blood glucose has not been established. Bile acid sequestrants could reduce intestinal glucose absorption, although there is no direct evidence of this. Bile acids also act as signaling molecules through nuclear receptors, some of which may act as glucose sensors.

ADME. Colesevelam is provided as a powder for oral solution and as 625-mg tablets; typical usage is 3 tablets twice daily before lunch and dinner or 6 tablets prior to the patient’s largest meal. The drug’s distribution is limited to the GI tract.

ADVERSE EFFECTS AND DRUG INTERACTIONS. Common side effects of colesevelam are gastrointestinal, with constipation, dyspepsia, abdominal pain, and nausea affecting up to 10% of treated patients. Like other bile acid binding resins, colesevelam can increase plasma triglycerides in persons with an inherent tendency to hypertriglyceridemia and should be used cautiously in patients with plasma triglycerides >200 mg/dL. Colesevelam can interfere with the absorption of commonly used agents (e.g., phenytoin, warfarin, verapamil, glyburide, L-thyroxine, and ethinyl estradiol, and fat-soluble vitamins). Colesevelam is a pregnancy Category B drug that has no contraindications in patients with renal or liver disease.

THERAPEUTIC USES. The bile acid binding resin colesevelam, approved for treatment of hypercholesterolemia, may be used for treatment of type 2 diabetes as an adjunct to diet and exercise. In clinical trials, colesevelam reduced A1c by 0.5% when added to metformin, sulfonylurea, or insulin treatment in type 2 diabetic patients.

BROMOCRIPTINE

A formulation of bromocriptine (CYCLOSET), a dopamine receptor agonist, is approved for the treatment of type 2 diabetes but is not yet available in the U.S. Bromocriptine is an established treatment for
Parkinson disease and hyperprolactinemia (see Chapters 13, 22, and 38). Effects of bromocriptine on blood glucose are modest and may reflect an action in the CNS.

**COMBINED PHARMACOLOGICAL APPROACHES TO TYPE 2 DIABETES**

**PROGRESSIVE MANAGEMENT OF TYPE 2 DIABETES**

There are several useful algorithms or flow charts for the treatment of type 2 diabetes (Figure 43–11). There are a number of pathways or combination of drugs that are used for treatment of type 2 diabetes if the glucose control does not reach the therapeutic target. Table 43–8 summarizes available pharmacological agents for the treatment of diabetes.
Patients diagnosed with type 2 diabetes, either by fasting glucose, oral glucose tolerance testing, or A1c measurement, should have diabetes education that includes instruction on medical nutrition therapy and physical activity. Most patients newly diagnosed with type 2 diabetes have had subclinical or undiagnosed diabetes for many years previously and should be evaluated for diabetic complications (retinal exam, test for excess protein or albumin excretion in the urine, and clinical evaluation for peripheral neuropathy and vascular insufficiency); common comorbidities (hypertension and dyslipidemia) should be treated. Metformin is the consensus first line of therapy and should be started at the time of diagnosis. Failure to reach the glycemic target, generally A1c <7% within 3-4 months, should prompt the addition of a second oral agent. Reinforce lifestyle interventions at every visit and check A1c every 3 months. Treatment may escalate to metformin plus 2 oral agents or metformin plus insulin, if necessary.

HYPOGLYCEMIA

In the absence of prolonged fasting, healthy humans almost never have blood glucose levels <3.5 mM. This is due to a highly adapted neuroendocrine counterregulatory system that prevents acute hypoglycemia, a hazardous and potentially lethal situation. The 2 major clinical scenarios for hypoglycemia are:

- Treatment of diabetes
- Inappropriate production of endogenous insulin or an insulin-like substance by a pancreatic islet tumor (insulinoma) or a non-islet tumor

Hypoglycemia in the first scenario can occur either in the fasting or fed state, whereas in the second scenario, hypoglycemia occurs almost exclusively in the fasting or postabsorptive state. Some drugs not used for the treatment of diabetes promote hypoglycemia (see Table 43–3).

The most common and serious adverse event related to diabetes therapy is hypoglycemia. Although an adverse reaction to a number of oral therapies, it is most pronounced and serious with insulin therapy. Hypoglycemia may result from an inappropriately large dose, from a mismatch between the time of peak
delivery of insulin and food intake, or from superimposition of additional factors that increase sensitivity to insulin (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). Hypoglycemia is the major risk that always must be weighed against benefits of efforts to normalize glucose control.

The first physiological response to hypoglycemia is a reduction of endogenous insulin secretion, which occurs at a plasma glucose level of ~70 mg/dL (3.9 mM); thereafter, the counterregulatory hormones (EPI, glucagon, growth hormone, cortisol, and NE) are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60-80 mg/dL (3.3-4.4 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., most important neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms.

In patients with type 1 and type 2 diabetes of longer duration, the glucagon secretory response to hypoglycemia becomes deficient. Diabetic patients thus become dependent on EPI for counterregulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases. Severe hypoglycemia can lead to convulsions and coma. With the ready availability of home glucose monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia. Mild-to-moderate hypoglycemia may be treated simply by ingestion of glucose (15 g of carbohydrate). When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon.

**AGENTS USED TO TREAT HYPOGLYCEMIA**

**Glucagon** is a single-chain polypeptide of 29 amino acids now produced by recombinant DNA technology. Glucagon interacts with a GPCR on the plasma membrane of target cells that signals through $G_\text{s}$. The primary effects of glucagon on the liver are mediated by cAMP. Glucagon is used to treat severe hypoglycemia, particularly in diabetic
patients when the patient cannot safely consume oral glucose and intravenous glucose is not available.

For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously. After the initial response to glucagon, patients should be given glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects.

**Diazoxide (PROGLYCEM)** is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally. Hyperglycemia results primarily from inhibition of insulin secretion. Diazoxide interacts with the K$_{ATP}$ channel on the β cell membrane and either prevents its closing or prolongs the open time; this effect is opposite to that of the sulfonylureas (see Figure 43–3).

The usual oral dose is 3-8 mg/kg per day in adults and children and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a t$_{1/2}$ of ~48 h. Diazoxide has a number of adverse effects, including retention of Na$^+$ and fluid, hyperuricemia, hypertrichosis, thrombocytopenia, and leucopenia, which sometimes limit its use. Despite these side effects, the drug may be useful in patients with inoperable insulinomas and in children with neonatal hyperinsulinism.

**OTHER PANCREATIC ISLET HORMONES**

**SOMATOSTATIN.** Somatostatin (SST) is produced by δ cells of the pancreatic islet, cells of the GI tract, and in the CNS. Somatostatin, a 14–amino acid or a 28–amino acid peptide molecule, acts through a family of 5 GPCRs, SSTR$_{1-5}$. SST inhibits a wide variety of endocrine and exocrine secretions, including TSH and GH from the pituitary, gastrin, motilin, VIP, glicentin, and insulin, glucagon, and pancreatic polypeptide from the pancreatic islet. The physiological role of somatostatin has not been defined precisely, but its short t$_{1/2}$ (3-6 min) prevents its use therapeutically. Longer-acting analogs such as octreotide (SANDOSTATIN) and lanreotide (SOMATULINE) are useful for treatment of carcinoid tumors,
glucagonomas, VIPomas, and acromegaly (see Chapter 38). Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the somatostatin analogs, as do GI symptoms.
Chapter 44
Agents Affecting Mineral Ion Homeostasis and Bone Turnover

Physiology of Mineral Ion Homeostasis

Calcium

Elemental calcium is essential for a variety of biological functions. Its ionized form, Ca\(^{2+}\), is an important component of current flow across excitable membranes. Ca\(^{2+}\) is vital for muscle contraction, fusion, and release of storage vesicles. In the submicromolar range, intracellular Ca\(^{2+}\) acts as a critical second messenger (see Chapter 3). In extracellular fluid, millimolar concentrations of Ca\(^{2+}\) promote blood coagulation and support the formation and continuous remodeling of the skeleton.

In the face of millimolar extracellular Ca\(^{2+}\), intracellular free Ca\(^{2+}\) is maintained at a low level, \(\sim\)100 nM in cells in their basal state, by active extrusion by Ca\(^{2+}\)–ATPases, by Na\(^+\)/Ca\(^{2+}\) exchange, and by accumulation into cellular storage networks such as the sarcoplasmic reticulum. Changes in cytosolic Ca\(^{2+}\) (whether released from intracellular stores or entering via membrane Ca\(^{2+}\) channels) can modulate effector targets, often by interacting with the Ca\(^{2+}\)-binding protein calmodulin. The rapid association–dissociation kinetics of Ca\(^{2+}\) and the relatively high affinity and selectivity of Ca\(^{2+}\)-binding domains permit effective regulation of Ca\(^{2+}\) over the 100 nM to 1 \(\sim\) range.

The body content of calcium in healthy adult men and women, respectively, is \(\sim\)1300 and 1000 g, of which >99% is in bone and teeth. Ca\(^{2+}\) in extracellular fluids is stringently regulated within narrow limits. In adult humans, the normal serum Ca\(^{2+}\) concentration ranges from 8.5-10.4 mg/dL (4.25-5.2 mEq/L, 2.1-2.6 mM) and
includes 3 distinct chemical forms of Ca\(^{2+}\): ionized (50%), protein-bound (40%), and complexed (10%). Thus, whereas total plasma Ca\(^{2+}\) concentration is ~2.5 mM, the concentration of ionized Ca\(^{2+}\) in plasma is ~1.2 mM. The various pools of Ca\(^{2+}\) are illustrated schematically in Figure 44–1. Only diffusible Ca\(^{2+}\) (i.e., ionized plus complexed) can cross cell membranes. Albumin accounts for some 90% of the serum Ca\(^{2+}\) bound to plasma proteins; a change of plasma albumin concentration of 1.0 g/dL from the normal value of 4.0 g/dL can be expected to alter total Ca\(^{2+}\) concentration by ~0.8 mg/dL. The remaining 10% of the serum Ca\(^{2+}\) is complexed with small polyvalent anions, primarily phosphate and citrate. The degree of complex formation depends on the ambient pH and the concentrations of ionized Ca\(^{2+}\) and complexing anions. Ionized Ca\(^{2+}\) is the physiologically relevant component, mediates calcium’s biological effects, and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia. The extracellular Ca\(^{2+}\) concentration is tightly controlled by hormones that affect calcium entry at the intestine and its exit at the kidney; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.
Figure 44–1 Pools of calcium in serum. Concentrations are expressed as mg/dL on the left-hand axis and as mM on the right. The total serum calcium concentration is 10 mg/dL or 2.5 mM, divided into 3 pools: protein-bound (40%), complexed with small anions (10%), and ionized calcium (50%). The complexed and ionized pools represent the diffusable forms of calcium.

Calcium Stores. The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite; other ions, including Na⁺, K⁺, Mg²⁺, and F⁻, also are present in the crystal lattice. The steady-state content of Ca²⁺ in bone reflects the net effect of bone resorption and bone formation.

Calcium Absorption and Excretion. In the U.S., ~75% of dietary Ca²⁺ is obtained from milk and dairy products. The adequate intake value for Ca²⁺ is 1300 mg/day in adolescents and 1000 mg/day in adults. After age 50, the adequate intake is 1200 mg/day. Figure 44–2 illustrates the components of whole-body daily Ca²⁺ turnover. Ca²⁺ enters the body only through the intestine. Active vitamin D–dependent Ca²⁺ transport occurs in the proximal duodenum, whereas facilitated diffusion throughout the small intestine accounts for most total Ca²⁺ uptake. This uptake is counterbalanced by an obligatory daily intestinal Ca²⁺ loss of ~150 mg/day that reflects the Ca²⁺ content of mucosal and biliary secretions and in sloughed intestinal cells. The efficiency of intestinal Ca²⁺ absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. Disease states associated with steatorrhea, chronic diarrhea, or malabsorption promote fecal loss of Ca²⁺. Drugs such as glucocorticoids and phenytoin depress intestinal Ca²⁺ transport.
Urinary Ca\textsuperscript{2+} excretion is the net difference between the quantity filtered at the glomerulus and the amount reabsorbed. About 9 g of Ca\textsuperscript{2+} are filtered each day, of which >98% is reabsorbed in the tubules. The efficiency of reabsorption is highly regulated by parathyroid hormone (PTH) and is influenced by filtered Na\textsuperscript{+}, the presence of nonreabsorbed anions, and diuretic agents (see Chapter 25).

**PHOSPHATE**

Phosphate is present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone; ~15% is in soft tissue. Additionally, phosphate is a dynamic constituent of intermediary and energy metabolism and as a key regulator of enzyme activity when transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues. Biologically, phosphorus (P) exists in both organic and inorganic (P\textsubscript{i}) forms. Organic forms include...
phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus is present as inorganic phosphate in the form of NaH$_2$PO$_4$ and Na$_2$HPO$_4$. The aggregate level of inorganic phosphate (P$_i$) modifies tissue concentrations of Ca$^{2+}$ and plays a major role in renal H$^+$ excretion. Within bone, phosphate is complexed with Ca$^{2+}$ as hydroxyapatites and as calcium phosphate.

**Absorption, Distribution, and Excretion.** Phosphate is absorbed from and, to a limited extent, secreted into the GI tract. Phosphate is a ubiquitous component of ordinary foods; even an inadequate diet rarely causes phosphate depletion. Transport of phosphate from the intestinal lumen is an active, energy-dependent process that is regulated by several factors, primarily vitamin D, which stimulates absorption. In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Phosphate excretion in the urine represents the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is actively reabsorbed, predominantly in the proximal convoluted tubule. Renal phosphate absorption is regulated by a variety of hormones and other factors; the most important are PTH and dietary phosphate, with extracellular volume and acid–base status playing lesser roles. Dietary phosphate deficiency upregulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of any effect on plasma P$_i$, Ca$^{2+}$, or PTH. PTH increases urinary phosphate excretion by blocking phosphate absorption. Expansion of plasma volume increases urinary phosphate excretion.

**ROLE OF PHOSPHATE IN URINE ACIDIFICATION.** Phosphate is concentrated progressively in the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H$^+$ and Na$^+$ in the tubular urine converts Na$_2$HPO$_4$ to NaH$_2$PO$_4$, permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H$^+$ transport.

**PHARMACOLOGICAL ACTIONS OF PHOSPHATE.** Phosphate salts are
employed as mild laxatives (see Chapter 46).

HORMONAL REGULATION OF CALCIUM AND PHOSPHATE HOMEOSTASIS

A number of hormones interact to regulate extracellular Ca\(^{2+}\) and phosphate balance. The most important are PTH and 1,25-dihydroxyvitamin D\(_3\) (calcitriol), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 44–3).

![Calcium homeostasis and its regulation by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D. PTH has stimulatory effects on bone and kidney, including the stimulation of 1α-hydroxylase activity in kidney mitochondria leading to the increased production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol, the monohydroxylated vitamin D](image-url)
metabolite (Figure 44–5). Calcitriol is the biologically active metabolite of vitamin D.

**PARATHYROID HORMONE**

PTH is a polypeptide that helps to regulate plasma Ca\(^{2+}\) by affecting bone resorption/formation, renal Ca\(^{2+}\) excretion/reabsorption, and calcitriol synthesis (thus, GI Ca\(^{2+}\) absorption).

PTH is single polypeptide chain of 84 amino acids with molecular mass of ~9500 Da. Biological activity is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTH receptor and hormone activity. Derivatives lacking the first and second residue bind to PTH receptors but do not activate the cyclic AMP or IP\(_3–Ca^{2+}\) signaling pathways. The PTH fragment lacking the first 6 amino acids inhibits PTH action.

**SYNTHESIS AND SECRETION.** PTH is synthesized as a 115–amino acid peptide called *preproparathyroid hormone*, which is converted to *proparathyroid hormone* by cleavage of 25 amino-terminal residues in the endoplasmic reticulum. Preparathyroid hormone is converted in the Golgi complex to PTH by cleavage of 6 amino acids. PTH(1-84) resides within secretory granules until it is discharged into the circulation. PTH(1-84) has a \(t_{1/2}\) in plasma of ~4 min; removal by the liver and kidney accounts for ~90% of its clearance. Proteolysis of PTH generates smaller fragments (e.g., a 33–36 amino acid N-terminal fragment that is fully active, a larger C-terminal peptide, and PTH[7-84]). PTH(7-84) and other amino-truncated PTH fragments are normally cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms.

**Physiological Functions.** The primary function of PTH is to maintain a constant concentration of Ca\(^{2+}\) and P\(_i\) in the extracellular fluid. The principal processes regulated are renal Ca\(^{2+}\) and P\(_i\) absorption, and mobilization of bone Ca\(^{2+}\) (see Figure 44–3). The actions of PTH are mediated by at least 2 receptors: the PTH\(_1\) and the PTH\(_2\) receptor.
Both of these are GPCRs that can couple with $G_s$ and $G_q$ in cell-type specific manners. PTH also can activate phospholipase D through a $G_{12/13}$–RhoA pathway. A third receptor, the CPTH receptor, interacts with forms of PTH that are truncated in the amino-terminal region, contain most of the carboxy terminus, and are inactive at the PTH$_1$ receptor; these CPTH receptors reportedly are expressed on osteocytes.

Regulation of Secretion. Plasma Ca$^{2+}$ is the major factor regulating PTH secretion. As the concentration of Ca$^{2+}$ diminishes, PTH secretion increases; hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca$^{2+}$ is high, PTH secretion decreases. Changes in plasma Ca$^{2+}$ regulate PTH secretion by the plasma membrane–associated calcium-sensing receptor (CaSR) on parathyroid cells. The CaSR is a GPCR that couples with $G_q$ and $G_i$. Occupancy of the CaSR by Ca$^{2+}$ stimulates the $G_q$-PLC-IP$_3$-Ca$^{2+}$ pathway leading to activation of PKC; this results in inhibition of PTH secretion, an unusual case in which elevation of cellular Ca$^{2+}$ inhibits secretion (another being the granular cells in the juxtaglomerular complex of the kidney, where elevation of cellular Ca$^{2+}$ inhibits renin secretion). Simultaneous activation of the $G_i$ pathway by Ca$^{2+}$ reduces cyclic AMP synthesis and lowers the activity of PKA, also a negative signal for PTH secretion. Conversely, reduced occupancy of CaSR by Ca$^{2+}$ reduces signaling through $G_i$ and $G_q$, thereby promoting PTH secretion. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and dopamine, also increase PTH secretion, but much less than does hypocalcemia. The active vitamin D metabolite, 1,25-dihydroxyvitamin D (calcitriol), directly suppresses PTH gene expression. Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

Effects on Bone. Chronically elevated PTH enhances bone resorption and thereby increases Ca$^{2+}$ delivery to the extracellular fluid, whereas intermittent exposure to PTH promotes anabolic actions. The primary skeletal target cell for PTH is the osteoblast.

Effects on Kidney. In the kidney, PTH enhances the efficiency of Ca$^{2+}$ reabsorption, inhibits tubular reabsorption of phosphate, and stimulates
conversion of vitamin D to its biologically active form, 1,25-dihydroxy vitamin D₃ (calcitriol; see Figure 44–3). As a result, filtered Ca²⁺ is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized 1,25-dihydroxy vitamin D₃ interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca²⁺ absorption, thereby contributing to the increase in plasma (Ca²⁺).

**Calcitriol Synthesis.** The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the enzymatic activity of the 25-hydroxyvitamin D₃-1 α-hydroxylase that catalyzes this step: Pᵢ, PTH, and Ca²⁺ (see later for further discussion). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating Pᵢ and a more direct effect of the hormone on the 1 α-hydroxylase lead to increased circulating concentrations of calcitriol.

**Integrated Regulation of Extracellular [Ca²⁺] by PTH.** Even modest reductions of serum Ca²⁺ stimulate PTH secretion. With prolonged hypocalcemia, the renal 1 α-hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal Ca²⁺ absorption (see Figure 44–3), and delivery of calcium from bone into the extracellular fluid is augmented. With prolonged and severe hypocalcemia, new bone remodeling units are activated to restore circulating Ca²⁺ concentrations, albeit at the expense of skeletal integrity. When plasma Ca²⁺ activity rises, PTH secretion is suppressed, and tubular Ca²⁺ reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate depress calcitriol production and thereby decrease intestinal Ca²⁺ absorption. Finally, bone remodeling is suppressed. These integrated physiological events
ensure a coherent response to positive or negative excursions of plasma Ca\textsuperscript{2+} concentrations.

**VITAMIN D**

Vitamin D is a hormone rather than a vitamin, and it plays an active role in Ca\textsuperscript{2+} homeostasis. The biological actions of vitamin D are mediated by the vitamin D receptor (VDR), a nuclear receptor. Vitamin D is the name applied to 2 related fat-soluble substances, vitamin D\textsubscript{3} (*cholecalciferol*) and vitamin D\textsubscript{2} (*ergocalciferol*) ([Figure 44–4](#)), that share the capacity to prevent or cure rickets. In humans there is no practical difference between the antirachitic potencies of vitamin D\textsubscript{2} and vitamin D\textsubscript{3}. Therefore, “vitamin D” is used here as a collective term for vitamins D\textsubscript{2} and D\textsubscript{3}.
The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D₃). Ergosterol, present only in plants and fungi, is the provitamin for vitamin D₂ (ergocalciferol). Vitamin D₂ is the active constituent of a number of commercial vitamin preparations and is in irradiated bread and irradiated milk.

**HUMAN REQUIREMENTS AND UNITS.** Although sunlight provides
adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation, especially in winter, may necessitate dietary vitamin D supplementation. Serum levels of vitamin D vary widely, likely reflecting genetic background, diet, latitude, time spent out of doors, body size, developmental stage, and state of health, as well as plasma levels of vitamin D binding protein, a specific α-globulin. The actions of vitamin D may vary with the expression of components of the synthetic and action pathways of vitamin D. Other factors contributing to the rise of vitamin D deficiency may include diminished consumption of vitamin D–fortified foods owing to concerns about fat intake; reduced intake of dairy products; increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging from exposure to ultraviolet radiation; and an increased prevalence and duration of exclusive breast-feeding (human milk is a poor source of vitamin D). There is no consensus regarding optimal vitamin D intake. The U.S. Institute of Medicine suggests achieving a serum level for 25-OH vitamin D of 50 nmol/L (20 ng/mL) and recommends a daily intake for most children and adults of 600 IU (15 µg) per day (Table 44–1).

\[A\text{ one-cup serving of most dairy products contains 200-300 mg of calcium and 100 IU of vitamin D. A serving of fish may contain 200-500 IU of vitamin D. The Goodan & Gilman website at AccessMedicine.com contains several updates on the debate about appropriate vitamin D intake and blood levels.}\]

ADME., Vitamins D\(_2\) and D\(_3\) are absorbed from the small intestine.
Bile is essential for adequate absorption of vitamin D (see Chapter 46). The primary route of vitamin D₃ excretion is the bile. Patients who have intestinal bypass surgery or have or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption. Absorbed vitamin D circulates in the blood in association with vitamin D binding protein. The vitamin disappears from plasma with a $t_{1/2}$ of 20-30 h but is stored in fat depots for prolonged periods.

**METABOLIC ACTIVATION.** Vitamin D requires modification to become biologically active. The primary active metabolite is 1α,25-dihydroxy vitamin D (*calcitriol*), the product of 2 successive hydroxylations (see Figure 44–4).

**25-Hydroxylation of Vitamin D.** The initial hydroxylation occurs in the liver to generate 25-OH-cholecalciferol (25-OHD, or *calcifediol*) and 25-OH-ergocalciferol, respectively. 25-OHD is the major circulating form of vitamin D₃; it has a biological $t_{1/2}$ of 19 days, and normal steady-state concentrations are 15-50 ng/mL.

**1α-Hydroxylation of 25-OHD.** After production in the liver, 25-OHD enters the circulation and is carried by vitamin D–binding globulin. Final activation occurs primarily in the kidney, where the enzyme 1 α-hydroxylase in the proximal tubules converts 25-OHD to *calcitriol*. This process is highly regulated (Figure 44–5). Calcitriol controls 1 α-hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma $t_{1/2}$ of calcitriol is estimated at 3-5 days in humans.
Figure 44–5 Regulation of 1 α-hydroxylase activity. Changes in the plasma levels of PTH, Ca\(^{2+}\), and phosphate modulate the hydroxylation of 25-OH vitamin D to the active form, 1,25-dihydroxyvitamin D. 25-OHD, 25-hydroxycholecalciferol; 1,25-(OH)\(_2\)-D, calcitriol; PTH, parathyroid hormone.

**PHYSIOLOGICAL FUNCTIONS AND MECHANISM OF ACTION.** Calcitriol augments absorption and retention of Ca\(^{2+}\) and phosphate. Calcitriol acts to maintain normal concentrations of Ca\(^{2+}\) and phosphate in plasma by facilitating their absorption in the small intestine, by interacting with PTH to enhance their mobilization from bone, and by decreasing their renal excretion. The actions of calcitriol are mediated by binding to cytosolic VDRs within target cells, and the
receptor–hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. The VDR belongs to the steroid and thyroid hormone receptor superfamily. Calcitriol also exerts nongenomic effects.

Calcium is absorbed predominantly in the duodenum. In the absence of calcitriol, GI calcium absorption is inefficient and involves passive diffusion via a paracellular pathway. Ca\(^{2+}\) absorption is potently augmented by calcitriol. It is likely that calcitriol enhances all 3 steps involved in intestinal Ca\(^{2+}\) absorption: entry across mucosal membranes (possibly involving TRPV6 Ca\(^{2+}\) channels), diffusion through the enterocytes, and active extrusion across serosal plasma membranes. Calcitriol upregulates the synthesis of calbindin-D\(_{9K}\), calbindin-D\(_{28K}\), and the serosal plasma membrane Ca\(^{2+}\)–ATPase. Calbindin-D\(_{9K}\) enhances the extrusion of Ca\(^{2+}\) by the Ca\(^{2+}\)–ATPase; the precise function of calbindin-D\(_{28K}\) is unsettled.

The primary role of calcitriol is to stimulate intestinal absorption of Ca\(^{2+}\), which, in turn, indirectly promotes bone mineralization. Thus, PTH and calcitriol act independently to enhance bone resorption. Osteoblasts, the cells responsible for bone formation, express the VDR, and calcitriol induces their production of several proteins, including osteocalcin, a vitamin K–dependent protein that contains \(\gamma\)-carboxyglutamic acid residues, and interleukin-1 (IL-1), a lymphokine that promotes bone resorption. Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone.

Osteoporosis is a disease in which osteoclast responsiveness to calcitriol or other bone-resorbing agents is profoundly impaired, leading to deficient bone resorption.

*Other Effects of Calcitriol.* Effects of calcitriol extend well beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body. Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function. Calcitriol inhibits epidermal proliferation and promotes epidermal differentiation and therefore is a potential treatment for psoriasis vulgaris (see Chapter 65).

**CALCITONIN**
Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH. The thyroid parafollicular C cells produce and secrete calcitonin. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation.

**Regulation of Secretion.** Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking cys1 and cys7. The biosynthesis and secretion of calcitonin are regulated by the plasma [Ca^{2+}]. Calcitonin secretion increases when plasma Ca^{2+} is high and decreases when plasma Ca^{2+} is low. The circulating concentrations of calcitonin are low, normally <15 and 10 pg/mL for males and females, respectively. The circulating t_{1/2} of calcitonin is ~10 min. Abnormally elevated levels of calcitonin are characteristic of thyroid C cell hyperplasia and medullary thyroid carcinoma. Differential splicing of the 6 exons of the calcitonin gene leads to tissue-specific production of calcitonin, katacalcin, and calcitonin gene-related peptide (CGRP).

**Mechanism of Action.** The calcitonin receptor (CTR), a GPCR that couples to multiple G proteins, mediates calcitonin’s actions. The hypocalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption. CGRP and the closely related peptide *adrenomedullin* are potent endogenous vasodilators.

**FIBROBLAST GROWTH FACTOR 23 AND KLOTHO**

Fibroblast growth factor 23 (*FGF23*), a protein of 251 amino acids, is produced primarily by bone cells including osteoblasts, osteocytes, and lining cells. FGF23 is secreted in response to dietary phosphorus load; its main function is the promotion of urinary phosphate excretion and the suppression of active vitamin D production by the kidney. Klotho is a membrane protein that serves as an essential cofactor in the transduction of FGF23 signaling. Exogenous FGF23 administration reduces serum P_i and calcitriol synthesis. Although no
clinical agents based on FGF23 have yet been developed, bioactive fragments or FGF23 inhibitors might become useful in counterbalancing the hyperphosphatemic actions of vitamin D therapy.

**BONE PHYSIOLOGY**

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

**BONE MASS.** Bone mineral density (BMD) and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for ~60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium. Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. In women, loss of estrogen at menopause accelerates the rate of bone loss. *Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all 3 areas, and deficiency of one is not compensated by excessive attention to another.*

**BONE REMODELING.** Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called *remodeling*, by which bone mass is adjusted throughout adult life. Remodeling is carried out by myriad independent “bone remodeling units” throughout the skeleton. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated osteoclasts that resorb, or excavate, a cavity into the bone. Osteoclast production is regulated by osteoblast-derived cytokines (e.g., IL-1 and IL-6). One important mechanism is the receptor for activating NF-nB (RANK) and its natural ligand, RANK ligand (RANKL; previously called
osteoclast differentiation factor). On binding to RANK, RANKL induces osteoclast formation (Figure 44–6). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce osteoprotegerin (OPG), which acts as a decoy ligand that inhibits osteoclast production by competing effectively with RANKL for binding to RANK. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK.

Figure 44–6 Receptor for activating NF-κB ligand (RANKL) and osteoclast formation. RANKL, acting on RANK, promotes osteoclast formation and subsequent resorption of bone matrix. Osteoprotegerin (OPG) binds to RANKL, reducing its binding to RANK and thereby inhibiting osteoclast differentiation.

The resorption phase is followed by invasion of preosteoblasts into the base of the resorption cavity. These cells become osteoblasts and elaborate new bone matrix constituents that help form osteoid. Once the newly formed osteoid
reaches a thickness of \( \sim 20 \, \mu m \), mineralization begins. A complete remodeling cycle normally requires \( \sim 6 \) months. Small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary sufficiency, exercise, hormones, and drugs, affect bone balance.

**DISORDERS OF MINERAL HOMEOSTASIS AND BONE**

**ABNORMAL CALCIUM METABOLISM**

**HYPERCALCEMIA.** In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by 1 or more parathyroid glands. Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrolithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption.

*Vitamin D excess* may cause hypercalcemia if sufficient 25-OHD is present to stimulate intestinal \( \text{Ca}^{2+} \) hyperabsorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-OHD is diagnostic. Serum assays for PTH, PTHrP, and 25-OH- and 1,25-(OH)\(_2\)D permit accurate diagnosis in the great majority of cases.

Hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTH-related protein (PTHrP) is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue. The PTHrP interacts with the PTH-1 receptor in target tissues, thereby causing the hypercalcemia and hypophosphatemia seen in humoral hypercalcemia of malignancy. In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the
tumor cells owing to expression of 1α-hydroxylase.

**HYPOCALCEMIA.** Combined deprivation of Ca\(^{2+}\) and vitamin D, as observed with malabsorption states, readily promotes hypocalcemia. When caused by malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mild hypocalcemia (i.e., serum Ca\(^{2+}\) in the range of 8-8.5 mg/dL [2-2.1 mM]), is usually asymptomatic. Patients exhibit greater symptoms if the hypocalcemia develops acutely.

Symptoms of hypocalcemia include tetany and related phenomena such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic hypoparathyroidism, ectodermal changes (e.g., consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts) occur. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present. Hypoparathyroidism is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. Pseudohypoparathyroidism is a diverse family of hypocalcemic and hyperphosphatemic disorders. Pseudohypoparathyroidism results from resistance to PTH; this resistance is due to mutations in Gsα (GNAS1), which normally mediates hormone-induced adenylyl cyclase activation. Multiple hormonal abnormalities have been associated with the GNAS1 mutation, but none is as severe as the deficient response to PTH.

**DISTURBED PHOSPHATE METABOLISM**

Dietary inadequacy very rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (see Chapter 45). Osteomalacia is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the GI tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action. Hyperphosphatemia occurs commonly in chronic renal failure. The increased phosphate level
reduces the serum Ca\textsuperscript{2+} concentration, which, in turn, activates the parathyroid gland calcium-sensing receptor, stimulates PTH secretion, and exacerbates the hyperphosphatemia. The FDA recently approved therapeutic use of the calcium-sensing receptor agonist cinacalcet to suppress PTH secretion.

**DISORDERS OF VITAMIN D**

**HYPERVITAMINOSIS D.** The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. In adults, hypervitaminosis D results from overtreatment of hypoparathyroidism and from faddist use of excessive doses. The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of >50,000 units may result in poisoning. The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia.

**Vitamin D Deficiency.** Vitamin D deficiency results in inadequate absorption of Ca\textsuperscript{2+} and phosphate. The consequent decrease of plasma Ca\textsuperscript{2+} concentration stimulates PTH secretion, which acts to restore plasma Ca\textsuperscript{2+} at the expense of bone. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH. In children, the result is a failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as rickets. In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations <8 ng/mL are highly predictive of osteomalacia.

**METABOLIC RICKETS AND OSTEOMALACIA.** These disorders are characterized by abnormalities in calcitriol synthesis or response. Variants include hypophosphatemic vitamin D–resistant rickets,

**OSTEOPOROSIS**

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Many women (30-50%) and men (15-30%) suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age, and spine and hip fractures are associated with reduced survival.

Osteoporosis can be categorized as *primary* or *secondary*. Primary osteoporosis represents 2 different conditions: *type I osteoporosis*, characterized by loss of trabecular bone owing to estrogen lack at menopause, and *type II osteoporosis*, characterized by loss of cortical and trabecular bone in men and women due to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. Secondary osteoporosis is due to systemic illness or medications such as glucocorticoids or phenytoin. The most successful approach to secondary osteoporosis is prompt resolution of the underlying cause or drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used.

**PAGET DISEASE.** Paget disease is characterized by single or multiple sites of disordered bone remodeling. It affects up to 2-3% of the population >60 years of age. The primary pathologic abnormality is increased bone resorption followed by exuberant bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget disease.
RENAL OSTEODYSTROPHY. Bone disease is a frequent consequence of chronic renal failure and dialysis. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa), vitamin D deficiency (osteomalacia), or a mixture of both. The underlying pathophysiology reflects increased serum phosphate and decreased calcium, leading to the loss of bone.

PHARMACOLOGICAL TREATMENT OF DISORDERS OF MINERAL ION HOMEOSTASIS AND BONE METABOLISM

HYPERCALCEMIA

Hypercalcemia can be life threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6-8 L/day). Agents that augment Ca\(^{2+}\) excretion, such as loop diuretics (see Chapter 25), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted.

Corticosteroids administered at high doses (e.g., 40-80 mg/day of prednisone) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (see Chapter 42). The response to steroid therapy is slow; from 1-2 weeks may be required before plasma Ca\(^{2+}\) concentration falls. Corticosteroids administered at high doses (e.g., 40-80 mg/day of prednisone) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (see Chapter 42). The response to steroid therapy is slow; from 1-2 weeks may be required before plasma Ca\(^{2+}\) concentration falls. Calcitonin (CALCIMAR, MICALCIN) may be useful in managing hypercalcemia. Reduction in Ca\(^{2+}\) can be rapid, although “escape” from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 h; if there is no response within 1-2 days, the dose may be increased to a maximum of 8 units/kg every 12 h. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 h. Calcitonin can lower serum calcium by 1-2 mg/dL.

Intravenous bisphosphonates (pamidronate, zoledronate) have proven very effective in the management of hypercalcemia (see below for discussion of bisphosphonates). These agents potently inhibit osteoclastic bone resorption. Pamidronate (AREDIA) is given as an intravenous infusion of 60-90 mg over 4-24 h. With pamidronate, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks. Zoledronate (ZOMETA) has...
superseded pamidronate because of its more rapid normalization of serum Ca\textsuperscript{2+} and longer duration of action.

Plicamycin (mithramycin, MITHRACIN) is a cytotoxic antibiotic that also decreases plasma Ca\textsuperscript{2+} concentrations by inhibiting bone resorption. Reduction in plasma Ca\textsuperscript{2+} concentrations occurs within 24-48 h when a relatively low dose of this agent is given (15-25 µg/kg of body weight) to minimize the high systemic toxicity of the drug; indeed, its toxicity generally precludes its use.

Once the hypercalcemic crisis has resolved or in patients with milder calcium elevations, long-term therapy is initiated. Parathyroidectomy remains the only definitive treatment for primary hyperparathyroidism. As described later, a calcium mimic that stimulates the CaSR is a promising new therapy for hyperparathyroidism. Therapy of hypercalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain Ca\textsuperscript{2+} levels within an acceptable range.

HYPOCALCEMIA AND OTHER THERAPEUTIC USES OF CALCIUM

Hypoparathyroidism is treated primarily with vitamin D and dietary supplementation with Ca\textsuperscript{2+} as various calcium salts. Calcium chloride (CaCl\textsubscript{2}•2H\textsubscript{2}O) contains 27% Ca\textsuperscript{2+}; it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and must never be injected into tissues. Injections of calcium chloride are accompanied by peripheral vasodilation and a cutaneous burning sensation. The salt usually is given intravenously in a concentration of 10% (equivalent to 1.36 mEq Ca\textsuperscript{2+}/mL). The rate of injection should be slow (not >1 mL/min) to prevent cardiac arrhythmias from a high concentration of Ca\textsuperscript{2+}. The injection may induce a moderate fall in blood pressure owing to vasodilation. Calcium gluceptate injection (a 22% solution; 18 mg or 0.9 mEq of Ca\textsuperscript{2+}/mL) is administered intravenously at a dose of 5-20 mL for the treatment of severe hypocalcemic tetany. Calcium gluconate injection (a 10% solution; 9.3 mg of Ca\textsuperscript{2+}/mL) given intravenously is the treatment of choice for severe hypocalcemic tetany. The intramuscular route should not be employed because abscess formation at the injection site may result.
Calcium carbonate and calcium acetate are used to restrict phosphate absorption in patients with chronic renal failure and oxalate absorption in patients with inflammatory bowel disease. Acute administration of Ca^{2+} may be lifesaving in patients with extreme hyperkalemia (serum K^+ > 7 mEq/L). Calcium gluconate (10-30 mL of a 10% solution) can reverse some of the cardiotoxic effects of hyperkalemia. Additional FDA-approved uses of Ca^{2+} include intravenous treatment for black widow spider envenomation and management of magnesium toxicity.

**THERAPEUTIC USES OF VITAMIN D**

**CLINICAL FORMS OF VITAMIN D.** Calcitriol (1,25-dihydroxycholecalciferol; CALCIJEX, ROCALTROL) is available for oral administration or injection. Several derivatives of vitamin D are also used therapeutically.

Doxercalciferol (1α-hydroxyvitamin D_2, HECTOROL), a prodrug that first must be activated by hepatic 25-hydroxylation, is approved for use in treating secondary hyperparathyroidism. Dihydrotachysterol (DHT, ROXANE) is a reduced form of vitamin D_2. In the liver, DHT is converted to its active form, 25-OH dihydrotachysterol. DHT is effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca^{2+} in hypoparathyroidism. DHT is well absorbed from the GI tract and maximally increases serum Ca^{2+} concentration after 2 weeks of daily administration. The hypercalcemic effects typically persist for 2 weeks but can last for up to 1 month. DHT is available for oral administration in doses ranging from 0.2-1 mg/day (average 0.6 mg/day).

Ergocalciferol (calciferol, DRISDOL) is pure vitamin D_2. It is available for oral, intramuscular, or intravenous administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D–resistant rickets type II, typically in doses of 50,000-200,000 units/day in conjunction with calcium supplements. 1α-Hydroxycholecalciferol (1-OHD_3, alphacalcidol; ONE-ALPHA) is a synthetic vitamin D_3 derivative that is already hydroxylated in the 1α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH)_2D_3. It is equal to calcitriol in assays for stimulation of intestinal absorption of Ca^{2+} and bone mineralization and does not require renal activation. It is available in the U.S. for
experimental purposes.

**ANALOGS OF CALCITRIOL.** Several vitamin D analogs suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

**Calcipotriol** (calcipotriene) is a synthetic derivative of calcitriol with a modified side chain. Calcipotriol is <1% as active as calcitriol in regulating $\text{Ca}^{2+}$ metabolism. Calcipotriol has been studied extensively as a treatment for psoriasis (see Chapter 65).

**Paricalcitol** (1,25-dihydroxy-19-norvitamin D$_2$, ZEMPLAR) is a synthetic calcitriol derivative that lacks the exocyclic C19 and has a vitamin D$_2$ rather than vitamin D$_3$ side chain (see Figure 44–4). It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus. Paricalcitol administered intravenously is FDA-approved for treating secondary hyperparathyroidism in patients with chronic renal failure.

**22-Oxacalcitriol** (1,25-dihydroxy-22-oxavitamin D$_3$, OCT, maxacalcitol, OXAROL) differs from calcitriol only in the substitution of C-22 with an O atom. Oxacalcitriol has a low affinity for vitamin D–binding protein; thus, more of the drug circulates in the free (unbound) form and is metabolized more rapidly than calcitriol with a consequent shorter $t_{1/2}$. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in chronic renal failure.

**THERAPEUTIC INDICATIONS FOR VITAMIN D**

The major therapeutic uses of vitamin D are:

- Prophylaxis and cure of nutritional rickets
- Treatment of metabolic rickets and osteomalacia, particularly in the setting of chronic renal failure
- Treatment of hypoparathyroidism
- Prevention and treatment of osteoporosis
• Dietary supplementation

**NUTRITIONAL RICKETS.** Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The incidence of this condition in the U.S. is now increasing. Infants and children receiving adequate amounts of vitamin D–fortified food do not require additional vitamin D; however, breast-fed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement (see Table 44–1), usually administered with vitamin A, for which purpose a number of balanced vitamin A and D preparations are available. *Because the fetus acquires >85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.* Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca\(^2+\) and phosphate concentrations in ~10 days, with radiographic evidence of healing within ~3 weeks. However, a larger dose of 3000–4000 units daily often is prescribed for more rapid healing, particularly when respiration is compromised by severe thoracic rickets.

**TREATMENT OF OSTEOMALACIA AND RENAL OSTEODYSTROPHY.** Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with chronic renal disease are at risk for developing osteomalacia but also may develop a complex bone disease called *renal osteodystrophy.* In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization that is due to decreased renal synthesis of calcitriol. In renal osteodystrophy, low bone mineral density may be accompanied by high-turnover bone lesions typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease. The therapeutic approach to the patient with renal osteodystrophy depends on its specific type. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended. Calcium-containing phosphate binders along with calcitriol administration may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease and an increased incidence of vascular calcification.

Highly effective non-calcium-containing phosphate binders have been developed. *Sevelamer hydrochloride* (**RENAGEL**), a nonabsorbable phosphate-
binding polymer, effectively lowers serum phosphate concentration in hemodialysis patients. Sevelamer is modestly water soluble and only trace amounts are absorbed from the GI tract. Side effects of sevelamer include vomiting, nausea, diarrhea, and dyspepsia. Sevelamer does not affect the bioavailability of digoxin, warfarin, enalapril, or metoprolol. Lanthanum carbonate (Fosrenol) is a poorly permeable trivalent cation that is useful in treating the hyperphosphatemia associated with renal osteodystrophy.

HYPOPARATHYROIDISM. Vitamin D and its analogs are a mainstay of the therapy of hypoparathyroidism. DHT has a faster onset, shorter duration of action, and a greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent. Calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

PREVENTION AND TREATMENT OF OSTEOPOROSIS. This is described separately, earlier in the chapter.

DIETARY SUPPLEMENTATION. See Table 44–1.

ADVERSE EFFECTS OF VITAMIN D THERAPY

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal absorption of Ca$^{2+}$ and phosphate, along with the potential to mobilize osseous Ca$^{2+}$ and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. Noncalcemic vitamin D analogs provide alternative interventions, although they do not obviate the need to monitor serum Ca$^{2+}$ and phosphorus concentrations. Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support; forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca$^{2+}$ concentration falls to normal, and Ca$^{2+}$ in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless renal damage has been severe.

CALCITONIN
DIAGNOSTIC USE. Calcitonin is a sensitive and specific marker for the presence of medullary thyroid carcinoma (MTC), a neuroendocrine malignancy originating in thyroid parafollicular C cells.

THERAPEUTIC USE. Calcitonin lowers plasma Ca\(^{2+}\) and phosphate concentrations in patients with hypercalcemia. Although calcitonin is effective for up to 6 h in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor downregulation. Use of calcitonin does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents. Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget disease, and in some patients with osteoporosis. For Paget disease, calcitonin generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/day, the dose typically is reduced to 50 units 3 times a week. Side effects of calcitonin include nausea, hand swelling, urticaria, and, rarely, intestinal cramping.

BISPHOSPHONATES

Bisphosphonates are analogs of pyrophosphate that contain 2 phosphonate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate (Figure 44–7). These agents form a 3-dimensional structure capable of chelating divalent cations such as Ca\(^{2+}\) and have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling.

![Pyrophosphate and bisphosphonates](image)
Bisphosphonates are used extensively in conditions characterized by osteoclast-mediated bone resorption, including osteoporosis, steroid-induced osteoporosis, Paget disease, tumor-associated osteolysis, breast and prostate cancer, and hypercalcemia. Calcium supplements, antacids, food or medications containing divalent cations, such as iron, may interfere with intestinal absorption of bisphosphonates. Recent evidence suggests that second- and third-generation bisphosphonates also may be effective anticancer drugs.

Bisphosphonates act by direct inhibition of bone resorption. First-generation bisphosphonates contain minimally modified side chains (medronate, clodronate, and etidronate) or possess a chlorophenol group (tiludronate) and are the least potent agents. Second-generation aminobisphosphonates (e.g., alendronate and pamidronate) contain a nitrogen group in the side chain and are 10-100 times more potent than first-generation compounds. Third-generation bisphosphonates (e.g., risedronate and zoledronate) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents.

Bisphosphonates concentrate at sites of active remodeling, remain in the matrix until the bone is remodeled, and then are released in the acid environment of the resorption lacunae and induce apoptosis in osteoclasts. Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physiochemical effects. The antiresorptive activity apparently involves 2 primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

**AVAILABLE BISPHOSPHONATES.** *Etidronate sodium* (DIDRONEL) is used for treatment of Paget disease. Etidronate has been supplanted largely by pamidronate and zoledronate for treating hypercalcemia. *Pamidronate* (AREDIA; available in the U.S. only for parenteral administration) is approved for management of hypercalcemia and for prevention of bone loss in breast cancer and multiple myeloma, and also is effective in other skeletal disorders. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60-90 mg over 4-24 h. Several newer bisphosphonates have been approved for treatment of Paget disease. These include *tiludronate* (SKELID), *alendronate* (FOSAMAX), and *risedronate* (ACTONEL). Tiludronate standard dosing is 400 mg/day orally for 3 months. Tiludronate in recommended doses does not interfere with bone mineralization, unlike etidronate. Zoledronate
(ZOMETA) is approved for treating Paget disease; administered as a single 5-mg infusion, zoledronate decreases bone turnover markers for 6 months with no loss of therapeutic effect. Zoledronate is widely used for prevention of osteoporosis in prostate and breast cancer patients receiving hormonal therapy. It reduces both vertebral and nonvertebral fractures. A 4-mg formulation is available for intravenous treatment of hypercalcemia of malignancy, multiple myeloma, or bone metastasis resulting from solid tumors. The potent bisphosphonate ibandronate (Boniva) is approved for the prevention and treatment of postmenopausal osteoporosis. The recommended oral dose is 2.5 mg daily or 150 mg once monthly.

For patients in whom oral bisphosphonates cause severe esophageal distress, intravenous zoledronate (Reclast) or ibandronate offer skeletal protection without causing adverse GI effects. For treatment of osteoporosis, ibandronate (3 mg) is given intravenously every 3 months. Zoledronate is the first bisphosphonate to be approved from once-yearly intravenous treatment of osteoporosis (5 mg annually).

ADME. All oral bisphosphonates are very poorly absorbed from the intestine and have remarkably limited bioavailability (<1% [alendronate, risedronate] to 6% [etidronate, tiludronate]). Hence, these drugs should be administered with a full glass of water following an overnight fast and at least 30 min before breakfast. Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton. Bisphosphonates are excreted primarily by the kidneys and are not recommended for patients with a creatinine clearance of <30 mL/min.

ADVERSE EFFECTS. Oral bisphosphonates can cause heartburn, esophageal irritation, or esophagitis. Other GI side effects include abdominal pain and diarrhea. Symptoms often abate when patients take the medication after an overnight fast, with tap or filtered water (not mineral water), and remain upright. Patients with active upper GI disease should not be given oral bisphosphonates. Serious osteonecrosis of the jaw is associated with use of bisphosphonates. Initial parenteral infusion of pamidronate may cause skin flushing, flu-like symptoms, muscle and joint aches and pains, nausea and vomiting, abdominal discomfort and diarrhea (or constipation) but mainly when given in higher concentrations or at faster rates than those recommended. These symptoms are
short lived and generally do not recur with subsequent administration. Zoledronate can cause severe hypocalcemia and has been associated with renal toxicity, deterioration of renal function, and potential renal failure. Infusion of zoledronate should be given over at least 15 min, and the dose should be 4 mg; patients should have standard laboratory and clinical parameters of renal function assessed prior to treatment and periodically after treatment to monitor for deterioration in renal function.

OTHER THERAPEUTIC USES

Postmenopausal Osteoporosis. Much interest is focused on the role of bisphosphonates in the treatment of osteoporosis. Clinical trials show that treatment is associated with increased bone mineral density and protection against fracture.

Cancer. Bisphosphonates may also have direct antitumor action by inhibiting oncogene activation and through their anti-angiogenic effects. Randomized clinical trials of bisphosphonates in patients with breast cancer suggest that these agents delay or prevent development of metastases as a component of endocrine adjuvant therapy.

PARATHYROID HORMONE

Continuous administration of PTH or high-circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, intermittent PTH administration promotes bone growth. Synthetic human 34-amino-acid amino-terminal PTH fragment [hPTH(1-34), teriparatide (FORTEO)] is approved for use in treating severe osteoporosis.

ADME. Pharmacokinetics and systemic actions of teriparatide on mineral metabolism are the same as for PTH. Teriparatide is administered by once-daily subcutaneous injection of 20 µg into the thigh or abdomen. Serum PTH concentrations peak at 30 min after the injection and are undetectable within 3 h, whereas the serum Ca\(^{2+}\) concentration peaks at 4-6 h after administration. Teriparatide bioavailability averages 95%; clearance averages 62 L/h in women and 94 L/h in men. The serum \(t_{1/2}\) of teriparatide is \(~1\) h when administered
subcutaneously versus 5 min when administered intravenously. The elimination of PTH(1-34) and full-length PTH proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion.

**CLINICAL EFFECTS.** In postmenopausal women with osteoporosis, teriparatide increases BMD and reduces the risk of vertebral and nonvertebral fractures. Candidates for teriparatide treatment include women who have a history of osteoporotic fracture, who have multiple risk factors for fracture, or who failed or are intolerant of previous osteoporosis therapy. Men with primary or hypogonadal osteoporosis are also candidates for treatment with teriparatide.

**ADVERSE EFFECTS.** Adverse effects include exacerbation of nephrolithiasis and elevation of serum uric acid levels. Teriparatide use should be limited to no more than 2 years and should not be used in patients who are at increased baseline risk for osteosarcoma (including those with Paget disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). A tumor registry-based analysis of the occurrence of osteosarcoma in teriparatide-treated patients is ongoing; cases of osteosarcoma associated with the drug should be reported to the FDA.

**CALCIUM SENSOR MIMETICS: CINACALCET**

*Calcimimetics* are drugs that mimic the stimulatory effect of Ca\(^{2+}\) on the calcium-sensing receptor (CaSR) to inhibit PTH secretion by the parathyroid glands. By enhancing the sensitivity of the CaSR to extracellular Ca\(^{2+}\), calcimimetics lower the concentration of Ca\(^{2+}\) at which PTH secretion is suppressed. Inorganic di- and trivalent cations, along with polycations such as spermine, aminoglycosides (e.g., streptomycin, gentamicin, and neomycin) and polybasic amino acids (e.g., polylysine) are full agonists and are referred to a *type I calcimimetics*. Phenylalkylamine derivatives that are allosteric CaSR modulators that require the presence of Ca\(^{2+}\) or other full agonists to enhance the sensitivity of activation without altering the maximal response are designated *type II calcimimetics*. Cinacalcet (*Sensipar*) is approved for the treatment of secondary hyperparathyroidism. Cinacalcet lowers serum PTH levels in patients with normal or reduced renal function.
ADME. Cinacalcet exhibits first-order absorption, with maximal serum concentrations achieved 2-6 h after oral administration. Maximal effects on serum PTH occur 2–4 h after administration. Cinacalcet has a $t_{1/2}$ of 30-40 h and is eliminated primarily by renal excretion (85%); the drug is also metabolized by multiple hepatic cytochromes, including CYPs 3A4, 2D6, and 1A2.

Cinacalcet is available in 30-, 60-, and 90-mg tablets. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis is 30 mg once daily, with a maximum of 180 mg/day. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg 4 times daily. The starting dose is titrated upward every 2-4 weeks to maintain the PTH level between 150 and 300 pg/mL (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

ADVERSE REACTIONS. The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum [Ca$^{2+}$] is <8.4 mg/dL; serum Ca$^{2+}$ and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy or after changing dosage. Seizure threshold is lowered by significant reductions in serum Ca$^{2+}$, so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is <100 pg/mL, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL.

DRUG INTERACTIONS. Potential drug interactions can be anticipated with drugs that interfere with Ca$^{2+}$ homeostasis or that hinder cinacalcet absorption. Potentially interfering drugs may include vitamin D analogs, phosphate binders,
bisphosphonates, calcitonin, glucocorticoids, gallium, and cisplatin. Caution is recommended when cinacalcet is coadministered with inhibitors of CYP3A4 (e.g., ketoconazole, erythromycin, or itraconazole), CYP2D6 (many β adrenergic receptor blockers, flecainide, vinblastine, and most tricyclic antidepressants), and many other drugs.

INTEGRATED APPROACH TO PREVENTION AND TREATMENT OF OSTEOPOROSIS

Osteoporosis is a major and growing public health problem in developed nations. Approximately 50% women and 25% of men >50 years of age will experience an osteoporosis-related fracture. However, important reductions in fracture risk can be achieved with appropriate lifelong attention to prevention (muscle strengthening exercise; avoiding smoking and excessive alcohol use). Attention to nutritional status (i.e., increased dietary calcium or calcium and/or vitamin D supplements) also may be required. Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Because bone remodeling is a coupled process, antiresorptive drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD.

Pharmacological treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. Antiresorptive drugs such as the bisphosphonates, estrogen, or the selective estrogen receptor modulator (SERM) raloxifene, and, to some extent, calcitonin inhibit osteoclast-mediated bone loss, thereby reducing bone turnover. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of hormone-replacement therapy (HRT) have mandated a major reexamination on treatment options (see later and Chapter 40). In addition to antiresorptive agents, the FDA has approved the biologically active PTH fragment PTH(1–34) (teriparatide, FORTEO) for use in treating postmenopausal women with osteoporosis and to increase bone mass in men with primary or hypogonadal osteoporosis.
ANTIRESORPTIVE AGENTS

Bisphosphonates. Bisphosphonates are the most frequently used drugs for the prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates alendronate and risedronate have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization. Alendronate (FOSAMAX), risedronate (ACTONEL), and ibandronate (BONIVA) are approved for prevention and treatment of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis.

Denosumab. RANKL binds to its cognate receptor RANK on the surface of precursor and mature osteoclasts, and stimulates these cells to mature and resorb bone. OPG, which competes with RANK for binding to RANKL, is the physiological inhibitor of RANKL. Denosumab is an investigational human monoclonal antibody that binds with high affinity to RANKL, mimicking the effect of OPG, and thereby reducing the binding of RANKL to RANK. Denosumab blocks osteoclast formation and activation. It increases BMD and decreases bone turnover markers when given subcutaneously, 60 mg once every 6 months.

Selective Estradiol Receptor Modulators (SERMs). Raloxifene (EVISTA) acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an anti-estrogen on the breast (see Chapter 40). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and has been shown to reduce the risk of vertebral compression fracture. Raloxifene is approved for both the prevention and treatment of osteoporosis. The major drawback of raloxifene is that it can worsen vasomotor symptoms.

Estrogen. Postmenopausal status or estrogen deficiency at any age significantly increases a patient’s risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (see Chapter 40). Since the outcome of the Women’s Health Initiative (WHI) studies has indicated significantly increased risks of heart disease and breast cancer, the consensus now is to reserve HRT only for the short-term relief of vasomotor symptoms associated with menopause.

Calcium. The rationale for using supplemental calcium to protect bone varies
with time of life. For preteens and adolescents, adequate substrate calcium is required for bone accretion. Higher calcium intake during the third decade of life is positively related to the final phase of bone acquisition. There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. In elderly subjects, supplemental calcium suppresses bone turnover and improves BMD.

**Vitamin D and Its Analogs.** Modest supplementation with vitamin D (400-800 IU/day) may improve intestinal Ca$^{2+}$ absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. A prospective study found that neither dietary calcium nor vitamin D intake was of major importance for the primary prevention of osteoporotic fractures in women. However, supplemental vitamin D in combination with calcium reduced fracture incidence in multiple trials. The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Calcitriol and the polar vitamin D metabolite 1e-hydroxycholecalciferol are used frequently in Japan and other countries, but experience in the U.S. has been mixed.

**Calcitonin.** Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis, most prominently in patients with high intrinsic rates of bone turnover. Calcitonin nasal spray (200 units/day) reportedly reduces the incidence of vertebral compression fractures by ~40% in osteoporotic women.

**Thiazide Diuretics.** Although not strictly antiresorptive, thiazides reduce urinary Ca$^{2+}$ excretion and constrain bone loss in patients with hypercalciuria. Hydrochlorothiazide, 25 mg once or twice daily, may reduce urinary Ca$^{2+}$ excretion substantially. Effective doses of thiazides for reducing urinary Ca$^{2+}$ excretion generally are lower than those necessary for blood pressure control (see Chapter 25).

**Teriparatide.** Teriparatide (Forteo) is the only agent currently available that increases new bone formation. It is FDA-approved for treatment of osteoporosis for up to 2 years in both men and postmenopausal women at high risk for fractures. Teriparatide significantly decreased the incidence of vertebral (4-5% vs. 14%) and nonvertebral fractures (3% vs. 6%) compared to placebo in a prospective, randomized control study. Teriparatide increases predominantly
trabecular bone at the lumbar spine and femoral neck; it has less significant effects at cortical sites. Teriparatide is approved at the 20 µg dose, administered once daily by subcutaneous injection in the thigh or abdominal wall. The most common adverse effects associated with teriparatide include injection-site pain, nausea, headaches, leg cramps, and dizziness.

**COMBINATION THERAPIES**

**OSTEOPOROSIS.** Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted that therapy combining the 2 would enhance the effect on BMD more than treatment with either one alone. However, addition of alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men. Sequential treatment with PTH(1-84) followed by alendronate increased vertebral BMD to a greater degree than alendronate or estrogen alone.

**PAGET DISEASE.** Although most patients with Paget disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective. Optimal therapy for Paget disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate seems to exhibit greater response rates and a longer median duration of complete response. Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects.

**FLUORIDE**

*Fluoride* is discussed because of its effects on dentition and bone and
its toxic properties.

**ADME.** Fluoride is obtained from the ingestion of plants and water, with most absorption taking place in the intestine. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure. Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone. The kidneys are the major site of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions.

**PHARMACOLOGICAL ACTIONS AND USES.** Because it is concentrated in the bone, the radionuclide \(^{18}\text{F}\) has been used in skeletal imaging. Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts. However, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or others. Fluoride can inhibit several enzyme systems and diminish tissue respiration and anaerobic glycolysis.

**Fluoride and Dental Caries.** Supplementation of water fluoride content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth. There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of fluoride solutions by dental personnel appears to be effective on newly erupted teeth and can reduce the incidence of caries by 30-40%. Dietary fluoride supplements should be considered for children <12 years of age whose drinking water contains <0.7 ppm fluoride. Adequate incorporation of fluoride into teeth hardens the outer layers of enamel and increases resistance to demineralization. The fluoride salts usually employed in dentifrices are sodium fluoride and stannous fluoride. Sodium fluoride also is available in a variety of preparations for oral and topical use.

Regulation of the fluoride concentration of community water supplies periodically encounters vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly
between communities with fluoridated and nonfluoridated water.

**ACUTE POISONING.** Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the central nervous system consistent with the Ca\(^{2+}\)-binding effect of fluoride and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for humans is ~5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with lime water (0.15% calcium hydroxide solution) or other Ca\(^{2+}\) salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

**CHRONIC POISONING.** In humans, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described >60 years ago. In very mild mottling, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown- to black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Mottling is one of the first visible signs of excess fluoride intake during childhood. Continuous use of water containing ~1 ppm of fluoride may result in very mild mottling in 10% of children; at 4-6 ppm the incidence approaches 100%, with a marked increase in severity. Severe dental fluorosis formerly occurred in regions where local water supplies had a very high fluoride content (e.g., Pompeii, Italy, and Pike’s Peak, Colorado). Current regulations in the U.S.
require lowering the fluoride content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a fluoride content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time.
Section VI
Drugs Affecting Gastrointestinal Function
The treatment and prevention of acid-related disorders are accomplished by decreasing gastric acidity and enhancing mucosal defense. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases has stimulated new approaches to prevention and therapy.

**PHYSIOLOGY OF GASTRIC SECRETION**

Gastric acid secretion is a complex and continuous process: neuronal (acetylcholine, ACh), paracrine (histamine), and endocrine (gastrin) factors all regulate the secretion of H⁺ by parietal cells (Figure 45–1).
**Figure 45–1** Pharmacologist’s view of gastric secretion and its regulation: the basis for therapy of acid-peptic disorders. Shown are the interactions among an enterochromaffin-like (ECL) cell that secretes histamine, a ganglion cell of the enteric nervous system (ENS), a parietal cell that secretes acid, and a superficial epithelial cell that secretes mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (–). 1 and 3 indicate possible inputs from postganglionic cholinergic fibers; 2 shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include acetylcholine (ACh), muscarinic (M), and nicotinic (N) receptors; gastrin, cholecystokinin receptor 2 (CCK\(_2\)); histamine (HIST), H\(_2\) receptor; and prostaglandin E\(_2\) (PGE\(_2\)), EP\(_3\) receptor. A red indicates targets of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in red are drugs used to treat acid-peptic disorders. NSAIDs are nonsteroidal anti-inflammatory drugs, which can induce ulcers via inhibition of cyclooxygenase.

Specific receptors (M\(_3\), H\(_2\), and CCK\(_2\), respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach. Some of these receptors are also present on enterochromaffin-like (ECL) cells, where they regulate the release of histamine. The H\(_2\) receptor is a GPCR that activates the G\(_s\)–adenylyl cyclase–cyclic AMP–PKA pathway. ACh and gastrin signal through GPCRs that couple to the G\(_q\)–PLC–IP\(_3\)–Ca\(_{2+}\) pathway in parietal cells. In parietal cells, the cyclic AMP and the Ca\(_{2+}\)-dependent pathways activate H\(^+\), K\(^+\)-ATPase (the proton pump), which exchanges H\(^+\) and K\(^+\) across the parietal cell membrane. This pump generates the largest ion gradient known in vertebrates, with an intracellular pH of ~7.3 and an intracanalicular pH of ~0.8.

ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M\(_3\) receptors on the basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the enteric nervous system via ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the “cephalic” phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the ECL cells and of gastrin from G cells. ECL cells, the source of gastric histamine, usually are in close proximity to parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H\(_2\) receptors to stimulate gastric acid secretion.
Gastrin, produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin release, including CNS activation, local distention, and chemical components of the gastric contents. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role. Somatostatin (SST), which is produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to <3 stimulates SST release, which in turn suppresses gastrin release in a negative feedback loop. SST-producing cells are decreased in patients with *H. pylori* infection, and the consequent reduction of SST’s inhibitory effect may contribute to excess gastrin production.

**GASTRIC DEFENSES AGAINST ACID.** The extremely high concentration of H⁺ in the gastric lumen requires robust defense mechanisms to protect the esophagus and the stomach. The primary esophageal defense is the lower esophageal sphincter, which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms that require adequate mucosal blood flow. One key defense is the secretion of a mucus layer that helps to protect gastric epithelial cells by trapping secreted bicarbonate at the cell surface. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by prostaglandins E₂ and I₂, which also directly inhibit gastric acid secretion by parietal cells. Thus, drugs that inhibit prostaglandin formation (e.g., NSAIDs, ethanol) decrease mucus secretion and predispose to the development of acid-peptic disease. Figure 45–1 outlines the rationale and pharmacological basis for the therapy of acid-peptic diseases. The proton pump inhibitors are used most commonly, followed by the histamine H₂ receptor antagonists.

**PROTON PUMP INHIBITORS**

The most potent suppressors of gastric acid secretion are inhibitors of the gastric H⁺, K⁺-ATPase (proton pump) (Figure 45–2). These drugs diminish the daily production of acid (basal and stimulated) by 80-95%.

*Figure 45–2 Activation of prodrug proton pump inhibitor.* Omeprazole is
converted to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulphydryl groups in the proton pump, thereby irreversibly inhibiting its activity. Lansoprazole, rabeprazole, and pantoprazole undergo analogous conversions.

**CHEMISTRY; MECHANISM OF ACTION; PHARMACOLOGY.** Six proton pump inhibitors are available for clinical use: *omeprazole* (Prilosec, others) and its S-isomer, *esomeprazole* (Nexium), *lansoprazole* (Prevacid) and its R-enantiomer, *dexlansoprazole* (KapideX), *rabeprazole* (Aciphex), and *pantoprazole* (Protonix, others). All proton pump inhibitors have equivalent efficacy at comparable doses.

Proton pump inhibitors (PPIs) are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (see Figure 45–2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with
sulfhydryl groups of cysteines in the H⁺, K⁺-ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24- to 48-h) suppression of acid secretion, despite the much shorter plasma $t_{1/2}$ ~ 0.5-2 h of the parent compounds.

To prevent degradation of PPIs by acid in the gastric lumen and improve oral bioavailability, oral dosage forms are supplied in different formulations:

- Enteric-coated drugs contained inside gelatin capsules (omeprazole, dexlansoprazole, esomeprazole, and lansoprazole)
- Enteric-coated granules supplied as a powder for suspension (lansoprazole)
- Enteric-coated tablets (pantoprazole, rabeprazole, and omeprazole)
- Powdered omeprazole combined with sodium bicarbonate (ZGERID) contained in capsules and formulated for oral suspension

Patients for whom the oral route of administration is not available can be treated parenterally with esomeprazole, pantoprazole, or lansoprazole. The FDA-approved dose of intravenous pantoprazole for gastroesophageal reflux disease is 40 mg daily for up to 10 days. Higher doses (e.g., 160-240 mg in divided doses) are used to manage hypersecretory conditions such as the Zollinger-Ellison syndrome.

ADME. Because an acidic pH in the parietal cell acid canaliculi is required for drug activation and food stimulates acid production, these drugs ideally should be given ~30 min before meals. Concurrent administration of food may reduce somewhat the rate of absorption of PPIs. Once in the small bowel, PPIs are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Asians are more likely than whites or African Americans to have the CYP2C19 genotype that correlates with slow metabolism of PPIs (23% vs. 3%, respectively), which may contribute to heightened efficacy and/or toxicity in this ethnic group.

Because not all pumps and all parietal cells are active simultaneously, maximal suppression of acid secretion requires several doses of the PPIs. For example, it may take 2-5 days of therapy with once-daily dosing to achieve the 70% inhibition of proton pumps that is seen at steady state. More frequent initial
dosing (e.g., twice daily) will reduce the time to achieve full inhibition but is not proven to improve patient outcome. The resulting proton pump inhibition is irreversible; thus, acid secretion is suppressed for 24-48 h, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells. Chronic renal failure does not lead to drug accumulation with once-a-day dosing of the PPIs. Hepatic disease substantially reduces the clearance of esomeprazole and lansoprazole.

**ADVERSE EFFECTS AND DRUG INTERACTIONS.** PPIs generally cause remarkably few adverse effects. The most common side effects are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, and skin rashes also have been reported. As noted earlier, PPIs are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. PPIs have been observed to interact with warfarin (esomeprazole, lansoprazole, omeprazole, and rabeprazole), diazepam (esomeprazole and omeprazole), and cyclosporine (omeprazole and rabeprazole). Among the PPIs, only omeprazole inhibits CYP2C19 (thereby decreasing the clearance of disulfiram, phenytoin, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of imipramine, several antipsychotic drugs, tacrine, and theophylline). There is emerging evidence that omeprazole can inhibit conversion of clopidogrel (at the level of CYP2C19) to the active anticoagulating form. Pantoprazole is less likely to result in this interaction; concurrent use of clopidogrel and PPIs (mainly pantoprazole) significantly reduces GI bleeding without increasing adverse cardiac events (see Chapter 30).

Chronic treatment with omeprazole decreases the absorption of vitamin B₁₂, but the clinical relevance of this effect is not clear. Loss of gastric acidity also may affect the bioavailability of such drugs as ketoconazole, ampicillin esters, and iron salts. Chronic use of PPIs has been reported to be associated with an increased risk of bone fracture and with increased susceptibility to certain infections (e.g., hospital-acquired pneumonia, community-acquired *Clostridium difficile*). Hypergastrinemia is more frequent and more severe with PPIs than with H₂ receptor antagonists. This hypergastrinemia may predispose to rebound hypersecretion of gastric acid upon discontinuation of therapy and also may promote the growth of GI tumors.
**Therapeutic Uses.** Prescription PPIs are used to promote healing of gastric and duodenal ulcers and to treat gastroesophageal reflux disease (GERD), including erosive esophagitis, which is either complicated or unresponsive to treatment with H₂ receptor antagonists. Over-the-counter omeprazole is approved for the self-treatment of heartburn. PPIs also are the mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. Lansoprazole and esomeprazole are approved for treatment and prevention of recurrence of NSAID-associated gastric ulcers in patients who continue NSAID use. It is not clear if PPIs affect the susceptibility to NSAID-induced damage and bleeding in the small and large intestine. All PPIs are approved for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections. Therapeutic applications of PPIs are further discussed later under “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

**H₂ RECEPTOR ANTAGONISTS**

The H₂ receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂ receptors on the basolateral membrane of parietal cells.

![Histamine and Ranitidine](image)

Four different H₂ receptor antagonists are available in the U.S.: *cimetidine* (Tagamet, others), *ranitidine* (Zantac, others), *famotidine* (Peptic, others), and *nizatidine* (Axid, others). These drugs are less potent than PPIs but still suppress 24-h gastric acid secretion by ~70%. Because the most important determinant of duodenal ulcer healing is the level of nocturnal acidity, evening dosing of H₂ receptor antagonists is adequate therapy in most instances. All 4 H₂ receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available.

**ADME.** The H₂ receptor antagonists are rapidly absorbed after oral
administration, with peak serum concentrations within 1-3 h. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4-5 h (cimetidine), 6-8 h (ranitidine), or 10-12 h (famotidine). Only a small percentage of H₂ receptor antagonists are protein bound. Small amounts (from <10% to ~35%) of these drugs undergo metabolism in the liver, but liver disease per se is not an indication for dose adjustment. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce drug doses in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of these drugs.

**ADVERSE REACTIONS AND DRUG INTERACTIONS.** H₂ receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects. Side effects are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Several reports have associated H₂ receptor antagonists with various blood dyscrasias, including thrombocytopenia. H₂ receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these agents, caution is warranted when they are used in pregnancy.

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H₂ receptor antagonists (see “Antacids” section). Drug interactions with H₂ receptor antagonists occur mainly with cimetidine, and its use has decreased markedly. Cimetidine inhibits CYPs (e.g., CYP1A2, CYP2C9, and CYP2D6), and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. Ranitidine also interacts with hepatic CYPs, but with an affinity of only 10% of that of cimetidine. Famotidine and nizatidine are even safer in this regard. Slight increases in blood-alcohol concentration may result from concomitant use of H₂ receptor antagonists.

**Therapeutic Uses.** The major therapeutic indications for H₂ receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated
GERD, and to prevent the occurrence of stress ulcers. For more information about the therapeutic applications of H₂ receptor antagonists, see below, “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

TOLERANCE AND REBOUND WITH ACID-SUPPRESING MEDICATIONS

Tolerance to the acid-suppressing effects of H₂ receptor antagonists may develop within 3 days of starting treatment and may be resistant to increased doses of the medications. Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells. PPIs do not cause this phenomenon; however, rebound increases in gastric acidity can occur when either of these drug classes is discontinued.

AGENTS THAT ENHANCE MUCOSAL DEFENSE

PROSTAGLANDIN ANALOGS: MISOPROSTOL

Prostaglandin E₂ (PGE₂) and prostacyclin (PGI₂) are the major prostaglandins synthesized by the gastric mucosa. Contrary to their cyclic AMP-elevating effects on many cells via EP₂ and EP₄ receptors, these prostanoids bind to the EP₃ receptor on parietal cells and stimulate the Gᵢ pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE₂ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Acid suppression appears to be the most important effect clinically.

Because NSAIDs diminish prostaglandin formation by inhibiting cyclooxygenase, synthetic prostaglandin analogs offer a logical approach to counteract NSAID-induced damage. Misoprostol (15-deoxy-16-hydroxy-16-methyl-PGE₁; CYTOTEC, others) is a synthetic analog of PGE₁ that is FDA-approved to prevent NSAID-induced mucosal injury. The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100-200 μg significantly inhibit basal acid secretion (up to 85-95% inhibition) or
food-stimulated acid secretion (up to 75-85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 μg 4 times a day.

**ADME.** Misoprostol is rarely used because of its side effects. The drug is rapidly absorbed after oral administration and is rapidly and extensively de-esterified to form misoprostol acid, the principal and active metabolite of the drug. A single dose inhibits acid production within 30 min; the therapeutic effect peaks at 60-90 min and lasts for up to 3 h. Food and antacids decrease the rate of misoprostol absorption. The free acid is excreted mainly in the urine, with an elimination $t_{1/2}$ of 20-40 min.

**ADVERSE EFFECTS.** Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take misoprostol. Apparently dose related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe cases may necessitate drug discontinuation. *Misoprostol can cause clinical exacerbations of inflammatory bowel disease* (see Chapter 47). *Misoprostol also is contraindicated during pregnancy* because it can increase uterine contractility.

**SUCRALFATE**

In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. Sucralfate *(CARAFATE, others)* consists of the octasulfate of sucrose to which Al(OH)$_3$ has been added. In an acid environment (pH <4), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 h after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, sucralfate may have additional cytoprotective effects, including stimulation of local production of prostaglandins and EGF. Sucralfate also binds bile salts; thus, some clinicians use sucralfate to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

**Therapeutic Uses.** The use of sucralfate to treat peptic acid disease has diminished in recent years. Nevertheless, because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients,
sucralfate may offer an advantage over PPIs and H₂ receptor antagonists for the prophylaxis of stress ulcers. Sucralfate also has been used in conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, sucralfate also has been used for radiation proctitis and solitary rectal ulcers. Because it is activated by acid, sucralfate should be taken on an empty stomach 1 h before meals. The use of antacids within 30 min of a dose of sucralfate should be avoided. The dose of sucralfate is 1 g 4 times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy).

**ADVERSE EFFECTS.** The most common side effect of sucralfate is constipation (~2%). Sucralfate should be avoided in patients with renal failure who are at risk for aluminum overload. Likewise, aluminum-containing antacids should not be combined with sucralfate in these patients. Sucralfate forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetidine, ketoconazole, and fluoroquinolone antibiotics. Sucralfate therefore should be taken at least 2 h after the administration of other drugs. The “sticky” nature of the viscous gel produced by sucralfate in the stomach also may be responsible for the development of bezoars in some patients.

**ANTACIDS**

There are more effective and persistent agents than antacids, but their price, accessibility, and rapid action make them popular with consumers. Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. CaCO₃ rapidly and effectively neutralizes gastric H⁺, but the release of CO₂ from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration. Combinations of Mg²⁺ (rapidly reacting) and Al³⁺ (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. Magaldrate, a hydroxymagnesium aluminate complex, is converted rapidly in gastric acid to
Mg(OH)$_2$ and Al(OH)$_3$, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of magnesium and aluminum theoretically counteract the adverse effects of each other on the bowel (Al$^{3+}$ can relax gastric smooth muscle, producing delayed gastric emptying and constipation; Mg$^{2+}$ exerts the opposite effects), such balance is not always achieved in practice. Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with aspirin, that are marketed for “acid indigestion” are potentially unsafe in patients predisposed to gastroduodenal ulcers, and should not be used.

For uncomplicated ulcers, antacids are given orally 1 and 3 h after meals and at bedtime. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30-60 min. In general, antacids should be administered in suspension form because this probably has a greater neutralizing capacity than powder or tablet dosage forms. Antacids are cleared from the empty stomach in ~30 min. However, the presence of food is sufficient to elevate gastric pH to ~5 for ~1 h and to prolong the neutralizing effects of antacids for ~2-3 h.

Antacids vary in the extent to which they are absorbed, and hence in their systemic effects. In general, most antacids can elevate urinary pH by ~1 pH unit. Antacids that contain Al$^{3+}$, Ca$^{2+}$, or Mg$^{2+}$ are absorbed less completely than are those that contain NaHCO$_3$. With renal insufficiency, absorbed Al$^{3+}$ can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca$^{2+}$ is absorbed, causing a transient hypercalcemia. The hypercalcemia from as little as 3-4 g of CaCO$_3$ per day can be problematic in patients with uremia. In the past, when large doses of NaHCO$_3$ and CaCO$_3$ were administered commonly with milk or cream for the management of peptic ulcer, the milk-alkali syndrome (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca$^{2+}$ (five to forty 500-mg tablets per day of calcium carbonate) taken with milk.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, allopurinol, and imidazole antifungals, by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al$^{3+}$ and Mg$^{2+}$ antacids also are notable for their propensity to chelate other drugs present
in the GI tract and thereby decrease their absorption. Most interactions can be avoided by taking antacids 2 h before or after ingestion of other drugs.

**OTHER ACID SUPPRESSANTS AND CYTOPROTECTANTS.** The M₁ muscarinic receptor antagonists *pirenzepine* and *telenzepine* (see Chapter 9) can reduce basal acid production by 40-50%. The ACh receptor on the parietal cell itself is of the M₃ subtype, and these drugs are believed to suppress neural stimulation of acid production via actions on M₁ receptors of intramural ganglia (see Figure 45–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (pirenzepine), they rarely are used today.

*Rebamipide* is used for ulcer therapy in parts of Asia. Its cytoprotective effects are exerted by increasing prostaglandin generation in gastric mucosa and by scavenging reactive oxygen species. *Ecabet* (GASTROM), which appears to increase the formation of PGE₂ and PGI₂, also is used for ulcer therapy, mostly in Japan. *Carbenoxolone*, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Unfortunately, carbenoxolone inhibits the type I isozyme of 11β-hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (see Chapter 42). *Bismuth compounds* (see Chapter 46) are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects.

**SPECIFIC ACID-PePTIC DISORDERS AND THERAPEUTIC STRATEGIES**

**GASTROESOPHAGEAL REFLUX DISEASE**

Although most cases of heartburn or gastroesophageal regurgitation follow a relatively benign course, these symptoms, often referred to as GERD, can be associated with severe erosive esophagitis; stricture
formation and Barrett metaplasia (replacement of squamous by intestinal columnar epithelium), in turn, is associated with a small but significant risk of adenocarcinoma. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis. PPIs clearly are more effective than H₂ receptor antagonists in achieving these goals (see Figure 45–3).

**Figure 45–3** Comparative success of therapy with proton pump inhibitors and H₂ receptor antagonists. Data show the effects of a proton pump inhibitor (given once daily) and an H₂ receptor antagonist (given twice daily) in elevating gastric pH to the target ranges (i.e., pH 3 for duodenal ulcer, pH 4 for GERD, and pH 5 for antibiotic eradication of *H. pylori*).

In general, the optimal dose for each patient is determined based on symptom control. Strictures associated with GERD also respond better to PPIs than to H₂ receptor antagonists. One of the complications of GERD, Barrett esophagus, appears to be more refractory to therapy because neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia.

Regimens for the treatment of GERD with PPIs and histamine H₂ receptor antagonists are listed in Table 45–1. Although some patients with mild GERD symptoms may be managed by nocturnal doses of H₂ receptor antagonists,
twice-daily dosing usually is required. Antacids are recommended only for the patient with mild, infrequent episodes of heartburn. In general, prokinetic agents (see Chapter 46) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications.

**SEVERE SYMPTOMS AND NOCTURNAL ACID BREAKTHROUGH.** In patients with severe symptoms or extraintestinal manifestations of GERD, twice-daily dosing with a PPI may be needed. However, it is difficult if not impossible to render patients achlorhydric and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called *nocturnal acid breakthrough*, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion remains to be established. Patients with continuing symptoms on twice-daily PPIs are often treated by adding an H₂ receptor antagonist at night. Although this can further suppress acid production, the effect is short lived, probably due to the development of tolerance.

**THERAPY FOR EXTRAINTESTINAL MANIFESTATIONS OF GERD.** Acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other ear, nose, and
throat conditions. PPIs (at higher doses) have been used with some success in certain patients with these disorders.

GERD AND PREGNANCY. Heartburn is estimated to occur in 30-50% of pregnancies, with an incidence approaching 80% in some populations. In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of data for the most commonly used drugs. In general, most drugs used to treat GERD fall in FDA Category B, with the exception of omeprazole (FDA Category C). Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H₂ receptor antagonists can be used, with ranitidine having the most established track record in this setting. PPIs are reserved for women with intractable symptoms or complicated reflux disease. In these situations, lansoprazole is considered the preferred choice.

PEPTIC ULCER DISEASE

Peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, prostaglandin, NO, and other peptides and growth factors) and injurious factors (acid and pepsin). On average, patients with duodenal ulcers produce more acid than do control subjects, particularly at night (basal secretion). Although patients with gastric ulcers have normal or even diminished acid production, ulcers rarely if ever occur in the complete absence of acid. Presumably, a weakened mucosal defense and reduced bicarbonate production contribute to the injury from the relatively lower levels of acid in these patients. H. pylori and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with H. pylori infection of the stomach. This infection may lead to impaired production of somatostatin by D cells and, in time, decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate
production.

Table 45–2 summarizes current recommendations for drug therapy of gastroduodenal ulcers. PPIs relieve symptoms of duodenal ulcers and promote healing more rapidly than do H$_2$ receptor antagonists, although both classes of drugs are very effective in this setting (see Figure 45–3). Peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation that H. pylori plays a major etiopathogenic role in the majority of peptic ulcers, prevention of relapse is focused on eliminating this organism from the stomach. Intravenous pantoprazole or lansoprazole is the preferred therapy in patients with acute bleeding ulcers. The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

*DU, duodenal ulcer; GU, gastric ulcer.

NSAIDs also are very frequently associated with peptic ulcers and bleeding. The effects of these drugs are mediated systemically; in the stomach, NSAIDS
suppress mucosal prostaglandin synthesis (particularly PGE\(_2\) and PGI\(_2\)) and thereby reduce mucous production and cytoprotection (see Figure 45–1). Thus, minimizing NSAID use is an important adjunct to gastroduodenal ulcer therapy.

**TREATMENT OF HELICOBACTER PYLORI INFECTION.** H. pylori, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma. Because of the critical role of H. pylori in the pathogenesis of peptic ulcers, to eradicate this infection is standard care in patients with gastric or duodenal ulcers. Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of H. pylori also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment.

Five important considerations influence the selection of an eradication regimen (Table 45–3).

- Single-antibiotic regimens are ineffective in eradicating H. pylori infection and lead to microbial resistance. Combination therapy with 2 or 3 antibiotics (plus acid-suppressive therapy) is associated with the highest rate of H. pylori eradication.
- A PPI or H\(_2\) receptor antagonist significantly enhances the effectiveness of
*H. pylori* antibiotic regimens containing amoxicillin or clarithromycin (see Figure 45–3).

- A regimen of 10-14 days of treatment appears to be better than shorter treatment regimens.
- Poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens, and to the inconvenience of 3 or 4 drug regimens administered several times per day. Packaging that combines the daily doses into 1 convenient unit is available and may improve patient compliance.
- The emergence of resistance to clarithromycin and metronidazole increasingly is recognized as an important factor in the failure to eradicate *H. pylori*. In the presence of in vitro evidence of resistance to metronidazole, amoxicillin should be used instead. In areas with a high frequency of resistance to clarithromycin and metronidazole, a 14-day quadruple-drug regimen (3 antibiotics combined with a PPI) generally is effective therapy.

**NSAID-RELATED ULCERS.** Chronic NSAID users have a 2-4% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. Healing of ulcers despite continued NSAID use is possible with the use of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (e.g., ≤8 weeks). PPIs are superior to H$_2$ receptor antagonists and misoprostol in promoting the healing of active ulcers, and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration.

**STRESS-RELATED ULCERS.** Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care. The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H$_2$ receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of PPIs are available, it is likely that they will prove to be equally beneficial. *However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu.* In this
setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia.

**ZOLLINGER-ELLISON SYNDROME.** Patients with this syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I. This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. PPIs are the drugs of choice, usually given at twice the routine dosage for peptic ulcers with the therapeutic goal of reducing acid secretion to 1-10 mmol/h.

**NONULCER DYSPEPSIA.** This term refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration. It may be associated with gastritis (with or without *H. pylori*) or with NSAID use, but the pathogenesis of this syndrome remains controversial.
GASTROINTESTINAL MOTILITY

The gastrointestinal (GI) tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle and epithelium, local nerves of the enteric nervous system (ENS), the autonomic nervous system (ANS), and circulating hormones. Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 46–1).

**Figure 46–1** The neuronal network that initiates and generates the peristaltic response. Mucosal stimulation leads to release of serotonin by enterochromaffin cells (8), which excites the intrinsic primary afferent neurons (1), which then communicate with ascending (2) and descending (3) interneurons in the local
reflex pathways. The reflex results in contraction at the oral end via the excitatory motor neuron (6) and aboral relaxation via the inhibitory motor neuron (5). The migratory myoelectric complex (see text) is shown here as being conducted by a different chain of interneurons (4). Another intrinsic primary afferent neuron with its cell body in the submucosa also is shown (7). MP, myenteric plexus; CM, circular muscle; LM, longitudinal muscle; SM, submucosa; Muc, mucosa. (Adapted with permission of Annual Reviews, from Kunze WA, Furness JB. The enteric nervous system and regulation of intestinal motility. *Annu Rev Physiol*, 1999;61:117–142. Permission conveyed through Copyright Clearance Center, Inc.)

The ENS is an extensive collection of nerves that constitutes the third division of the ANS. It is the only part of the ANS truly capable of autonomous function if separated from the central nervous system (CNS). The ENS lies within the wall of the GI tract organized into 2 connected networks of neurons and nerve fibers: the myenteric (Auerbach) plexus, found between the circular and longitudinal muscle layers, and the submucosal (Meissner) plexus, located in the submucosa. The former is largely responsible for motor control, whereas the latter regulates secretion, fluid transport, and blood flow. The ENS and the ANS are also involved in host defense and innervate organs and cells of the immune system.

**GENERATION AND REGULATION OF GI ACTIVITY**

The ENS is responsible for the largely autonomous nature of most GI activity. This activity is organized into relatively distinct programs that respond to input from the local environment of the gut, as well as the ANS-CNS. Each program consists of a series of complex, but coordinated, patterns of secretion and movement that show regional and temporal variation. The *fasting program* of the gut is called the MMC (*migrating myoelectric complex* when referring to electrical activity and *migrating motor complex* when referring to the accompanying contractions) and consists of a series of 4 phasic activities. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6-10 min before proceeding caudally (toward the anus). Phase II of the MMC is associated with the release of the peptide hormone *motilin*. Motilin agonists stimulate motility in the proximal gut. One whole MMC cycle (i.e., all 4 phases) takes ~80-110 min. The MMC occurs in the fasting state, helping to sweep debris caudad in the gut
and limiting the overgrowth of luminal bacteria. The MMC is interrupted by the fed program in intermittently feeding animals such as humans. The fed program consists of high-frequency (12-15/min) contractions that are either propagated for short segments (propulsive) or are irregular and not propagated (mixing).

**Peristalsis** is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, whereas the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudad. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems) that are of 2 broad types, excitatory and inhibitory. The primary neurotransmitter of the excitatory motor neurons is acetylcholine (ACh). The principal neurotransmitter in the inhibitory motor neurons appears to be NO, although important contributions may also be made by ATP, vasoactive intestinal peptide (VIP), and pituitary adenylyl cyclase–activating peptide (PACAP). Enterochromaffin cells, scattered throughout the epithelium of the intestine, release serotonin (5HT) to initiate many gut reflexes by acting locally on enteric neurons. Excessive release of 5HT from the gut wall (e.g., by chemotherapeutic agents) leads to vomiting by actions of 5HT on vagal nerve endings in the proximal small intestine. Compounds targeting the 5HT system are important modulators of motility, secretion, and emesis.

Other cell types are important, including the interstitial cells of Cajal, distributed within the gut wall and responsible for setting the electrical rhythm and the pace of contractions in various regions of the gut. These cells also translate or modulate excitatory and inhibitory neuronal communication to the smooth muscle.

**EXCITATION-CONTRACTION COUPLING IN GI SMOOTH MUSCLE**

Control of tension in GI smooth muscle is dependent on the intracellular Ca\(^{2+}\) concentration. There are basically 2 types of excitation-contraction coupling in these cells. **Ionotropic receptors** can mediate changes in membrane potential, which in turn activate voltage-dependent Ca\(^{2+}\) channels to trigger an influx of Ca\(^{2+}\) (electromechanical coupling); **metabotropic receptors** activate various
signal transduction pathways to release Ca\textsuperscript{2+} from intracellular stores (pharmaco-mechanical coupling). Inhibitory receptors act via PKA and PKG and lead to hyperpolarization, decreased cytosolic [Ca\textsuperscript{2+}], and reduced interaction of actin and myosin. As an example, NO may induce relaxation via activation of guanylyl cyclase-cyclic GMP pathway and cause the opening of several types of K\textsuperscript{+} channels.

**FUNCTIONAL AND MOTILITY DISORDERS OF THE BOWEL**

GI motility disorders are a heterogeneous group of syndromes. Typical motility disorders include achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), myopathic and neuropathic forms of intestinal dysmotility, and others. These disorders can be congenital, idiopathic, or secondary to systemic diseases (e.g., diabetes mellitus or scleroderma). This term also has traditionally included disorders such as irritable bowel syndrome (IBS) and noncardiac chest pain. For most of these disorders, treatment remains empirical and symptom based, reflecting ignorance of the pathophysiology involved.

**PROKINETIC AGENTS AND OTHER STIMULANTS OF GI CONTRACTILITY**

Prokinetic agents are medications that enhance coordinated GI motility and transit of material in the GI tract. These agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. By contrast, activation of muscarinic receptors with the older cholinomimetic agents (see Chapter 9) or AChE inhibitors (see Chapter 10) enhances contractions in a relatively uncoordinated fashion that produces little or no net propulsive activity.

**DOPAMINE RECEPTOR ANTAGONISTS**

Dopamine (DA) is present in significant amounts in the GI tract and
has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which result from suppression of ACh release from myenteric motor neurons, are mediated by D₂ dopaminergic receptors. DA receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of DA receptors in the chemoreceptor trigger zone. Examples are metoclopramide and domperidone.

**METOCLOPRAMIDE.** Metoclopramide (RSCEGLAN, others) and other substituted benzamides are derivatives of para-aminobenzoic acid and are structurally related to procainamide.

The mechanisms of action of metoclopramide are complex and involve 5HT₄ receptor agonism, vagal and central 5HT₃ antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to DA receptor antagonism. Administration of metoclopramide results in coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. Metoclopramide has no clinically significant effects on large-bowel motility.

**ADME.** Metoclopramide is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a \( t_{1/2} \) of 4-6 h. Peak concentrations occur within 1 h after a single oral dose; the duration of action is 1-2 h.

**Therapeutic Use.** Metoclopramide is indicated in symptomatic patients with gastroparesis, in whom it may cause modest improvements of gastric emptying. Metoclopramide injection is used as an adjunctive measure in medical or diagnostic procedures such as intestinal intubation or contrast radiography of the GI tract. Its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes. Metoclopramide is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous or intramuscular use. The initial regimen is 10 mg orally, 30 min before each meal and at bedtime. The onset of action is within 30-
60 min. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10-15 min) or intravenously (onset of action 1-3 min). For prevention of chemotherapy-induced emesis, metoclopramide can be given as an infusion of 1-2 mg/kg administered over at least 15 min, beginning 30 min before the chemotherapy is begun and repeated as needed every 2 h for 2 doses, then every 3 h for 3 doses.

**Adverse Effects.** The major side effects of metoclopramide include extrapyramidal effects. Dystonias, usually occurring acutely after intravenous administration, and parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and reverse upon discontinuation of metoclopramide. Tardive dyskinesia also can occur with chronic treatment (months to years) and may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. Metoclopramide also can cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin release (seen infrequently in clinical practice). Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving metoclopramide.

**DOMPERIDONE, A D₂ RECEPTOR ANTAGONIST.** In contrast to metoclopramide, domperidone predominantly antagonizes the D₂ receptor without major involvement of other receptors.

Domperidone (MOTILIUM, others) is not available for use in the U.S. but is used elsewhere and has modest prokinetic activity in doses of 10-20 mg 3 times a day. Although it does not readily cross the blood-brain barrier to cause extrapyramidal side effects, domperidone exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release. Domperidone does not appear to have any significant effects on lower GI motility.

**SEROTONIN RECEPTOR AGONISTS**

5HT plays an important role in the normal motor and secretory function of the gut (see Chapter 13). Indeed, >90% of the total 5HT in the body exists in the GI tract. The enterochromaffin cell produces
most of this 5HT and rapidly releases 5HT in response to chemical and mechanical stimulation (e.g., food boluses; noxious agents such as cisplatin; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5HT triggers the peristaltic reflex (see Figure 46–1) by stimulating intrinsic sensory neurons in the myenteric plexus (via 5HT$_1$P and 5HT$_4$ receptors), as well as extrinsic vagal and spinal sensory neurons (via 5HT$_3$ receptors). Additionally, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes resulting in epithelial secretion.

5HT receptors also are found on other neurons in the ENS, where they can be either stimulatory (5HT$_3$ and 5HT$_4$) or inhibitory (5HT$_1$). In addition, serotonin also stimulates the release of other neurotransmitters. Thus, 5HT$_1$ stimulation of the gastric fundus results in release of NO and reduces smooth muscle tone. 5HT$_4$ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5HT$_3$ and 5HT$_4$ receptors facilitate interneuronal signaling. Developmentally, 5HT acts as a neurotrophic factor for enteric neurons via the 5HT$_2B$ and 5HT$_4$ receptors. Reuptake of serotonin by enteric neurons and epithelium is mediated by the same transporter (SERT; see Chapters 5 and 13) as 5HT reuptake by serotonergic neurons in the CNS. This reuptake also is blocked by selective serotonin reuptake inhibitors (SSRIs; see Figure 15–1 and Table 15–1), which explains the common side effect of diarrhea that accompanies the use of these agents. Modulation of the multiple, complex, and sometimes opposing effects of 5HT on gut motor function has become a major target for drug development. The availability of serotonergic prokinetic drugs has in recent years been restricted because of serious adverse cardiac events. Tegaserod maleate (ZELNORM) has been discontinued; cisapride is available only via a restricted investigational drug protocol. A novel 5HT$_4$ agonist, prucalopride (RESOLOR), is approved in Europe for symptomatic treatment of chronic constipation in women in whom laxatives fail to provide adequate relief.

**CISAPRIDE.** Cisapride (PROPULSID; Figure 46–2) is a 5HT$_4$ agonist that stimulates adenylyl cyclase activity in neurons. It also has weak 5HT$_3$ antagonistic properties and may directly stimulate smooth muscle. Cisapride was
a commonly used prokinetic agent, however, it no longer is available in the U.S. because of its potential to induce serious and occasionally fatal cardiac arrhythmias that result from a prolonged QT interval. Cisapride is metabolized by CYP3A4 (see Chapter 6). Cisapride is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities, or concomitant medications known to prolong the QT interval. Cisapride is available only through an investigational, limited-access program for patients with GERD, gastroparesis, pseudo-obstruction, refractory severe chronic constipation, and neonatal enteral feeding intolerance who have failed all standard therapeutic modalities and who have undergone a thorough diagnostic evaluation, including an ECG.

![Table of Serotonergic Agents](image)

**Figure 46–2 Serotonergic agents modulating GI motility.**

**PRUCALOPRIDE.** Prucalopride (Reselor; see Figure 46–2) is a specific 5HT$_4$ receptor agonist that facilitates cholinergic neurotransmission. It acts throughout the length of the intestine, increasing oral-cecal transit and colonic transit without affecting gastric emptying in healthy volunteers. Given in doses of 2 and 4 mg orally, once daily, the drug improves bowel habits. Prucalopride is approved in Europe for use in women with chronic constipation in whom laxatives fail to provide adequate relief.

**MOTILIDES**

**MACROLIDES AND ERYTHROMYCIN.** Motilin, a 22–amino acid peptide hormone found in the M cells and in some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the migrating motor complex and appear to be responsible for the
amplification, if not the actual induction, of phase III activity. In addition, motilin receptors are found on smooth muscle cells and enteric neurons.

The effects of motilin can be mimicked by erythromycin, a property shared to varying extents by other macrolide antibiotics (e.g., oleandomycin, azithromycin, and clarithromycin; see Chapter 55). In addition to its motilin-like effects, which are most pronounced at higher doses (250-500 mg), erythromycin at lower doses (e.g., 40-80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation. Erythromycin has multiple effects on upper GI motility, increasing lower esophageal pressure and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

**THERAPEUTIC USE.** Erythromycin is used as a prokinetic agent in patients with diabetic gastroparesis, where it can improve gastric emptying in the short term. Erythromycin-stimulated gastric contractions can be intense and result in “dumping” of relatively undigested food into the small bowel. This potential disadvantage can be exploited clinically to clear the stomach of undigestible residue such as plastic tubes or bezoars. Rapid development of tolerance to erythromycin, possibly by downregulation of the motilin receptor, and antibiotic effects (undesirable in this context) limit the use of this drug as a prokinetic agent. A standard dose of erythromycin for gastric stimulation is 3 mg/kg intravenously or 200-250 mg orally every 8 h. For small-bowel stimulation, a smaller dose (e.g., 40 mg intravenously) may be more useful; higher doses may actually retard the motility. Concerns about toxicity, pseudomembranous colitis, and the induction of resistant strains of bacteria, among other things, limit the use of erythromycin to acute situations or in circumstances where patients are resistant to other medications.

*Mitomycin* (GM-611), a macrolide non-antibiotic, shows promise for the treatment of gastroparesis.

**MISCELLANEOUS AGENTS FOR STIMULATING MOTILITY**
The hormone cholecystokinin (CCK) is released from the intestine in response to meals and delays gastric emptying, causes contraction of the gallbladder, stimulates pancreatic enzyme secretion, increases intestinal motility, and promotes satiety. The C-terminal octapeptide of CCK, sircalide (KINEVAC), is useful for stimulating the gallbladder and/or pancreas and for accelerating barium transit through the small bowel for diagnostic testing of these organs. Dexloiglumide is a CCK₁ (or CCK-A) receptor antagonist that can improve gastric emptying and has been investigated as a treatment for gastroparesis and for constipation-dominant IBS and may also have uses in feeding intolerance in critically ill individuals. Clonidine also has been reported to be of benefit in patients with gastroparesis. Octreotide acetate (SANDOSTATIN, others), a somatostatin analogue, also is used in some patients with intestinal dysmotility.

AGENTS THAT SUPPRESS MOTILITY

Smooth muscle relaxants such as organic nitrates and Ca²⁺ channel antagonists often produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in severe difficulty in swallowing. Preparations of botulinum toxin (BOTOX, DYSPORT, MYOBLOC), injected directly into the lower esophageal sphincter via an endoscope, in doses of 80-100 units, inhibit ACh release from nerve endings and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance.

LAXATIVES, CATHARTICS, AND THERAPY FOR CONSTIPATION

OVERVIEW OF GI WATER AND ELECTROLYTE FLUX. Water normally accounts for 70-85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion and secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper expulsion of waste.
material via the process of defecation.

Normally ~8-9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 46–3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only ~1-1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving ~100 mL of fecal water daily. Under normal circumstances, these quantities are within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4-5 L). Neurohumoral mechanisms, pathogens, and drugs can alter secretion and absorption of fluid by the intestinal epithelium. Altered motility also contributes in a general way to this process. With decreased motility and excess fluid removal, feces can become incompssated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea occurs.

![Figure 46–3](image)

*Figure 46–3* The approximate volume and composition of fluid that traverses the small and large intestines daily. Of the 9 L of fluid typically presented to the small intestine each day, 2 L are from the diet and 7 L are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4-5 L per day.

**CONSTIPATION: GENERAL PRINCIPLES OF PATHOPHYSIOLOGY AND TREATMENT.** Patients use the term
constipation not only for decreased frequency, but also for difficulty in initiation or passage, passage of firm or small-volume feces, or a feeling of incomplete evacuation.

Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation have normal colonic transit. These patients either have IBS or define constipation in terms other than stool frequency. In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility or, less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the rectoanal region.

Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions. Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is based, in most cases, on nonspecific principles.

Constitution generally may be corrected by adherence to a fiber-rich (20-35 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs. Constipation related to medications can be corrected by use of alternative drugs where possible, or adjustment of dosage. If nonpharmacological measures alone are inadequate, they may be supplemented with bulk-forming agents or osmotic laxatives.

When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period of time to avoid abuse. In addition to perpetuating dependence on drugs, the laxative habit may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with
hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported. Laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable. The terms laxatives, cathartics, purgatives, aperients, and evacuants often are used interchangeably. There is a distinction, however, between laxation (the evacuation of formed fecal material from the rectum) and catharsis (the evacuation of unformed, usually watery fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are actually cathartics that act as laxatives at low doses.

Laxatives relieve constipation and promote evacuation of the bowel via:

- Enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms
- Decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport
- Altering motility by either inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions

Laxatives can be classified based on their actions (Table 46–1) or by the pattern of effects produced by the usual clinical dosage (Table 46–2), with some overlap between classifications.

**Table 46–1**

**Classification of Laxatives**

1. Luminally active agents
   - Hydrophilic colloids; bulk-forming agents (bran, psyllium, etc.)
   - Osmotic agents (nonabsorbable inorganic salts or sugars)
   - Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)
2. Nonspecific stimulants or irritants (with effects on fluid secretion and motility)
   - Diphenylmethanes (bisacodyl)
   - Anthraquinones (senna and cascara)
   - Castor oil
3. Prokinetic agents (acting primarily on motility)
   - 5HT₄ receptor agonists
   - Dopamine receptor antagonists
   - Motilides (erythromycin)
A variety of laxatives, both osmotic agents and stimulants, increase the activity of NO synthase and the biosynthesis of platelet-activating factor in the gut. Platelet-activating factor is a phospholipid proinflammatory mediator that stimulates colonic secretion and GI motility. NO also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, and bisacodyl (but not senna), as well as magnesium sulfate.

**DIETARY FIBER AND SUPPLEMENTS**

Bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is defined as that part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying degrees, depending on its chemical nature and water solubility. Fermentation of fiber has 2 important effects: (1) it produces short-chain fatty acids that are trophic for colonic epithelium; (2) it increases bacterial mass. Although fermentation of fiber generally decreases stool water, short-chain fatty acids may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. However, fiber that is not fermented can
attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 46–3). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Table 46–3

In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Bran, the residue left when flour is made from cereal grains, contains >40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight. Fruits and vegetables contain more pectins and hemicelluloses, which are more readily fermentable and produce less effect on stool transit. Psyllium husk, derived from the seed of the plantago herb, is a component of many commercial products for constipation (Metamucil, others). Psyllium husk contains a hydrophilic muciloid that undergoes significant fermentation in the colon, leading to an increase in colonic bacterial mass. The usual dose is 2.5-4 g (1-3 teaspoonfuls in 250 mL of fruit juice), titrated upward until the desired goal is reached. A variety of semisynthetic celluloses—e.g., methylcellulose (Citrucel, others) and the hydrophilic resin calcium polycarbofil (Fiber Cson, Fiberall, others), a polymer of acrylic acid resin—also are available. These poorly fermentable compounds absorb water and increase fecal bulk. Malt soup extract (MalsupeX, others), an extract of malt, is another orally administered bulk-forming agent. Bloating is the most common side effect of soluble fiber products (perhaps due to colonic fermentation), but it usually decreases with time.
OSMOTICALLY ACTIVE AGENTS

POLYETHYLENE GLYCOL–ELECTROLYTE SOLUTIONS. Long-chain polyethylene glycols (PEGs; MW ~3350 Da) are poorly absorbed and retain water via their high osmotic nature. When used in high volume, aqueous solutions of PEGs with electrolytes (Colyte, GolyteLY, others) produce an effective catharsis and have replaced oral sodium phosphates as the most widely used preparations for colonic cleansing prior to radiological, surgical, and endoscopic procedures.

Usually 240 mL of this solution is taken every 10 min until 4 L is consumed or the rectal effluent is clear. To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride. The osmotic activity of the PEG molecules retains the added water and the electrolyte concentration assures little or no net ionic shifts. A powder form of polyethylene glycol 3350 (Miralax, others) is now available for the short-term treatment (≤2 weeks) of occasional constipation. The usual dose is 17 g of powder per day in 8 ounces of water.

SALINE LAXATIVES. Laxatives containing magnesium cations or phosphate anions commonly are called saline laxatives: magnesium sulfate, magnesium hydroxide, magnesium citrate, sodium phosphate. Their cathartic action is believed to result from osmotic water retention, which then stimulates peristalsis. Other mechanisms may contribute, including the production of inflammatory mediators.

Magnesium-containing laxatives may stimulate the release of cholecystokinin, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. For every additional mEq of Mg²⁺ in the intestinal lumen, fecal weight increases by ~7 g. The usual dose of magnesium salts contains 40-120 mEq of Mg²⁺ and produces 300-600 mL of stool within 6 h.

Phosphate salts are better absorbed than magnesium-based agents and therefore need to be given in larger doses to induce catharsis. The most frequently
employed preparations of sodium phosphate are an oral solution (FLEET PHOSPHO-SODA) and tablets (VISICOL, OSMOprep). The FDA has ruled that only prescription medications should be available for this purpose. To reduce the likelihood of acute phosphate nephropathy, oral phosphates should be avoided in patients at risk (the elderly, patients with known bowel pathology or renal dysfunction, and patients on angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and nonsteroidal anti-inflammatory drugs [NSAIDs]) and the 2-dose regimens should be split evenly with the first dose taken the evening before the exam and the second starting 3-5 h before the exam. Adequate fluid intake (1-3 L) is essential for any oral sodium phosphate regimen used for colonic preparation.

Magnesium- and phosphate-containing preparations must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities, and in patients on diuretic therapy. Patients taking >45 mL of oral sodium phosphate as a prescribed bowel preparation may experience electrolyte shifts that pose a risk for the development of symptomatic dehydration, renal failure, metabolic acidosis, tetany from hypocalcemia, and even death in vulnerable populations.

**Nondigestible Sugars and Alcohols.** *Lactulose* (CEPHULAC, CHRONULAC, others) is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other nonabsorbable sugars such as sorbitol and mannitol are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and vincristine, of constipation in the elderly, and of idiopathic chronic constipation. They are available as 70% solutions, which are given in doses of 15-30 mL at night, with increases as needed up to 60 mL per day in divided doses. Effects may not be seen for 24-48 h after dosing is begun. Abdominal discomfort or distention and flatulence are relatively common but usually subside with continued administration.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver
disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in “trapping” of the ammonia by its conversion to the polar ammonium ion.

Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give sufficient amounts of lactulose (usually 20-30 g, 3 to 4 times per day) to produce 2 to 3 soft stools a day with a pH of 5-5.5.

**STOOL-WETTING AGENTS AND EMOLLIENTS**

*Docusate salts* are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool and permitting easier defecation. These agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. Docusate sodium (dioctyl sodium sulfosuccinate; Colace, Doxinate, others) and docusate calcium (dioctyl calcium sulfosuccinate; Surfax, others) are available in several dosage forms. These agents have marginal efficacy in most cases of constipation.

*Mineral oil* is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2-3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include interference with absorption of fat-soluble substances (such as vitamins), elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

**STIMULANT (IRRITANT) LAXATIVES**

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle and probably induce a limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility. This group
incudes: diphenylmethane derivatives, anthraquinones, and ricinoleic acid.

**DIPHENYL METHANE DERIVATIVES.** *Bisacodyl* (Dulcolax, Correctol, others) is marketed as enteric-coated and regular tablets and as a suppository for rectal administration. The usual oral daily dose of bisacodyl is 10-15 mg for adults and 5-10 mg for children ages 6-12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, and so the laxative effects after an oral dose usually are not produced in <6 h. Suppositories work within 30-60 min. Due to the possibility of developing an atonic nonfunctioning colon, bisacodyl should not be used for >10 consecutive days. Bisacodyl is mainly excreted in the stool; ~5% is absorbed and excreted in the urine as a glucuronide. Overdosage can lead to catharsis and fluid and electrolyte deficits. The diphenylmethanes can damage the mucosa and initiate an inflammatory response in the small bowel and colon.

Sodium *picosulfate* (Lubrilex, Sur-Lax) is a diphenylmethane derivative widely available outside of the U.S. It is hydrolyzed by colonic bacteria to its active form and acts locally only in the colon. Effective doses of the diphenylmethane derivatives vary as much as 4- to 8-fold in individual patients. *Phenolphthalein*, once among the most popular components of laxatives, has been withdrawn from the market in the U.S. because of potential carcinogenicity. *Oxyphenisatin* was withdrawn due to hepatotoxicity.

**ANTHRAQUINONE LAXATIVES.** These derivatives of plants such as aloe, cascara, and senna share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones, such as rhein and frangula. For use, monoanthrones (oral mucosal irritants) are converted to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms.

*Senna* (Senokot, Ex-Lax, others) is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia* and contains the rhein dianthrone glycosides sennoside A and B. *Cascara sagrada* is obtained from the bark of the buckthorn tree and contains the glycosides barbaloin and chrysaloin. The synthetic monoanthrone danthon was withdrawn from the U.S. market because of concerns over possible carcinogenicity. Aloe and cascara sagrada products
sold as laxatives have been categorized by FDA as not generally recognized as
safe and effective for over the counter use because of a lack of scientific
information about potential carcinogenicity. These ingredients may still be sold
over-the-counter in the U.S., but legally they cannot be labeled for use as
laxatives. This judgment is medically prudent but may provoke a longing for
times past amongst Joyceans, who recall that cascara sagrada, the sacred bark,
worked well for Leopold Bloom, in Dublin, on the morning of June 16, 1904:

Midway, his last resistance yielding, he allowed his
bowels to ease themselves quietly as he read, reading still
patiently that slight constipation of yesterday quite gone.
Hope its not too big to bring on piles again. No, just right.
So. Ah! Costive one tabloid of cascara sagrada. Life
might be so. (Ulysses, James Joyce, 1922)

CASTOR OIL. A bane of childhood since the time of the ancient Egyptians,
castor oil (PURGE, NEOLOID, others) is derived from the bean of the castor plant,
Ricinus communis. The castor bean is the source of an extremely toxic protein,
ricin, as well as the oil (chiefly of the triglyceride of ricinoleic acid). The
triglyceride is hydrolyzed in the small bowel by the action of lipases into
glycerol and the active agent, ricinoleic acid, which acts primarily in the small
intestine to stimulate secretion of fluid and electrolytes and speed intestinal
transit. When taken on an empty stomach, as little as 4 mL of castor oil may
produce a laxative effect within 1-3 h; however, the usual dose for a cathartic
effect is 15-60 mL for adults. Because of its unpleasant taste and its potential
toxic effects on intestinal epithelium and enteric neurons, castor oil is seldom
recommended now.

PROKINETIC AND OTHER AGENTS FOR CONSTIPATION

The term prokinetic generally is reserved for agents that enhance GI
transit via interaction with specific receptors involved in the
regulation of motility.

The potent 5HT4 receptor agonist prucalopride may be useful for the treatment
of chronic constipation. Misoprostol, a synthetic prostaglandin analog, is
primarily used for protection against gastric ulcers resulting from the use of
NSAIDs (see Chapters 34 and 45). Prostaglandins can stimulate colonic contractions, particularly in the descending colon; this may account for the diarrhea that limits the usefulness of misoprostol as a gastroprotectant and find utility in patients with intractable constipation. *Colchicine*, a microtubule formation inhibitor used for gout (see Chapter 34), also has been shown to be effective in constipation, but its toxicity has limited widespread use. Neurotrophin-3 (NT-3) recently was shown to be effective in improving frequency and stool consistency by an unknown mechanism of action.

*Lubiprostone* (*AMITIZA*) is a prostanoid activator of Cl– channels. The drug appears to bind to EP4 receptors linked to activation of adenylyl cyclase, leading to enhanced apical Cl– conductance. The drug promotes the secretion of a chloride-rich fluid, thereby improving stool consistency and promoting increased frequency by reflexly activating motility. A dose of 8 μg twice daily was found to be effective in IBS-C, though higher doses (24 μg twice daily) are given for chronic constipation. The drug is poorly bioavailable, acting only in the lumen of the bowel. Side effects of lubiprostone include nausea, headache, diarrhea, allergic reactions, and dyspnea.

Another class of secretory agent is represented by *linaclotide* (*LINZESS*), a 14–amino acid peptide agonist of guanylate cyclase C that stimulates secretion and motility. This compound is approved in the treatment of IBS-C and chronic constipation. Common side effects include gas, abdominal pain, and diarrhea.

**OPIOID-INDUCED CONSTIPATION**

Opioid analgesics can cause severe constipation. Laxatives and dietary strategies are frequently ineffective in the management of opioid-induced constipation. A promising strategy is the prevention of opioid-induced constipation with peripherally acting μ opioid receptor (MOR) antagonists that specifically target the underlying reason for this condition, without limiting centrally produced analgesia. *Methylnaltrexone* (*RELISTOR*), a peripherally restricted MOR antagonist, is approved for the treatment of opioid-induced constipation. In multicenter trials, when methylnaltrexone (0.15–0.3 mg/kg) was administered repeatedly every other day for 2 weeks, bowel movements occurred in 50% of the patients, compared with 8-15% of patients receiving placebo. Another MOR antagonist, *alvimopan* (*ENTEREG*, 0.5-1 mg twice daily for 6 weeks), increased
spontaneous bowel movements and improved other symptoms of opioid-induced constipation without compromising analgesia.

POSTOPERATIVE ILEUS

Postoperative ileus refers to the intolerance to oral intake and nonmechanical obstruction of the bowel that occurs after abdominal and nonabdominal surgery. The pathogenesis is complex and is a combination of activation of neural inhibitory reflexes involving enteric MOR and the activation of local inflammatory mechanisms that reduce smooth muscle contractility. The condition is exacerbated by opioids, which are the mainstay of postoperative analgesia. Prokinetic agents typically do not have much effect in this condition, but recently, 2 new therapeutic agents have been introduced that have benefit in reducing GI recovery time after surgery.

Alvimopan (ENTEREG) is an orally active peripherally restricted μ opioid receptor antagonist that is approved for limited indications following surgery (12 mg prior to surgery and then once daily for up to 7 days or until discharge; not to exceed 15 doses total). Methylaltrexone (see above) is FDA-approved for the treatment of opioid-induced constipation in patients receiving palliative care when laxative therapy is insufficient. Dexpanthenol (ILOPAN, others) is the alcohol of pantothenic acid (vitamin B5). The drug is a congener of pantothenic acid, a precursor of coenzyme A, which serves as a cofactor in the synthesis of ACh by choline acetyl transferase. It is proposed to act by enhancing synthesis of ACh, major excitatory transmitter of the gut. Dexpanthenol is used as an injection immediately postoperatively after major abdominal surgery to minimize the occurrence of paralytic ileus. It is given by intramuscular injection (200-500 mg) immediately and then 2 h later and every 6 h after that until the situation has resolved. It may cause mild hypotension and shortness of breath as well as local irritation.

ENEMAS AND SUPPOSITORIES

Enemas are employed either by themselves or as adjuncts to bowel preparation regimens, to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this.
Specialized enemas contain additional substances that are either osmotically active or irritant; however, their safety and efficacy have not been studied. Repeated enemas with hypotonic solutions can cause hyponatremia; repeated enemas with sodium phosphate–containing solution can cause hypocalcemia.

Glycerin is absorbed when given orally but acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository or as 5-15 mL of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. CEO-TWO suppositories contain sodium bicarbonate and potassium bitartrate and make use of rectal distension to initiate laxation. When administered rectally, the suppository produces CO₂, which initiates a bowel movement in 5-30 min.

ANTI-DIARRHEAL AGENTS

DIARRHEA: GENERAL PRINCIPLES AND APPROACH TO TREATMENT. An appreciation and knowledge of the underlying causative processes in diarrhea facilitates effective treatment. From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a benign, self-limited illness requiring no treatment or evaluation. In severe cases of diarrhea, dehydration and electrolyte imbalances are the principal risk. Oral rehydration therapy therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute
diarrhea. Na\(^+\) and Cl\(^-\) absorption links to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea in adults should be reserved for patients with significant or persistent symptoms. Nonspecific anti-diarrheal agents typically do not address the underlying pathophysiology responsible for the diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms.

**BULK-FORMING AND HYDROSCOPIC AGENTS.** Hydrophilic and poorly fermentable colloids or polymers such as carboxymethylcellulose and calcium polycarbophil absorb water and increase stool bulk (calcium polycarbophil absorbs 60 times its weight in water). They usually are used for constipation but are sometimes useful in acute episodic diarrhea and in mild chronic diarrheas in patients suffering with IBS. Some of these agents also may bind bacterial toxins and bile salts. Clays such as kaolin (a hydrated aluminum silicate) and other silicates such as attapulgite (magnesium aluminum disilicate; Diasorb, others) bind water avidly and also may bind enterotoxins. However, binding is not selective and may involve other drugs and nutrients; hence these agents are best avoided within 2-3 h of taking other medications. A mixture of kaolin and pectin (a plant polysaccharide) is a popular over-the-counter remedy (Kaopectolin, others) and may provide useful symptomatic relief of mild diarrhea.

**BILE ACID SEQUESTRANTS.** Cholestyramine, colestipol, and colesevelam effectively bind bile acids and some bacterial toxins. Cholestyramine is useful in the treatment of bile salt-induced diarrhea, as in patients with resection of the distal ileum. In these patients, excessive concentrations of bile salts reach the colon and stimulate water and electrolyte secretion. Patients with extensive ileal resection (usually >100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of cholestyramine aggravates the diarrhea. In patients having bile salt-induced diarrhea, cholestyramine (Questran, Questran Light, others) can be given at a dose of 4 g of the dried resin (4 times
If successful, the dose may be titrated down to achieve the desired stool frequency.

**BISMUTH.** Bismuth compounds are used to treat a variety of GI diseases, although their mechanism of action remains poorly understood. **Pepto-Bismol** is a popular over-the-counter preparation that consists of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid. Although 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, the product carries the same warning regarding Reye syndrome as other salicylates.

Bismuth is thought to have anti-secretory, anti-inflammatory, and antimicrobial effects. Nausea and abdominal cramps also are relieved by bismuth. The clay in **Pepto-Bismol** and generic formulations also may have some additional benefits in diarrhea, but this is not clear. Bismuth subsalicylate is used for the prevention and treatment of traveler’s diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis. Today, the most common antibacterial use of this agent is in the treatment of *Helicobacter pylori* (see Chapter 45). A recommended dose of the bismuth subsalicylate (30 mL of regular strength liquid or 2 tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30-60 min, as needed, up to 8 times a day. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract.

**PROBIOTICS.** The GI tract contains a vast commensal microflora that is necessary for health. Alterations in the balance or composition of the microflora are responsible for antibiotic-associated diarrhea, and possibly other disease conditions. Probiotic preparations containing a variety of bacterial strains have shown some degree of benefit in acute diarrheal conditions, antibiotic-associated diarrhea, and infectious diarrhea, but most clinical studies have been small and conclusions are therefore limited.

**ANTI-MOTILITY AND ANTI-SECRETORY AGENTS**
OPIOIDS. Opioids continue to be widely used in the treatment of diarrhea. They act by several different mechanisms, mediated principally through either μ- or δ-opioid receptors on enteric nerves, epithelial cells, and muscle (see Chapter 18). These mechanisms include effects on intestinal motility (μ receptors), intestinal secretion (δ receptors), or absorption (μ and δ receptors). Commonly used anti-diarrheals such as diphenoxylate, difenoxin, and loperamide act principally via peripheral μ opioid receptors and are preferred over opioids that penetrate the CNS.

Loperamide. Loperamide (IMODIUM, IMODIUM A-D, others), a compound with MOR activity, is an orally active anti-diarrheal agent. The drug is 40-50 times more potent than morphine as an anti-diarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. Loperamide also increases anal sphincter tone. In addition, loperamide has anti-secretory activity against cholera toxin and some forms of Escherichia coli toxin, presumably by acting on G₁-linked receptors to counter the stimulation of adenylyl cyclase activity by the toxins.

Loperamide is available OTC in capsule, solution, and chewable tablet forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3-5 h. It has a \( t_{1/2} \) of ~11 h and undergoes extensive hepatic metabolism. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg per day. If clinical improvement in acute diarrhea does not occur within 48 h, loperamide should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2-5 years, 4 mg for ages 6-8 years, and 6 mg for ages 8-12 years. Loperamide is not recommended for use in children <2 years of age. Loperamide is effective against traveler’s diarrhea, used alone or in combination with antimicrobial agents (trimethoprim, trimethoprim-sulfamethoxazole, or a fluoroquinolone). Loperamide is used as adjunct treatment in most forms of chronic diarrheal disease, with few adverse effects. Loperamide lacks significant abuse potential and is more effective in treating diarrhea than diphenoxylate. Overdosage, however, can result in CNS depression (especially in children) and paralytic ileus. In patients with active inflammatory bowel disease involving the colon (see Chapter 47), loperamide should be used with great caution, if at all, to avoid development of toxic megacolon.
Diphenoxylate and Difenoxin. Diphenoxylate and its active metabolite difenoxin (diphenoxyllic acid) are related structurally to meperidine. As anti-diarrheal agents, diphenoxylate and difenoxin are somewhat more potent than morphine. Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1-2 h. Diphenoxylate is rapidly de-esterified to difenoxin, which is eliminated with a $t_{1/2}$ of ~12 h. Both drugs can produce CNS effects when used in higher doses (40-60 mg per day) and thus have a potential for abuse and/or addiction. They are available in preparations containing small doses of atropine (considered sub-therapeutic) to discourage abuse and deliberate overdose: 25 μg of atropine sulfate per tablet with either 2.5 mg diphenoxylate hydrochloride (LOMOTIL) or 1 mg of difenoxin hydrochloride (MOTOFEN). The usual dosage is 2 tablets initially, then 1 tablet every 3-4 h, not to exceed 8 tablets per day. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (dry mouth, blurred vision, etc.) (see Chapter 9).

OTHER OPIOIDS. Opioids used for diarrhea include codeine (in doses of 30 mg given 3 or 4 times daily) and opium-containing compounds. Paregoric (camphorated opium tincture) contains the equivalent of 2 mg of morphine per 5 mL (0.4 mg/mL); deodorized tincture of opium, which is 25 times stronger, contains the equivalent of 50 mg of morphine per 5 mL (10 mg/mL). The 2 tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The anti-diarrheal dose of opium tincture for adults is 0.6 mL (equivalent to 6 mg morphine) 4 times daily; the adult dose of paregoric is 5-10 mL (equivalent to 2-4 mg morphine) 1 to 4 times daily. Paregoric is used in children at a dose of 0.25-0.5 mL/kg (equivalent to 0.1-0.2 mg morphine/kg) 1 to 4 times daily.

Enkephalins are endogenous opioids that are important enteric neurotransmitters; they can inhibit intestinal secretion without affecting motility. Racecadotril (acetorphan), a dipeptide inhibitor of enkephalinase, potentiates the effects of endogenous enkephalins on the δ opioid receptor to produce an anti-diarrheal effect.

$\alpha_2$ ADRENERGIC RECEPTOR AGONISTS. $\alpha_2$ Adrenergic receptor agonists such as clonidine can interact with specific receptors on
enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a special role in diabetics with chronic diarrhea.

Oral clonidine (beginning at 0.1 mg twice a day) has been used in these patients; the use of a topical preparation (e.g., Catapres TTS, 2 patches a week) may result in more steady plasma levels of the drug. Clonidine also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients.

**OCTREOTIDE AND SOMATOSTATIN.** Octreotide (Sandostatin, others) (see Chapter 43) is an octapeptide analog of somatostatin (SST) that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract.

Octreotide inhibits secretion of 5HT and various GI peptides. Its greatest utility may be in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty, in whom octreotide inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects. Octreotide has a $t_{1/2}$ of 1-2 h and is administered either subcutaneously or intravenously as a bolus dose. Standard initial therapy with octreotide is 50-100 μg, given subcutaneously 2 or 3 times a day, with titration to a maximum dose of 500 μg 3 times a day based on clinical and biochemical responses. A long-acting preparation of octreotide acetate enclosed in biodegradable microspheres (Sandostatin LAR Despect) is available for use in the treatment of diarrheas associated with carcinoid tumors and VIP–secreting tumors, as well as in the treatment of acromegaly (see Chapter 38). This preparation is injected intramuscularly once per month in a dose of 20 or 30 mg. Side effects of octreotide depend on the duration of therapy; transient nausea, bloating, or pain at sites of injection in the short term, gallstone formation and hypo- or hyperglycemia in the long term. A long-acting SST analog, lanreotide (Somatuline, others), is available in Europe; another, vapreotide, is under development. SST (Stilamin) also is available in Europe.
**Variceal Bleeding.** SST and octreotide are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchnic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. Octreotide also may act through the ANS. Because of its short $t_{1/2}$ (1-2 min), SST can be given only by intravenous infusion (a 250 μg bolus dose followed by 250 μg hourly for 5 days). Higher doses (up to 500 μg/h) are more efficacious and can be used for patients who continue to bleed on the lower dose. For patients with variceal bleeding, therapy with octreotide usually is initiated while the patient is awaiting endoscopy.

**Intestinal Dysmotility.** Octreotide has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, octreotide also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with scleroderma and small-bowel dysfunction.

**Pancreatitis.** Both SST and octreotide inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis. The rationale for their use is to rest the pancreas so as to not aggravate inflammation by the continuing production of proteolytic enzymes, to reduce intraductal pressures, and to ameliorate pain. Octreotide probably is less effective than SST in this regard because it may cause an increase in sphincter of Oddi pressure and perhaps also have a deleterious effect on pancreatic blood flow.

**OTHER AGENTS**

*Berberine* is a plant alkaloid that has complex pharmacological actions that include antimicrobial effects, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly in bacterial diarrhea and cholera, but is also apparently effective against intestinal parasites. The anti-diarrheal effects in part may be related to its antimicrobial activity, as well as its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of ACh (by competitive and noncompetitive mechanisms) and blocking the entry of Ca$^{2+}$ into cells. In addition, it inhibits intestinal secretion.
IRRITABLE BOWEL SYNDROME (IBS)

IBS affects up to 15% of the population in the U.S. Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. IBS appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders. The disturbances in bowel function can be either constipation or diarrhea or both at different times. Considerable evidence suggests a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological stimuli in this syndrome.

Many patients can be managed with dietary restrictions and fiber supplementation; many cannot. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific using agents discussed above. A possible role for serotonin in IBS has been suggested based on its known involvement in sensitization of nociceptor neurons in inflammatory conditions. This has led to the development of specific receptor modulators, such as the 5HT₃ antagonist alosetron (see Figure 46–2).

An effective class of agents for IBS has been the tricyclic antidepressants (see Chapter 15), which can have neuromodulatory and analgesic properties independent of their antidepressant effect. Tricyclic antidepressants have a proven track record in the management of chronic “functional” visceral pain. Effective analgesic doses of these drugs (e.g., 25-75 mg per day of nortriptyline) are significantly lower than those required to treat depression. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns. Selective serotonin reuptake inhibitors have fewer side effects and have been advocated particularly for patients with functional constipation because they can increase bowel movements and even cause diarrhea. However, they probably are not as effective as tricyclic antidepressants in the management of visceral pain.

α₂ Adrenergic agonists, such as clonidine (see Chapter 12), also can increase visceral compliance and reduce distention-induced pain. The SST analog
octreotide has selective inhibitory effects on peripheral afferent nerves projecting from the gut to the spinal cord in healthy human beings and has been shown to blunt the perception of rectal distention in patients with IBS.

**ALOSETRON, 5HT3 ANTAGONIST**

The 5HT3 receptor participates in sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. The clinical effect of 5HT3 antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. Alosetron (LOTRONEX), a potent antagonist of the 5HT3 receptor, was initially withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. Nevertheless, the FDA has reapproved this drug for diarrhea-predominant IBS under a limited distribution system. The manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing. Alosetron is rapidly absorbed from the GI tract; its duration of action (~ 10 h) is longer than expected from its $t_{1/2}$ of 1.5 h. It is metabolized by hepatic CYPs. The drug should be started at 1 mg per day for the first 4 weeks and advanced to a maximum of 1 mg twice daily. Other 5HT3 antagonists currently available in the U.S. are approved for nausea and vomiting (see later in this chapter and Chapter 13).

**ANTI-SPASMODICS AND OTHER AGENTS**

Anticholinergic agents (“spasmolytics” or “anti-spasmodics”) often are used in patients with IBS. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (see Chapter 9) and include the tertiary amines dicyclomine (BENTYL, others) and hyoscyamine (LEVSIN, others) and the quaternary ammonium compounds glycopyrrolate (ROBINUL, others) and methscopolamine (PAMINE, others). The advantage of the
latter 2 compounds is that they have a limited propensity to cross the blood-brain barrier and hence a lower risk for neurological side effects such as lightheadedness, drowsiness, or nervousness. These agents typically are given either on an as-needed basis or before meals to prevent the pain and fecal urgency that occur in some patients with IBS.

Dicyclomine is given in doses of 20 mg orally every 6 h initially and increased to 40 mg every 6 h unless limited by side effects. Hyoscyamine is available as immediate-release oral capsules, tablets, elixir, drops, and a nonaerosol spray (all administered as 0.125-0.25 mg every 4 h as needed), and extended-release forms for oral use (0.25-0.375 mg every 12 h as needed). Glycopyrrolate is available as immediate-release tablets; the dose is 1-2 mg 2 or 3 times daily, not to exceed 8 mg/day. Methscopolamine is provided as 2.5-mg and 5-mg tablets; the dose is 2.5 mg a half hour before meals and 2.5-5 mg at bedtime.

OTHER DRUGS. Cimetropium, an antimuscarinic compound that is effective in patients with IBS, is not available in the U.S. Otilonium bromide is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca$^{2+}$ channels and neurokinin NK$_2$ receptors; it is not available in the U.S. Mebeverine hydrochloride, a derivative of hydroxybenzamide, appears to have a direct effect on the smooth muscle cell, blocking K$^+$, Na$^+$, and Ca$^{2+}$ channels, and is used outside of the U.S. as an anti-spasmodic agent.

ANTI-NAUSEANTS AND ANTI-EMETICS

NAUSEA AND VOMITING

Emesis and the sensation of nausea that accompanies it generally are viewed as protective reflexes that serve to rid the stomach and intestine of toxic substances and prevent their further ingestion. Vomiting is a complex process that appears to be coordinated by a central emesis center in the lateral reticular formation of the mid-brainstem adjacent to both the chemoreceptor trigger zone (CTZ) in the area postrema (AP) at the bottom of the fourth ventricle and the solitary tract nucleus (STN). The lack of a blood-brain barrier allows the CTZ to monitor blood and cerebrospinal fluid constantly for toxic
substances and to relay information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (via the STN) but also by splanchnic afferents via the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). The CTZ has high concentrations of receptors for serotonin (5HT3), dopamine (D2), and opioids; the STN is rich in receptors for enkephalin, histamine, and ACh, and also contains 5HT3 receptors. A variety of these neurotransmitters are involved in nausea and vomiting (Figure 46–4). Anti-emetics generally are classified according to the predominant receptor on which they are proposed to act (Table 46–4). For treatment and prevention of the nausea and emesis associated with cancer chemotherapy, several anti-emetic agents from different pharmacological classes may be used in combination (Table 46–5).
Figure 46–4 *Pharmacologist*’s view of emetic stimuli. Myriad signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in italics. These pathways involve specific neurotransmitters and their receptors (**bold** type). Receptors are shown for dopamine (D₂), acetylcholine (muscarinic, M), histamine (H₁), cannabinoids (CB₁), substance P (NK₁), and 5-hydroxytryptamine (5HT₃). Some of these receptors also may mediate signaling in the emetic center.

*The most effective agents for chemotherapy-induced nausea and vomiting are the 5HT₃ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy as well as reduce the incidence of side effects. See Table 46–5.

*Also has some peripheral activity at 5HT, receptors.

*Also has some antihistaminic and anticholinergic activity.

---

**Low risk of emesis:**
- Pre-chemotherapy
  - Dexamethasone
  - Metoclopramide ± diphenhydramine
  - Prochlorperazine ± lorazepam
- Post-chemotherapy (delayed emesis)
  - None

**Moderate risk of emesis:**
- Pre-chemotherapy
  - 5HT₃ antagonist + dexamethasone
  - 5HT₁ receptor antagonist + dexamethasone + aprepitant
- Post-chemotherapy (delayed emesis)
  - Aprepitant (days 2 and 3)
  - Dexamethasone or 5HT₃ antagonist (days 2-3 or 4)
  - Aprepitant (days 2-3, if used pre-chemo) ± dexamethasone (days 2-4) ± lorazepam (days 2-4)

**High risk of emesis:**
- Pre-chemotherapy
  - 5HT₁ antagonist + dexamethasone + aprepitant ± lorazepam
- Post-chemotherapy (delayed emesis)
  - Dexamethasone + aprepitant
  - Dexamethasone (days 2-4) + aprepitant (days 2 and 3) ± lorazepam (days 2-4)

₃H, histamine; NK, neurokinin; 5HT, 5 hydroxytryptamine (serotonin).

*Specific recommendations and doses are tailored to the patient and the chemotherapeutic regimen. For updated information, see the National Cancer Institute website (see Cancer Topics: Nausea and Vomiting).

Some patients profit from cannabinoids (dronabinol, nabilone) ± a phenothiazine or dexamethasone. Ginger powder (Zingiber officinale) is being evaluated as an anti-emetic.

---

**5HT₃ RECEPTOR ANTAGONISTS**
Ondansetron (ZOFRAN, others) is the prototypical drug in this class. The 5HT\textsubscript{3} receptor antagonists (Table 46–6) are the most widely used drugs for chemotherapy-induced emesis. Other agents in this class include granisetron (KYTRIL, others), dolasetron (ANZEMET), palonosetron (ALOXI), and tropisetron (not available in the U.S.).

\textit{IV, intravenous.}

5HT\textsubscript{3} receptors are present in several critical sites involved in emesis, including vagal afferents, the STN (which receives signals from vagal afferents), and the AP itself (see Figure 46–4). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and may stimulate vagal afferents (via 5HT\textsubscript{3} receptors) to initiate the vomiting reflex. The highest concentrations of 5HT\textsubscript{3} receptors in the CNS are found in the STN and CTZ, and antagonists of 5HT\textsubscript{3} receptors also may suppress nausea and vomiting by acting at these sites.

\textbf{ADME.} These agents are absorbed well from the GI tract. Ondansetron is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. Granisetron also is metabolized predominantly by the liver by the CYP3A family. Dolasetron is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver while about one-third of it is excreted unchanged in the urine. Palonosetron is metabolized principally by CYP2D6 and excreted in the urine as the metabolized and the unchanged forms in about equal proportions. The anti-emetic effects of
these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level; these drugs can be administered effectively just once a day.

**Therapeutic Use.** These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation. They also are effective against hyperemesis of pregnancy, and to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, palonosetron may be helpful in delayed emesis, perhaps reflecting its long $t_{1/2}$. These agents are available as tablets, oral solution, and intravenous preparations for injection. For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (see Table 46–6) infused over 15 min, beginning 30 min before chemotherapy, or in 2-3 divided doses, with the first usually given 30 min before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly (ondansetron only) or orally. Granisetron is available as a transdermal formulation that is applied 24-48 h before chemotherapy and worn for up to 7 days.

**Adverse Effects.** In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and lightheadedness.

**DOPAMINE RECEPTOR ANTAGONISTS**

*Phenothiazines* such as prochlorperazine, thiethylperazine (discontinued in the U.S.), and chlorpromazine (see Chapter 16) are among the most commonly used “general-purpose” anti-nauseants and anti-emetics. Their principal mechanism of action is $D_2$ receptor antagonism at the CTZ. These drugs are not uniformly effective in cancer chemotherapy-induced emesis but they possess antihistaminic and anticholinergic activities that are of value in other forms of nausea, such as motion sickness.

**ANTIHISTAMINES**

Histamine $H_1$ antagonists are primarily useful for motion sickness and postoperative emesis. They act on vestibular afferents and within the brainstem. *Cyclizine, hydroxyzine, promethazine*, and *diphenhydramine* are examples of this
class of agents. Cyclizine has additional anticholinergic effects that may be useful for patients with abdominal cancer. For a detailed discussion of these drugs, see Chapter 32.

ANTICHOLINERGIC AGENTS

The most commonly used muscarinic receptor antagonist is scopolamine (hyoscine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (Transderm-Scop). Its principal utility is in the prevention and treatment of motion sickness, with some activity in postoperative nausea and vomiting. In general, however, anticholinergic agents have no role in chemotherapy-induced nausea.

SUBSTANCE P RECEPTOR ANTAGONISTS

The nausea and vomiting associated with cisplatin (see Chapter 61) have 2 components: an acute phase that universally is experienced (within 24 h after chemotherapy) and a delayed phase that affects only some patients (on days 2-5). 5HT₃ receptor antagonists are not very effective against delayed emesis. Antagonists of the NK₁ receptors for substance P, such as aprepitant (and its parenteral formulation, fosaprepitant; Emend), have anti-emetic effects in delayed nausea and improve the efficacy of standard anti-emetic regimens in patients receiving multiple cycles of chemotherapy.

After absorption, aprepitant is bound extensively to plasma proteins (>95%); it is metabolized primarily by hepatic CYP3A4, and is excreted in the stools; its $t_{1/2}$ is 9-13 h. Aprepitant has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including dexamethasone, methylprednisolone (whose dose may need to be reduced by 50%), and warfarin. Aprepitant is contraindicated in patients on cisapride or pimozide, in whom life-threatening QT prolongation has been reported. Aprepitant is supplied in 40-, 80- and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy, along with a 5HT₃ antagonist and a corticosteroid. The recommended adult dosage of aprepitant is 125 mg administered 1 h before chemotherapy on day 1, followed by 80 mg once daily in the morning on days 2
and 3 of the treatment regimen.

**CANNABINOIDs**

**Dronabinol** (δ-9-tetrahydrocannabinol; MARINOL) is a naturally occurring cannabinoid that can be synthesized chemically or extracted from the marijuana plant, *Cannabis sativa*. The exact mechanism of the anti-emetic action of dronabinol is not known but probably relates to stimulation of the CB₁ subtype of cannabinoid receptors on neurons in and around the CTZ and emetic center (see Figure 46–4).

![Dronabinol](image)

**ADME.** Dronabinol is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2-4 h. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10-20%). The principal active metabolite is 11-OH-delta-9-tetrahydrocannabinol. These metabolites are excreted primarily via the biliary-fecal route, with only 10-15% excreted in the urine. Both dronabinol and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of dronabinol can result in detectable levels of metabolites for several weeks.

**Therapeutic Use.** Dronabinol is a useful prophylactic agent in patients receiving cancer chemotherapy when other anti-emetic medications are not effective. It also can stimulate appetite and has been used in patients with acquired immunodeficiency syndrome (AIDS) and anorexia. As an anti-emetic agent, it is administered at an initial dose of 5 mg/m² given 1-3 h before chemotherapy and then every 2-4 h afterward for a total of 4 to 6 doses. If this is inadequate, incremental increases can be made up to a maximum of 15 mg/m² per dose. For
other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to a maximum of 20 mg per day.

**Adverse Effects.** Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like “highs” (e.g., euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and thinking abnormalities. After abrupt withdrawal of dronabinol, an abstinence syndrome (irritability, insomnia, and restlessness) can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it, too, may be abused by these patients.

**Nabilone (CESAMET)** is a synthetic cannabinoid with a mode of action similar to that of dronabinol.

**ADME.** Nabilone is a highly lipid-soluble compound that is rapidly absorbed after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 h. The $t_{1/2}$ is $\sim 2$ h for the parent compound and 35 h for metabolites. The metabolites are excreted primarily via the biliary-fecal route (60%), with only $\sim 125\%$ excreted in the urine.

**Therapeutic Use.** Nabilone is a useful prophylactic agent in patients receiving cancer chemotherapy when other anti-emetic medications are not effective. A dose (1-2 mg) can be given the night before chemotherapy; usual dosing starts 1-3 h before treatment and then every 8-12 h during the course of chemotherapy and for 2 days following its cessation.

**Adverse Effects.** The adverse effects are largely the same as for dronabinol, with significant CNS actions in $>10\%$ of patients. Cardiovascular, GI, and other side effects are also common and together with the CNS actions limit the usefulness of this agent.

**GLUCOCORTICOIDS AND ANTI-INFLAMMATORY**
AGENTS

Glucocorticoids such as dexamethasone can be useful adjuncts (see Table 46–5) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of NSAIDs in the nausea and vomiting induced by systemic irradiation. For a detailed discussion of these drugs, see Chapters 34 and 42.

BENZODIAZEPINES

Benzodiazepines, such as lorazepam and alprazolam, by themselves are not very effective anti-emetics, but their sedative, amnesic, and antianxiety effects can be helpful in reducing the anticipatory component of nausea and vomiting in patients. For a detailed discussion of these drugs, see Chapter 17.

PHOSPHORATED CARBOHYDRATE SOLUTIONS

Aqueous solutions of glucose, fructose, and phosphoric acid (Emetrol, Nausetrol) are available over the counter to relieve nausea. Their mechanisms of action are unclear.

MISCELLANEOUS GI DISORDERS

CHRONIC PANCREATITIS AND STEATORRHEA

Pancreatic Enzymes. Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). The goals of pharmacological therapy are prevention of malabsorption and palliation of pain.

Enzyme Formulations. Pancreatic enzymes are typically prescribed on the basis of the lipase content. Only pancrelipase (Creon, Zenpep, Pancreaze, Pertzye) is licensed for sale in the U.S. Pancrelipase products contain various amounts of lipase, protease, and amylase and thus may not be interchangeable.

Replacement Therapy for Malabsorption. Fat malabsorption (steatorrhea) and
protein maldigestion occur when the pancreas loses >90% of its ability to produce digestive enzymes. The resultant diarrhea and malabsorption can be managed well if 30,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-h period with and after meals. Alternatively, one can titrate the dosage to the fat content of the diet, with ~8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes contain up to 20,000 units of lipase and 76,000 units of protease, and the typical dose of pancrelipase is 1-3 capsules with or just before meals. The loss of pancreatic amylase does not present a problem because of other sources of this enzyme (e.g., salivary glands).

*Enzymes for Pain.* Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative feedback inhibition of the pancreas by the presence of duodenal proteases. The release of CCK, the principal secretagogue for pancreatic enzymes, is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

Pancreatic enzyme preparations are tolerated extremely well by patients. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.

**BILE ACIDS**

Bile acids and their conjugates are synthesized from cholesterol in the liver. Bile acids induce bile flow, feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the dispersion and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine, returned to the liver, and then again secreted
in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids; lithocholic acid and ursodeoxycholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called bile salts. Ursodeoxycholic acid (UDCA; ursodiol, ACTIGALL, others) (Figure 46–5) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid (CDCA; chenodiol) in the gut by intestinal bacteria. When administered orally, litholytic bile acids such as chenodiol and ursodiol alter relative concentrations of bile acids, decrease biliary lipid secretion and reduce the cholesterol content of the bile so that it is less lithogenic. Ursodiol also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases.

Figure 46–5 Major bile acids in adults.

FLATULENCE

“Gas” is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation but also bloating or fullness. Over-the-counter and herbal preparations are popular. Simethicone (MYLICON, GAS-X, others), a mixture of siloxane polymers stabilized with silicon dioxide, is an inert nontoxic
insoluble liquid. Because of its capacity to collapse bubbles by forming a thin layer on their surface, it is an effective anti-foaming agent; whether this accomplishes a therapeutic effect in the GI tract is not clear. Simethicone is available in chewable tablets, liquid-filled capsules, suspensions, and orally disintegrating strips, either by itself or in combination with other over-the-counter medications including antacids and other digestants. The usual dosage in adults is 40-25 mg 4 times daily. Activated charcoal may be used alone or in combination with simethicone, but has not been shown conclusively to have much benefit. An alphagalactosidase preparation (BEANO) is available over the counter to reduce gas from baked beans.

**SHORT BOWEL SYNDROME**

**GLP-2 Receptor Agonist**

Teduglutide (GATTEX) is a 33-amino acid GLP-2 analog approved for the treatment of short-bowel syndrome. Teduglutide injection is administered by subcutaneously once daily to help improve intestinal absorption of nutrients to reduce the need of parenteral support. Common side effects include abdominal pain, nausea, headache, and flu-like symptoms. Teduglutide may cause serious side effects including cancer of the bowel, blockage of the bowel, and inflammation of the gallbladder or pancreas. Teduglutide has orphan drug status.
Inflammatory bowel disease (IBD) is a spectrum of chronic, idiopathic, inflammatory intestinal conditions. IBD causes significant gastrointestinal (GI) symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD conventionally is divided into 2 major subtypes: ulcerative colitis and Crohn disease. *Ulcerative colitis* is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis). *Crohn disease*, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve. The inflammation in Crohn disease is not necessarily confluent, frequently leaving “skip areas” of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or fistula formation.

**PATHOGENESIS OF IBD.** Crohn disease and ulcerative colitis are chronic idiopathic inflammatory disorders of the GI tract; a summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 47–1. Crohn disease and ulcerative colitis result from distinct pathogenetic mechanisms. Histologically, the transmural lesions in Crohn disease exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in ulcerative colitis have lymphocytic and neutrophilic infiltrates. Within the diseased bowel in Crohn disease, the cytokine profile includes increased levels of interleukin (IL)-12, IL-23, interferon-γ, and tumor necrosis factor-α (TNFα), findings characteristic of T-helper 1 (T_H1)–mediated inflammatory processes. In contrast, the inflammatory response in ulcerative colitis resembles aspects of that mediated by the T_H2 pathway. Understanding of the inflammatory processes has evolved with the description of regulatory T cells and pro-inflammatory T_H17 cells, a novel T-cell population that expresses IL-23 receptor as a surface marker and produces, among others, the pro-inflammatory cytokines IL-17, IL-21, IL-
22, and IL-26. T<sub>H</sub>17 cells seem to play a prominent role in intestinal inflammation, particularly in Crohn disease.

Figure 47–1 Proposed pathogenesis of inflammatory bowel disease and target sites for pharmacological intervention. Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the epithelial barrier is impaired, bacterial antigens can gain access to antigen-presenting cells (APC) such as dendritic cells in the lamina propria. These cells then present the antigen(s) to CD4<sup>+</sup> lymphocytes and also secrete cytokines such interleukin (IL)-12 and IL-18, thereby inducing the differentiation of T<sub>H</sub>1 cells in Crohn’s disease (or, under the control of IL-4, type 2 helper T cells [T<sub>H</sub>2] in
ulcerative colitis). The balance of pro-inflammatory and anti-inflammatory events is also governed by regulatory $T_H 17$ and $T_{Reg}$ cells, both of which serve to limit immune and inflammatory responses in the GI tract. Transforming growth factor (TGF)$\beta$ and IL-6 are important cytokines that drive the expansion of the regulatory T cell subsets. The $T_H 1$ cells produce a characteristic array of cytokines, including interferon (IFN)$\gamma$ and TNF$\alpha$, which in turn activate macrophages. Macrophages positively regulate $T_H 1$ cells by secreting additional cytokines, including IFN$\gamma$ and TNF$\alpha$. Recruitment of a variety of leukocytes is mediated by activation of resident immune cells including neutrophils. Cell adhesion molecules such as integrins are important in the infiltration of leukocytes and novel biological therapeutic strategies aimed at blocking leukocyte recruitment are effective at reducing inflammation. General immunosuppressants (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine) affect multiple sites of inflammation. More site-specific intervention involve intestinal bacteria (antibiotics, prebiotics, and probiotics) and therapy directed at TNF$\alpha$ or IL-12.

**PHARMACOTHERAPY FOR IBD.** Medical therapy for IBD is problematic. Because no unique abnormality has been identified, therapy for IBD seeks to dampen the generalized inflammatory response. Regrettably, no agent can reliably accomplish this, and the response of an individual patient to a given medicine may be limited and unpredictable. Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications such as fistulas. The major therapeutic options are considered below and summarized at chapter’s end by Table 47–1.

**Table 47–1**

Medications Commonly Used to Treat Inflammatory Bowel Disease
First-line therapy for mild to moderate ulcerative colitis generally involves mesalamine (5-aminosalicylic acid, or 5-ASA). The archetype for this class of medications is sulfasalazine (AZULFIDINE), which consists of 5-ASA linked to sulfapyridine by an azo bond (Figure 47–2).

**Figure 47–2** Generation of mesalamine from the prodrug sulfasalazine. The red N atoms indicate the diazo linkage that is cleaved in the colon to generate the active moiety.

**MESALAMINE (5-ASA)-BASED THERAPY**
Sulfasalazine is an oral prodrug that effectively delivers 5-ASA to the distal GI tract. The azo linkage in sulfasalazine prevents absorption in the stomach and small intestine, and the individual components are not liberated for absorption until colonic bacteria cleave the bond. 5-ASA is the therapeutic moiety, with little, if any, contribution by sulfapyridine. Although 5-ASA is a salicylate, its therapeutic effect does not appear to be related to cyclooxygenase inhibition; indeed, traditional nonsteroidal anti-inflammatory drugs may exacerbate IBD. Many potential sites of action (effects on immune function and inflammation) have been demonstrated in vitro for either sulfasalazine or mesalamine (inhibition of the production of IL-1 and TNFα, inhibition of the lipoxygenase pathway, scavenging of free radicals and oxidants, and inhibition of NFκB, a transcription factor pivotal to production of inflammatory mediators), however, specific mechanisms of action have not been identified.

Although not active therapeutically, sulfapyridine causes many of the adverse effects observed in patients taking sulfasalazine. To preserve the therapeutic effect of 5-ASA without the adverse effects of sulfapyridine, several second-generation 5-ASA compounds have been developed (Figures 47–2, 47–3, and 47–4). They are divided into 2 groups: prodrugs and coated drugs. Prodrugs contain the same azo bond as sulfasalazine but replace the linked sulfapyridine with either another 5-ASA (olsalazine, DIPENTUM) or an inert compound (balsalazide, COLAZIDE). The alternative approaches employ either a delayed-release formulation (PENTASA) or a pH-sensitive coating (ASACOL; LIALDA/MEZAVANT). Delayed-release mesalamine is released throughout the small intestine and colon, whereas pH-sensitive mesalamine is released in the terminal ileum and colon. These different distributions of drug delivery have potential therapeutic implications.
Oral sulfasalazine is effective in patients with mild or moderately active ulcerative colitis, with response rates of 60-80%. The usual dose is 4 g/day in 4 divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/day can be used but cause an increased incidence of side effects. For patients with severe colitis, sulfasalazine is of less certain value, even though it is often added as an adjunct to systemic glucocorticoids. The drug plays a useful role in preventing relapses once remission has been achieved. Because they lack the dose-related side effects of sulfapyridine, the newer formulations can be used to provide higher doses of mesalamine with some improvement in disease control. The usual doses to treat active disease are 800 mg 3 times a day for ASACOL and 1 g 4 times a day for PENTASA. Lower doses are used for maintenance (e.g., ASACOL, 800 mg twice a day). The efficacy of 5-ASA preparations (e.g., sulfasalazine) in Crohn disease is less striking, with modest benefit at best in controlled trials. The second-
generation 5-ASA prodrugs (e.g., olsalazine and balsalazide) do not have a significant effect in small-bowel Crohn disease.

Topical preparations of mesalamine suspended in a wax matrix suppository (ROWASA) or in a suspension enema (CANASA) are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical hydrocortisone in this setting, with response rates of 75-90%. Mesalamine enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 h; the suppository (500 mg) should be used 2 to 3 times a day with the objective of retaining it for at least 3 h. Response to local therapy with mesalamine may occur within 3-21 days; however, the usual course of therapy is from 3-6 weeks. Once remission has occurred, lower doses are used for maintenance.

ADME. About 20-30% of orally administered sulfasalazine is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg mesalamine for every gram of the parent compound. Thereafter, the individual components of sulfasalazine follow different metabolic pathways. Sulfapyridine is absorbed rapidly from the colon. It undergoes extensive hepatic metabolism, including acetylation and hydroxylation, conjugation with glucuronic acid, and excretion in the urine. The acetylation phenotype of the patient determines plasma levels of sulfapyridine and the probability of side effects; rapid acetylators have lower systemic levels of the drug and fewer adverse effects. Only 25% of mesalamine is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and liver and then excreted in the urine. Intraluminal concentrations of mesalamine therefore are very high (~1500 μg/mL).

The pH-sensitive coatings of ASACOL (EUDAGRIT) and LIALDA/MEZAVANT limit gastric and small intestinal absorption of 5-ASA. The pharmacokinetics of PENTASA differ somewhat. The ethylcellulose-coated microgranules are released in the upper GI tract as discrete prolonged-release units of mesalamine. Acetylated mesalamine can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, but some intact
microgranules also can be detected in the colon. Because it is released in the small bowel, a greater fraction of PENTASA is absorbed systemically compared with the other 5-ASA preparations.

ADVERSE EFFECTS. Side effects of sulfasalazine occur in 10-45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose related, including headache, nausea, and fatigue; these can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. Sulfasalazine reversibly decreases the number and motility of sperm but does not impair female fertility. Sulfasalazine inhibits intestinal folate absorption and is usually administered with folate. The newer mesalamine formulations generally are well tolerated. Headache, dyspepsia, and skin rash are the most common. Diarrhea appears to be particularly common with olsalazine (occurring in 10-20% of patients). Nephrotoxicity, although rare, is a more serious concern. Mesalamine has been associated with interstitial nephritis; renal function should be monitored in all patients receiving these drugs. Both sulfasalazine and its metabolites cross the placenta but have not been shown to harm the fetus. The newer formulations also appear to be safe in pregnancy.

GLUCOCORTICOIDS

The effects of glucocorticoids on the inflammatory response are numerous (see Chapters 38 and 42). Glucocorticoids are indicated for moderate to severe IBD. Patients with IBD segregate into 3 general groups with respect to their response to glucocorticoids:

- **Glucocorticoid-responsive patients** improve clinically within 1-2 weeks and remain in remission as the steroids are tapered and then discontinued.
- **Glucocorticoid-dependent patients** respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered.
- **Glucocorticoid-unresponsive patients** do not improve even with prolonged high-dose steroids.

Approximately 40% of patients are glucocorticoid responsive, 30-40% have only a partial response or become glucocorticoid dependent, and 15-20% of patients
do not respond to therapy. Glucocorticoids sometimes are used for prolonged periods to control symptoms in corticosteroid-dependent patients. However, the failure to respond to steroids with prolonged remission (i.e., a disease relapse) should prompt consideration of alternative therapies, including immunosuppressive agents and anti-TNFα therapies. Glucocorticoids are not effective in maintaining remission in either ulcerative colitis or Crohn disease.

Initial doses in IBD are 40-60 mg of prednisone or equivalent per day; higher doses generally are no more effective. The glucocorticoid dose in IBD is tapered over weeks to months. Efforts should be made to minimize the duration of therapy. Glucocorticoids induce remission in most patients with either ulcerative colitis or Crohn disease. Most patients improve substantially within 5 days of initiating treatment; others require treatment for several weeks before remission occurs. For more severe cases, glucocorticoids such as methylprednisolone or hydrocortisone are given intravenously. Some experts believe that ACTH is more effective in patients who have not previously received any steroids.

Glucocorticoid enemas are useful mainly in patients whose disease is limited to the rectum and left colon. Hydrocortisone is available as a retention enema (100 mg/60 mL), and the usual dose is one 60-mL enema per night for 2 or 3 weeks. Patients with distal disease usually respond within 3-7 days. Absorption, although less than with oral preparations, is still substantial (up to 50-75%). Hydrocortisone also can be given once or twice daily as a 10% foam suspension (CORTIFOAM) that delivers 80 mg hydrocortisone per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining fluid.

**Budesonide** (ENTOCORT ER) is an enteric-release form of a synthetic steroid that is used for ileocecal Crohn disease. It is proposed to deliver adequate steroid therapy to a specific portion of inflamed gut while minimizing systemic side effects owing to extensive first-pass hepatic metabolism to inactive derivatives. Topical therapy (e.g., enemas and suppositories) also is effective in treating colitis limited to the left side of the colon. Budesonide (9 mg/day for up to 8 weeks followed by 6 mg/day for maintenance of remission for up to 3 months) is effective in the acute management of mild-to-moderate exacerbations of Crohn disease.
**IMMUNOSUPPRESSIVE AGENTS**

Several drugs developed for cancer chemotherapy or as immunosuppressive agents in organ transplants have been adapted for treatment of IBD. Clinical experience has defined specific roles for each of these agents as mainstays in the pharmacotherapy of IBD. However, their potential for serious adverse effects mandates a careful assessment of risks and benefits in each patient.

**THIOPURINE DERIVATIVES**

The cytotoxic thiopurine derivatives mercaptopurine (6-MP, PURINETHOL) and azathioprine (IMURAN) (see Chapters 35 and 61) are used to treat patients with severe IBD or those who are steroid-resistant or steroid-dependent. These thiopurines impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: azathioprine is converted to mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides, the putative active moieties (Figure 47–5).

![Metabolism of azathioprine and 6-mercaptopurine](image)

**Figure 47–5** *Metabolism of azathioprine and 6-mercaptopurine.* HGPRT, hypoxanthine–guanine phosphoribosyl transferase; TPMT, thiopurine methyltransferase; XO, xanthine oxidase. The activities of these enzymes vary among humans due to differential expression of genetic polymorphisms, explaining responses and side effects when azathioprine–mercaptopurine therapy is employed (see text for details).
These drugs generally are used interchangeably with appropriate dose adjustments, typically azathioprine (2-2.5 mg/kg) or mercaptopurine (1.5 mg/kg). Because of concerns about side effects, these drugs were used initially only in Crohn disease, which lacks a surgical curative option. They now are considered equally effective in Crohn disease and ulcerative colitis. These drugs effectively maintain remission in both diseases; they also may prevent or delay recurrence of Crohn disease after surgical resection. Finally, they are used successfully to treat fistulas in Crohn disease. The clinical response to azathioprine or mercaptopurine may take weeks to months, such that other drugs with a more rapid onset of action (e.g., mesalamine, glucocorticoids, or infliximab) are preferred in the acute setting.

In general, physicians who treat IBD believe that the long-term risks of azathioprine–mercaptopurine are lower than those of steroids. Thus, these purines are used in glucocorticoid-unresponsive or glucocorticoid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. Additionally, patients who have not responded adequately to mesalamine but are not acutely ill may benefit by conversion from glucocorticoids to immunosuppressive drugs. Immunosuppressives therefore may be viewed as steroid-sparing agents.

Adverse effects of azathioprine–mercaptopurine can be divided into 3 general categories: idiosyncratic, dose related, and possible. Adverse effects occur at any time after initiation of treatment and can affect up to 10% of patients. The most serious idiosyncratic reaction is pancreatitis, which affects ~5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally, whereas nausea and vomiting are somewhat more frequent. The major dose-related adverse effect is bone marrow suppression, and circulating blood counts should be monitored closely when therapy is initiated and at less frequent intervals during maintenance therapy. Elevations in liver function tests also may be dose related. The serious adverse effect of cholestatic hepatitis is relatively rare. Immunosuppressive regimens given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin’s lymphoma.
METABOLISM AND PHARMACOGENETICS. Favorable responses to azathioprine–mercaptopurine are seen in up to two-thirds of patients. Mercaptopurine has 3 metabolic fates (see Figure 47–5):

- Conversion by xanthine oxidase to 6-thiouric acid
- Metabolism by thiopurine methyltransferase (TPMT) to 6-methyl-mercaptopurine (6-MMP)
- Conversion by hypoxanthine–guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides and other metabolites

The relative activities of these different pathways may explain, in part, individual variations in efficacy and adverse effects of these immunosuppressives.

The plasma t\(\text{1/2}\) of mercaptopurine is limited by its relatively rapid (i.e., within 1-2 h) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug’s fate. Approximately 80% of the U.S. population has what is considered “normal” metabolism, whereas 1 in 300 individuals has minimal TPMT activity. In the latter setting, mercaptopurine metabolism is shifted away from 6-methyl-mercaptopurine and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, ~10% of the population are rapid metabolizers. In these individuals, mercaptopurine is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Pharmacogenetic typing can guide therapy (see Chapter 7).

Xanthine oxidase in the small intestine and liver converts mercaptopurine to thiouric acid, which is inactive as an immunosuppressant. Inhibition of xanthine oxidase by allopurinol diverts mercaptopurine to more active metabolites such as 6-thioguanine and increases both immunosuppressant and potential toxic effects. Thus, patients on mercaptopurine should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose
should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

**METHOTREXATE**

Methotrexate is reserved for patients whose IBD is either steroid-resistant or steroid-dependent. In Crohn disease, it both induces and maintains remission. Therapy of IBD with methotrexate differs somewhat from its use in other autoimmune diseases. Most importantly, higher doses (e.g., 15-25 mg/week) are given parenterally. The increased efficacy with parenteral administration may reflect the unpredictable intestinal absorption at higher doses of methotrexate.

*Methotrexate* inhibits dihydrofolate reductase, thereby blocking DNA synthesis and causing cell death (*see Figure 61–4*). The anti-inflammatory effects of methotrexate may involve mechanisms in addition to inhibition of dihydrofolate reductase.

**CYCLOSPORINE**

Cyclosporine is an inhibitor of calcineurin and is a potent immunomodulator used most frequently after organ transplantation (*see Figure 35–1* and text). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication. Cyclosporine is effective in patients with severe ulcerative colitis who have failed to respond adequately to glucocorticoid therapy.

Between 50% and 80% of these severely ill patients improve significantly (generally within 7 days) in response to intravenous cyclosporine (2-4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of cyclosporine levels is necessary to maintain a therapeutic level in whole blood between 300 and 400 ng/mL. Oral cyclosporine is less effective as maintenance therapy in Crohn disease, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with NEORAL or GENGRAF (formulations of
cyclosporine with increased oral bioavailability) may be more effective. Cyclosporin can be used to treat fistulous complications of Crohn disease. A significant rapid response to intravenous cyclosporine has been observed; however, frequent relapses accompany oral cyclosporine therapy, and other medical strategies are required to maintain fistula closure. Thus, calcineurin inhibitors generally are used to treat specific problems over a short term while providing a bridge to longer-term therapy.

Other immunomodulators that are being evaluated in IBD include the calcineurin inhibitor tacrolimus (FK 506, Prograf), mycophenolate mofetil and mycophenolate (CellCept, Myfortic), inhibitors of inosine monophosphate dehydrogenase to which lymphocytes are especially susceptible (see Chapter 35).

BIOLOGICAL THERAPIES

CROHN DISEASE

*Infliximab* (Remicade, cA2) is a chimeric immunoglobulin (25% mouse, 75% human) that binds to and neutralizes TNFα, 1 of the principal cytokines mediating the Th1 immune response characteristic of Crohn disease (see Figure 47–1).

Although infliximab was designed specifically to target TNFα, it may have more complex actions. Infliximab binds membrane-bound TNFα and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, infliximab may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma t½ of 8-10 days, may explain the prolonged clinical effects of infliximab. Infliximab (5 mg/kg infused intravenously at intervals of several weeks to months) decreases the frequency of acute flares in approximately two-thirds of patients with moderate to severe Crohn disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn disease. Emerging evidence also supports its efficacy in maintaining remission and in preventing recurrence of fistulas. The combination of infliximab and azathioprine is more effective than infliximab alone in induction of remission and mucosal healing in steroid-resistant patients. Infliximab has also proven to be an effective treatment for refractory ulcerative
colitis.

Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion. Antibodies to infliximab can decrease its clinical efficacy. Strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy. Infliximab therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or other granulomatous infections with subsequent dissemination. The FDA recommends that candidates for infliximab therapy be tested for latent tuberculosis with purified protein derivative; patients testing positive should be treated prophylactically with isoniazid. Infliximab is contraindicated in patients with severe congestive heart failure. There is concern about a possible increased incidence of non-Hodgkin lymphoma, but a causal role has not been established. The significant cost of infliximab is an important consideration for some patients.

*Adalimumab* (HUMIRA) is a humanized recombinant human IgG1 monoclonal antibody against TNFα. It is effective in inducing remission in mild to moderate, severe, and fistulizing Crohn disease.

*Certolizumab pegol* (CIMZIA) is a pegylated humanized fragment antigen binding (Fab) that binds TNFα. It is approved in the U.S. for the treatment of Crohn disease. With both adalimumab and certolizumab pegol, immunogenicity appears to be less of a problem than that associated with infliximab.

*Natalizumab* (TYSABRI) is a humanized monoclonal antibody against α4-integrin (also known as VLA-4). Binding of the antibody to this adhesion molecule will reduce extravasation of certain leukocytes (e.g., lymphocytes), preventing them from migrating to sites of inflammation where they may exacerbate tissue injury.

Natalizumab is approved in the U.S. for induction and maintenance of remission of moderate to severe Crohn disease. Natalizumab is contraindicated for use with
other immunomodulators; patients taking natalizumab for the treatment of Crohn disease should have their doses of corticosteroids reduced before starting natalizumab treatment.

*Etanercept* (ENBREL), an anti-TNFα agent, is a fusion protein of the ligand-binding portion of the TNFα receptor and the Fc portion of human IgG1. This construct binds to TNFα and blocks its biologic effects but is ineffective in Crohn disease.

**Ulcerative Colitis**
The role of anti-TNF therapies for steroid-refractory or steroid-dependent ulcerative colitis is less clear. Large controlled clinical trials have demonstrated that anti-TNF agents significantly reduce the severity of the inflammation. Unlike Crohn disease, ulcerative colitis is cured with surgery; thus, the cost and serious adverse events associated with anti-TNF therapy need to be balanced with the effectiveness of the drug at preventing the need for colectomy.

**ANTIBIOTICS AND PROBIOTICS**
A balance normally exists in the GI tract among the mucosal epithelium, the normal gut flora, and the immune response. Colonic bacteria may either initiate or perpetuate the inflammation of IBD, and recent studies have implicated specific bacterial antigens in the pathogenesis of Crohn disease. Thus, certain bacterial strains may be either pro- (e.g., *Bacteroides*) or anti-inflammatory (e.g., *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used most prominently in Crohn disease.

Antibiotics can be used as:

- Adjunctive treatment along with other medications for active IBD
- Treatment for a specific complication of Crohn disease
- Prophylaxis for recurrence in postoperative Crohn disease

*Metronidazole, ciprofloxacin,* and *clarithromycin* are the antibiotics used most frequently. Crohn disease-related complications that may benefit from antibiotic
therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small-bowel bacterial overgrowth secondary to partial small-bowel obstruction, secondary infections with organisms such as *Clostridium difficile*, and postoperative complications. More recently, *probiotics* have been used to treat specific clinical situations in IBD. Probiotics are mixtures of putatively beneficial lyophilized bacteria given orally. Several studies have provided evidence for beneficial effects of probiotics in ulcerative colitis and pouchitis. However, the utility of probiotics as a primary therapy for IBD remains unclear.

**SUPPORTIVE THERAPY IN IBD**

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. Oral iron, folate, and vitamin B<sub>12</sub> should be administered as indicated. Loperamide or diphenoxylate (see Chapter 46) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. Cholestyramine can be used to prevent bile salt–induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (dicyclomine hydrochloride, etc.; Chapter 9) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected.

**THERAPY OF IBD DURING PREGNANCY**

IBD is a chronic disease that affects women in their reproductive years. In general, decreased disease activity increases fertility and improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease. Mesalamine and glucocorticoids are FDA Category B drugs that are used frequently in pregnancy and generally are considered safe, whereas methotrexate is clearly contraindicated in pregnant patients. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives.
SUMMARY OF AVAILABLE DRUG THERAPIES

Table 47–1 summarizes the medications routinely used to treat IBD.
Section VII
Chemotherapy of Microbial Diseases
ANTIMICROBIAL CHEMOTHERAPY

Microorganisms of medical importance fall into 4 categories: bacteria, viruses, fungi, and parasites. Likewise, antibiotics are broadly classified as (1) antibacterial, (2) antiviral, (3) antifungal, and (4) antiparasitic agents. Antimicrobial molecules should be viewed as ligands whose receptors are microbial proteins. The microbial proteins targeted by the antibiotic are essential components of biochemical reactions in the microbes, and interference with these physiological pathways kills the microorganisms. The biochemical processes commonly inhibited include cell wall synthesis in bacteria and fungi, cell membrane synthesis, synthesis of 30s and 50s ribosomal subunits, nucleic acid metabolism, function of topoisomerases, viral proteases, viral integrases, viral envelope fusion proteins, folate synthesis in parasites, and parasitic chemical detoxification processes.

Classification of an antibiotic is based on:

- The class and spectrum of microorganisms it kills
- The biochemical pathway it interferes with
- The chemical structure of its pharmacophore

The relationship between antimicrobial concentration and effect on a population of organisms is modeled using the standard Hill-type curve for receptor and agonist (see Chapters 2 and 3), characterized by 3 parameters: the inhibitory concentration 50, or IC$_{50}$ (also termed EC$_{50}$), a measure of the antimicrobial agent’s potency; the maximal effect, E$_{max}$; and H, the slope of the curve, or Hill factor. In antimicrobial therapy, the relationship is often expressed as an inhibitory sigmoid E$_{max}$ model, to take into account the control bacterial population without treatment (E$_{con}$) as a fourth parameter (Equation 48–1 and Figure 48–1), where E is the effect as measured by microbial burden.
THE PHARMACOKINETIC BASIS OF ANTIMICROBIAL THERAPY

PENETRATION OF ANTIMICROBIAL AGENTS INTO ANATOMIC COMPARTMENTS. In many infections, the pathogen causes disease not in the whole body, but in specific organs. Antibiotics are often administered far away from these sites of infection. Therefore, in choosing an antimicrobial agent for therapy, a crucial consideration is whether the drug can penetrate to the site of infection.

For example, the antibiotic levofloxacin achieves skin tissue/plasma peak concentration ratio of 1.4, epithelial lining fluid to plasma ratio of 2.8, and urine-to-plasma ratios of 67. In clinical trials with levofloxacin, the failure rate of therapy was 0% in patients with urinary tract infections, 3% in patients with pulmonary infections, and 16% in patients with skin and soft tissue infections. Clearly, the poorer the penetration into the anatomical compartment, the higher the likelihood of failure. Penetration of a drug into an anatomical compartment depends on the physical barriers that the molecule must traverse, the chemical properties of the drug, and the presence of multidrug transporters. The physical

Figure 48–1 Inhibitory sigmoid $E_{\text{max}}$ curve. CFU, colony-forming unit.

$$E = E_{\text{con}} - E_{\text{max}} \times \frac{[IC]}{[IC] + [IC_{\text{so}}]} \quad \text{(Equation 48–1)}$$
barriers are usually due to layers of epithelial and endothelial cells, and the type of junctions formed between these cells. Penetration across this physical barrier generally correlates with the octanol-water partition coefficient of the antimicrobial agent, a measure of its hydrophobicity. Hydrophobic molecules get concentrated in the cell membrane bilayer, whereas hydrophilic molecules tend to concentrate in the blood, the cytosol, and other aqueous compartments (see Figure 2–3).

![Response vs. Antimicrobial](image)

**Figure 48–3** Changes in sigmoid $E_{\text{max}}$ model with increases in drug resistance. Increase in resistance may show changes in $IC_{50}$ (panel A: the $IC_{50}$ increases from 70 [orange line] to 100 [green line], to 140 [blue line]) or decrease in $E_{\text{max}}$ (panel B: efficacy decreases from full response [orange line] to 70% [green line]).

Membrane transporters comprise another barrier; they actively export drugs from the cellular or tissue compartment back into the blood (see Chapter 5). A
well-known example is the *P-glycoprotein*. Although the octanol-water partition coefficient would favor lipophilic molecules to transverse across cell barriers, P-glycoprotein exports structurally unrelated amphiphilic and lipophilic molecules of 3-4 kDa, reducing their effective penetration. Antimicrobial agents that are P-glycoprotein substrates include HIV protease inhibitors, the antiparasitic agent ivermectin, the antibacterial agent telithromycin, and the antifungal agent itraconazole.

The CNS is guarded by the *blood-brain barrier*. The movement of antibiotics across the blood-brain barrier is restricted by tight junctions that connect endothelial cells of cerebral micro-vessels to one another in the brain parenchyma, as well as by protein transporters. Antimicrobial agents that are polar at physiological pH generally penetrate poorly; some, such as *penicillin G*, are actively transported out of the cerebrospinal fluid (CSF) and achieve CSF concentrations of only 0.5-5% of that achieved in plasma. However, the integrity of the blood-brain barrier is diminished during active bacterial infection; tight junctions in cerebral capillaries open, leading to a marked increase in the penetration of even polar drugs.

The eye, the epithelial lining fluid of the lung, and biofilms and vegetations on artificial heart valves and indwelling catheters pose special problems for drug penetration and effective therapy.

**PHARMACOKINETIC COMPARTMENTS.** Once an antibiotic has penetrated to the site of infection, it may be subjected to processes of elimination and distribution that differ from those in the blood. These sites where the concentration-time profiles differ from each other are considered separate pharmacokinetic compartments, thus, the human body is viewed as multicompartmental. The concentration of antibiotic within each compartment is assumed to be homogeneous. The model is also defined as *open or not open*; an open model is one in which the drug is eliminated out of the body from the compartment (e.g., kidneys). The order of the process must also be specified (see Chapter 2): a first-order process is directly correlated to concentration of drug D, or \([D]^1\), as opposed to zero order, which is independent of \([D]\) and reflects a process that is saturated at ambient levels of D.

Suppose a patient has pneumonia with the pathogen in the lung epithelial lining fluid (ELF). The patient ingests an antibiotic that is absorbed via the GI tract (g)
into blood or central compartment (compartment 1), as a first-order input. In this process, the transfer constant from the GI tract to central compartment is termed the *absorption constant* and is designated $k_a$. The antibiotic in the central compartment is then delivered to the lungs where it penetrates into the ELF (compartment 2). However, it also penetrates into other tissues of the body peripheral to the site of infection, termed the *peripheral compartment* (compartment 3). Thus, we have 4 compartments (including $g$, a specific compartment, the GI tract, from the set of initial absorption compartments labeled “p” in Figure 48–2), each with its own concentration-time profile, as shown in Figure 48–2. The penetration of drug from compartment 1 to 2 is based on the penetration factors discussed earlier and is defined by the transfer constant $k_{12}$. However, the drug also redistributes from compartment 2 back to 1, defined by transfer constant $k_{21}$. A similar process between the blood and peripheral tissues leads to transfer constants $k_{13}$ and $k_{31}$. The drug may also be lost from the body (i.e., open system) via the lungs and other peripheral tissues (e.g., kidneys or liver) at a rate proportional to the concentration.

![Diagrammatic depiction of a multicompartment model.](Figure 48–2)

Antibiotic concentrations within each compartment change with time (the changes are described using standard differential equations). If $X$ is the amount of antibiotic in a compartment, SCL the drug clearance, and $V_c$ the volume of central compartment, then equations for absorption compartment (*Equation 48–2*), central compartment (*Equation 48–3*), site of infection or compartment 2
(Equation 48–4), and peripheral compartment (Equation 48–5) are as follows:

\[
\begin{align*}
\frac{dX_1}{dt} &= -k_a \cdot X_1 \\
\frac{dX_2}{dt} &= k_{12} \cdot X_1 - k_{21} \cdot X_2 \\
\frac{dX_3}{dt} &= k_{13} \cdot X_1 - k_{31} \cdot X_3
\end{align*}
\]

Such models have been used in conjunction with population pharmacokinetics to describe and model a plethora of antimicrobials used to treat bacteria, fungi, viruses, and parasites. Recently, the models have been refined to include sub-populations of the pathogen (killed, inhibited, or resistant to the antibiotic) and other refinements described in Chapter 48 of the 12th edition of the parent text.

**POPULATION PHARMACOKINETICS AND VARIABILITY IN DRUG RESPONSE.** When multiple patients are treated with the same dose of a drug, each patient will achieve pharmacokinetic parameters that differ from others. This is termed *between-patient variability*. Even when the same dose is administered to the same patient on 2 separate occasions, the patient may achieve a different concentration-time profile of the drug between the 2 occasions. This is termed *inter-occasion* or *within-patient variability*. The variability is reflected at the level of the compartmental pharmacokinetic parameters such as $k_a$, $k_{12}$, $k_{21}$, SCL, $V_c$, and so on. Even when a recommended dose is administered, the drug may fail to reach a therapeutic concentration in some patients. In other patients, the drug may reach high and toxic concentrations. Such variability could be due to genetic variability. In addition, weight, height, and age also lead to variability. Furthermore, patients may have comorbid conditions such as renal and liver dysfunction, which may lead to variability. Drug interactions are an important source of variability with potentially dangerous consequences (see Chapters 5 and 6). Even when such factors are accounted for, there remains residual variability due to computational noise, assay variability, and unexplainable factors. The common practice of using an “average” value of data or “naive pooling” may prevent recognition of subgroups of patients at risk for therapeutic failure or increased toxicity of antibiotic. Knowledge of covariates associated with pharmacokinetic variability leads to better dose adjustments, or switching therapy from one antibiotic to
another, or changing concomitant medications.

**IMPACT OF SUSCEPTIBILITY TESTING ON SUCCESS OF ANTIMICROBIAL AGENTS**

Once the microbial species causing the disease has been identified, a rational choice of the class of antibiotics likely to work in the patient can be made. The microbiology laboratory then plays a second role, which is to perform susceptibility testing to narrow down the list of possible antimicrobials that could be used.

Millions of individuals across the globe get infected by many different isolates of the same species of pathogen. Evolutionary processes cause each isolate to be slightly different from the next, so that each will have a unique susceptibility to antimicrobial agents. As the microorganisms divide within the patient, they may undergo further evolution. Therefore, we expect that there will be a wide distribution of concentrations of antimicrobial agents that can kill pathogens. Often, this distribution is Gaussian, with a skew that depends on where the patient lives. These factors will affect the shape of the inhibitory sigmoid $E_{\text{max}}$ model curve described by \textbf{Equation 48–1}.

With changes in susceptibility, the sigmoid $E_{\text{max}}$ curve shifts in 1 of 2 basic ways. The first is a shift to the right, an \textit{increase in IC$_{50}$}, as shown in \textbf{Figure 48–3A}. This means that much higher concentrations than before are now needed to show specific effect. Susceptibility tests for bacteria, fungi, parasites, and viruses have been developed to determine whether these shifts have occurred at a sufficient magnitude to warrant higher doses of drug to achieve particular effect. The change in IC$_{50}$ may become so large that it is not possible to overcome the concentration deficit by increasing the antimicrobial dose without causing toxicity to the patient. At that stage, the organism is now “resistant” to the particular antibiotic. A second possible change in the curve is a \textit{decrease in $E_{\text{max}}$} (\textbf{Figure 48–3B}), such that increasing the dose of the antimicrobial agent beyond a certain point will achieve no further effect; i.e., changes in the microbe are such that eradication of the microbe by the particular drug can never be achieved. This occurs because the available target proteins have been reduced or the microbe has developed an alternative pathway to overcome the biochemical inhibition.
**Bacteria.** Dilution tests for bacterial drug susceptibility employ antibiotics in serially diluted drug concentrations on solid agar or in broth medium that contains a culture of the test microorganism. The lowest concentration of the agent that prevents visible growth after 18-24 h of incubation is known as the *minimum inhibitory concentration* (MIC).

**Fungi.** For fungi that are yeasts (i.e., *Candida*), susceptibility testing methods are similar to those used for bacteria. However, the definitions of MIC differ based on drug and the type of yeast, so there are cutoff points of 50% decreases in turbidity compared to controls at 24 h, or 80% at 48 h, or total clearance of the turbidity. Susceptibility tests and MICs for triazoles have been extensively shown to correlate with clinical outcomes.

**Viruses.** In HIV phenotypic assays, the patient’s HIV-RNA is extracted from plasma, and genes for targets of antiretroviral drugs such as reverse transcriptase and protease are amplified. The genes are then inserted into a standard HIV vector that lacks analogous gene sequences to produce a recombinant virus, which is co-incubated with drug of interest in a mammalian cell viability assay. Growth is compared to a standardized wild-type control virus. For HIV reverse transcriptase, e.g., <4-fold increase in IC$_{50}$ is defined as “sensitive,” 4- to 10-fold increase in IC$_{50}$ is “intermediate,” and >10-fold increase is “resistant.” Further use has been made of the viral IC$_{50}$ to establish the inhibitory quotient (IQ). The IQ is the ratio of plasma concentration of antiviral drug to the IC$_{50}$. The phenotypic IQ is the ratio of plasma trough concentration to the IC$_{50}$.

**Parasites.** Susceptibility testing for parasites, especially malaria, has been performed in the laboratory. The tests are similar to the broth tests for bacteria, fungi, and viruses. *Plasmodium* species in the patient’s blood are cultured ex vivo in the presence of different dilutions of antimalarial drug. A sigmoid $E_{\text{max}}$ curve for effect versus drug concentration is used to identify IC$_{50}$ and $E_{\text{max}}$. These tests are primarily used in the research setting and not for individualization of therapy.

**BASIS FOR SELECTION OF DOSE AND DOSING SCHEDULE**

Although susceptibility testing is central to decision making, it does not completely predict patient response. Microorganisms in patients
are exposed to dynamic concentrations of drug, and antibiotics are prescribed at a certain schedule (e.g., 3 times a day) so that there is a periodicity in the fluctuations of drug at the site of infection. Thus, the microbe is exposed to a particular shape of the concentration-time curve, an important determinant of the efficacy of the antibiotic for which we can write 3 corollaries:

1. In determining therapeutic outcomes, it is important to apply knowledge of susceptibility (MIC or EC$_{90}$) of the organism to the antimicrobial agent and index drug exposure to MIC.
2. The optimal dose of the antibiotic for a patient is the dose that achieves IC$_{80}$ to IC$_{90}$ exposures at the site of infection.
3. Optimal microbial kill by the antibiotic may be best achieved by maximizing certain shapes of the concentration-time curve, using the fact that certain dosing schedules maximize the antimicrobial effect (see below).

As an example, consider an antibiotic with a serum $t_{1/2}$ of 3 h that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L, administered with a dosing interval of 24 h (that is, a once-daily schedule). Figure 48–4A depicts the concentration-time curve of the antibiotic, with definitions of peak concentration ($C_{P_{\text{max}}}$), area under the curve (AUC), and the fraction of the dosing interval for which the drug concentration remains above the MIC ($T > \text{MIC}$), as shown. The AUC is a measure of the total concentration of drug and is calculated by taking an integral between 2 time points, 0-24 h (AUC$_{0-24}$) in this case. With a change in the dosing schedule of the same antibiotic amount by splitting it into 3 equal doses administered at 0, 8, and 16 h, the shape of the concentration-time curves changes to that shown in Figure 48–4B. Because the same cumulative dose has been given for the dosing interval of 24 h, the AUC$_{0-24}$will be similar whether it was given once a day or 3 times a day. However, the $C_{P_{\text{max}}}$ will decrease by one-third when the total dose is split into thirds and administered more frequently (see Figure 48–4B). Thus, when a dose is fractionated and administered more frequently, the $C_{P_{\text{max}}}$/MIC ratio decreases. In contrast, the time that the drug concentration persists above MIC ($T > \text{MIC}$) increases with the more frequent dosing schedule.
Figure 48–4 Effect of different dose schedules on shape of concentration-time curve. The total AUC for the fractionated dose in curve B is determined by adding AUC_{0-8h}, AUC_{8-16h}, and AUC_{16-24h}, which adds up to the same AUC_{0-24h} in curve A. The time that the drug concentration exceeds MIC in curve B is also determined by adding up T_{1} MIC, T_{2} MIC, and T_{3} MIC, which results in a fraction greater than that for curve A.

Some classes of antimicrobial agents kill best when concentration persists above MIC for longer durations of the dosing interval. Indeed, increasing the drug concentration beyond 4 and 6 times the MIC does not increase microbial kill. Two good examples are β-lactam antibacterials (e.g., penicillin) and the
antifungal agent 5-fluorocytosine (5-FC). In fact, there are usually good biochemical explanations for this pattern for the drugs. The clinical implication, however, is that a drug optimized by \( T > \text{MIC} \) should be dosed more frequently, or have its \( t_{1/2} \) prolonged by other drugs, so that drug concentrations persist above MIC (or \( \text{EC}_{95} \)) as long as possible. Thus, the effectiveness of penicillin is enhanced when it is given as a continuous infusion. HIV protease inhibitors are often “boosted” with ritonavir; this “boosting” inhibits the metabolism of the protease inhibitors by CYPs 3A4 and 2D6, thereby prolonging time above \( \text{EC}_{95} \).

Conversely, the peak concentration is paramount for some antimicrobial agents. Persistence of concentration above MIC has less relevance for these drugs, meaning that these drugs can be dosed more intermittently. Aminoglycosides are a prime example of this class: they used to be given 3 times a day but are highly effective when given once a day. These \( C_{\text{Pmax}}/\text{MIC} \)-linked drugs are administered less frequently due to their long duration of post-antibiotic effect (PAE). In other words, effect continues long after antibiotic concentrations decline below the MIC. Consider rifampin. The entry of rifampin into \textit{Mycobacterium tuberculosis} increases with increased concentration in the bacillus microenvironment. Once inside the bacteria, the drug’s macrocyclic ring binds the \( \beta \) subunit of DNA-dependent RNA polymerase (\textit{rpoB}) to form a very stable drug-enzyme complex within 10 min, a process not enhanced by longer incubation of drug and enzyme. The PAE of the rifampin is long and concentration dependent.

There is a third group of drugs for which the dosing schedule has no effect on efficacy but the cumulative dose matters. Thus, it is the ratio of total concentration over time (AUC)-to-MIC that matters and not the time that concentration persists above a certain threshold. Antibacterial agents such as daptomycin fall into this class. These agents also have a good PAE. The AUC/\( IC_{50} \) explains why the nucleoside analogue reverse transcriptase inhibitors tenofovir and emtricitabine have been combined into 1 pill, administered once a day for the treatment of AIDS.

The shape of concentration-time curve that optimizes resistance suppression is often different from that which optimizes microbial kill. In many instances, the drug exposure associated with resistance suppression is much higher than for optimal kill. The optimal dose should be designed to achieve a high probability
of exceeding the EC₈₀ microbial PK/PD (pharmacokinetic/pharmacodynamic) index, or index associated with suppression of resistance, given the population pharmacokinetic variability and the MIC distribution of clinical microbe isolates. The population pharmacokinetic variability enables integration of pharmacogenetics, anthropometric measures, and residual variability into the decision to choose optimal dose. Once that has been achieved, the dose schedule is chosen according to whether efficacy is driven by AUC/MIC (or AUC/EC₉₅), Cₚₘₐₓ/MIC, or T > MIC. Duration of therapy is then chosen, based on best available evidence.

**TYPES AND GOALS OF ANTIMICROBIAL THERAPY**

A useful way to organize the types and goals of antimicrobial therapy is to consider where along the disease progression timetable therapy is initiated (Figure 48–5); therapy can be prophylactic, preemptive, empirical, definitive, or suppressive.

*Figure 48–5 Antimicrobial therapy-disease progression timeline.*

**PROPHYLACTIC THERAPY.** Prophylaxis involves treating patients who are not yet infected or have not yet developed disease. The goal of prophylaxis is to prevent infection in some patients or to prevent development of a potentially dangerous disease in those who already have evidence of infection. The main principle behind prophylaxis is targeted therapy.

Prophylaxis is used in immunosuppressed patients such as those with HIV-AIDS
or are post-transplantation and on anti-rejection medications. In these groups of patients, specific antiparasitic, antibacterial, antiviral, and antifungal therapy is administered based on the well-defined pattern of pathogens that are major causes of morbidity during immunosuppression. A risk-to-benefit analysis is used to determine choice and duration of prophylaxis. In AIDS patients, prophylaxis is discontinued when the CD4 count climbs above 200 cells/mm³. Infections for which prophylaxis is given include *Pneumocystis jiroveci*, *Mycobacterium avium-intracellulare*, *Toxoplasma gondii*, *Candida* species, *Aspergillus* species, *Cytomegalovirus*, and other *Herpesviridae*.

**Chemoprophylaxis** is used to prevent wound infections after various surgical procedures. Several factors are important for the use of antibiotics for surgical prophylaxis. First, antimicrobial activity must be present at the wound site at the time of its closure. Thus, infusion of the first antimicrobial dose should begin within 60 min before surgical incision and should be discontinued within 24 h of the end of surgery. Second, the antibiotic must be active against the most likely contaminating microorganisms for that type of surgery. Chemoprophylaxis can be justified in dirty or contaminated surgical procedures (e.g., resection of the colon), where the incidence of wound infections is high. In clean surgical procedures, which account for ~75% of the total, the expected incidence of wound infection is <5%, and antibiotics should not be used routinely. When the surgery involves insertion of a prosthetic implant (e.g., prosthetic valve, vascular graft, prosthetic joint), cardiac surgery, or neurosurgical procedures, the complications of infection are so drastic that most authorities currently agree to chemoprophylaxis for these indications.

Prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorganisms to which they are exposed. This is termed **postexposure prophylaxis**. Examples include rifampin administration to prevent meningococcal meningitis in people who are in close contact with a case, prevention of gonorrhea or syphilis after contact with an infected person, and macrolides after contact with confirmed cases of pertussis. Post-exposure prophylaxis is recommended in those patients inadvertently exposed to HIV infection.

Mother-to-child transmission of HIV and syphilis are important public health problems. Anti-retroviral therapy is administered for HIV prophylaxis during the pregnancy and peripartum periods. Prophylactic therapy for syphilis during
pregnancy is effective in reducing neonatal death and infant neurological, auditory, and bone malformations.

**PRE-EMPTIVE THERAPY.** Pre-emptive therapy is early, targeted therapy in high-risk patients who already have a laboratory or other test indicating that an asymptomatic patient has become infected. The principle is that delivery of therapy prior to development of symptoms (presymptomatic) aborts impending disease, and the therapy is for a short and defined duration.

This has been applied in the therapy for cytomegalovirus after both hematopoietic stem cell transplants and after solid organ transplantation.

**EMPIRICAL THERAPY IN THE SYMPTOMATIC PATIENT.** Once a patient is symptomatic, should the patient be treated immediately? The first consideration in selecting an antimicrobial is to determine if the drug is indicated. *The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.*

The diagnosis may be masked if therapy is started and appropriate cultures are not obtained. Antimicrobial agents are potentially toxic and may promote selection of resistant microorganisms. For some diseases, the cost of waiting a few days for microbiological evidence of infection is low. If the risks of waiting are high, based either on the patient’s immune status or other known risk factors for poor outcome, initiation of optimal empirical antimicrobial therapy should rely on the clinical presentation and clinical experience. The most valuable and time-tested method for immediate identification of bacteria is examination of the infected secretion or body fluid with Gram stain. In malaria-endemic areas, or in travelers returning from such an area, a simple thick and thin blood smear may mean the difference between a patient’s receiving appropriate lifesaving therapy or dying while on wrong therapy for presumed bacterial infection. Similarly, neutropenic patients with fever have high risks of mortality, and, when febrile, they are presumed to have either a bacterial or fungal infection; thus, a broad-spectrum combination of antibacterial and antifungal agents covering common infections encountered in granulocytopenic patients is recommended.
Performance of cultures is still mandatory with a view to modify antimicrobial therapy with culture results.

**DEFINITIVE THERAPY WITH KNOWN PATHOGEN.** Once a pathogen has been isolated and susceptibilities results are available, therapy should be streamlined to a narrow targeted antibiotic. Monotherapy is preferred to decrease the risk of antimicrobial toxicity and selection of antimicrobial-resistant pathogens. Proper antimicrobial doses and dose schedules are crucial to maximizing efficacy and minimizing toxicity. In addition, the duration of therapy should be as short as is necessary.

Combination therapy is an exception, rather than a rule. Once a pathogen has been isolated, there should be no reason to use multiple antibiotics, except when evidence overwhelmingly suggests otherwise. Using 2 antimicrobial agents where one is required leads to increased toxicity and unnecessary damage to the patient’s otherwise protective fungal and bacterial flora. Special circumstances where evidence is in favor of combination therapy include:

- Preventing resistance to monotherapy
- Accelerating the rapidity of microbial kill
- Enhancing therapeutic efficacy by use of synergistic interactions
- Reducing toxicity (i.e., when sufficient efficacy of 1 antibacterial agent can be achieved at doses that are toxic to the patient and a second drug is coadministered to permit lowering dose of first drug)

Clinical situations for which combination therapy is advised include antiretroviral therapy for AIDS, antiviral therapy for hepatitis B and C, the treatment of tuberculosis, *Mycobacterium avium-intracellulare* and leprosy, fixed-dose combinations of antimalarial drugs, the treatment of *Cryptococcus neoformans* with flucytosine and amphotericin B, during empirical therapy for patients with febrile neutropenia, and advanced AIDS with fever. The combination of a sulfonamide and an inhibitor of dihydrofolate reductase, such as trimethoprim, is synergistic owing to the blocking of sequential steps in microbial folate synthesis.
POST-TREATMENT SUPPRESSIVE THERAPY. In some patients, after the initial disease is controlled by the antimicrobial agent, therapy is continued at a lower dose if the infection is not completely eradicated and the immunological or anatomical defect that led to the original infection is still present. This is common in AIDS patients and post-transplant patients, for example. The goal is more as secondary prophylaxis. Nevertheless, risks of toxicity from long durations of the therapy are still real. In this group of patients, the suppressive therapy is eventually discontinued if the patient’s immune system improves.

MECHANISMS OF RESISTANCE TO ANTIMICROBIAL AGENTS

Today, significant resistance is emerging to every major class of antibiotic. Two major factors are associated with emergence of antibiotic resistance: evolution and clinical/environmental practices. Pathogens will evolve to develop resistance to the chemical warfare to which we subject them. This evolution is mostly aided by poor therapeutic practices by healthcare workers, as well as indiscriminant use of antibiotics for agricultural and animal husbandry purposes.

Antimicrobial resistance development may develop due to:

- Reduced entry of antibiotic into pathogen
- Enhanced export of antibiotic by efflux pumps
- Release of microbial enzymes that destroy the antibiotic
- Alteration of microbial proteins that transform prodrugs to the effective moieties
- Alteration of target proteins
- Development of alternative pathways to those inhibited by the antibiotic

Mechanisms by which such resistance develops can include acquisition of genetic elements that code for the resistant mechanism, mutations that develop under antibiotic pressure, or constitutive induction.
RESISTANCE DUE TO REDUCED ENTRY OF DRUG INTO PATHOGEN. The outer membrane of gram-negative bacteria is a permeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called porins. Absence of, mutation in, or loss of a favored porin channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that slows or abolishes this transport mechanism can confer resistance.

For example, Trypanosoma brucei is treated with suramin and pentamidine during early stages, but with melarsoprol and eflornithine when CNS disease (sleeping sickness) is present. Melarsoprol is actively taken up by trypanosome P2 protein transporter. When the parasite either lacks the P2 transporter, or has a mutant form, resistance to melarsoprol and cross-resistance to pentamidine occur due to reduced uptake.

RESISTANCE DUE TO DRUG EFFLUX. Microorganisms can overexpress efflux pumps and then expel antibiotics to which the microbes would otherwise be susceptible. There are 5 major systems of efflux pumps that are relevant to antimicrobial agents:

- The multidrug and toxic compound extruder (MATE)
- The major facilitator superfamily (MFS) transporters
- The small multidrug resistance (SMR) system
- The resistance nodulation division (RND) exporters
- The ATP binding cassette (ABC) transporters

Efflux pumps are a prominent mechanism of resistance for parasites, bacteria, and fungi. One of the tragic consequences of resistance emergence has been the development of drug resistance by Plasmodium falciparum. Drug resistance to most antimalarial drugs is mediated by an ABC transporter encoded by Plasmodium falciparum multidrug resistance gene 1 (Pfmdr1). Point mutations
in the Pfmdr1 gene lead to drug resistance and failure of chemotherapy.

**RESISTANCE DUE TO DESTRUCTION OF ANTIBIOTIC.** Drug inactivation is a common mechanism of drug resistance. Bacterial resistance to aminoglycosides and to β-lactam antibiotics usually is due to production of an aminoglycoside-modifying enzyme or β-lactamase, respectively.

**RESISTANCE DUE TO REDUCED AFFINITY OF DRUG TO ALTERED TARGET STRUCTURE.** Common consequences of single point and multiple point mutations are alterations in amino acid composition and conformation of the target protein. This change leads to a reduced affinity of drug for its target, or of a prodrug for the enzyme that converts the prodrug to active drug.

Such alterations may be due to mutation of the natural target (e.g., fluoroquinolone resistance), target modification (e.g., ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (e.g., staphylococcal methicillin resistance caused by production of a low-affinity penicillin-binding protein). In HIV, resistance mutations associated with reduced affinity are encountered in protease inhibitors, integrase inhibitors, fusion inhibitors, and nonnucleoside reverse transcriptase inhibitors. Similarly, point mutations in the β-tubulin gene of worms and protozoa lead to modification of the tubulin and resistance to benzimidazoles.

**DRUG DEPENDENCE IN BACTERIA.** An uncommon situation occurs when an organism not only becomes resistant to an antimicrobial agent but subsequently starts requiring it for growth.

Enterococcus, which easily develops vancomycin resistance, can, after prolonged exposure to the antibiotic, develop vancomycin-requiring strains.

**RESISTANCE DUE TO ENHANCED EXCISION OF INCORPORATED DRUG.** Nucleoside reverse transcriptase inhibitors such as zidovudine are 2′-deoxyribonucleoside analogs that
are converted to their 5′-triphosphate form and compete with natural nucleotides. These drugs are incorporated into the viral DNA chain and cause chain termination. When resistance emerges via mutations at a variety of points in the reverse transcriptase gene, phosphorolytic excision of the incorporated chain-terminating nucleoside analog is enhanced.

**HETERO-RESISTANCE AND VIRAL QUASI-SPECIES.** Hetero-resistance is said to be present when a subset of the total microbial population is resistant, despite the total population being considered susceptible on testing. A subclone that has alterations in genes associated with drug resistance is expected to reflect the normal mutation rates and occur at between $10^{-6}$ and $10^{-5}$ colonies.

In bacteria, hetero-resistance has been described especially for vancomycin in *Staphylococcus aureus*, vancomycin in *Enterococcus faecium*, colistin in *Acinetobacter baumannii-calcoaceticus*, rifampin, isoniazid, and streptomycin in *M. tuberculosis*, and penicillin in *Streptococcus pneumoniae*. Increased therapeutic failures and mortality may occur in patients with hetero-resistant staphylococci and *M. tuberculosis*. In fungi, hetero-resistance leading to clinical failure has been described for fluconazole in *Cryptococcus neoformans* and *Candida albicans*.

In viruses, replication is more error prone than replication in bacteria and fungi. Viral evolution under drug and immune pressure occurs relatively easily, commonly resulting in variants or quasi-species that may contain drug-resistant subpopulations. This is not often termed hetero-resistance, but the principle is the same as described for bacteria and fungi. These minority quasi-species that are resistant to antiretroviral agents are associated with failure of antiretroviral therapy.

**EVOLUTIONARY BASIS OF RESISTANCE EMERGENCE**

**DEVELOPMENT OF RESISTANCE VIA MUTATION SELECTION.** Mutation and antibiotic selection of the resistant mutant are the molecular basis for resistance for many bacteria,
viruses, and fungi. Mutations may occur in the gene encoding

- The target protein, altering its structure so that it no longer binds the drug
- A protein involved in drug transport
- A protein important for drug activation or inactivation
- In a regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme

*Mutations are not caused by drug exposure. They are random events that confer a survival advantage when drug is present. Any large population of drug susceptible bacteria is likely to contain rare mutants that are only slightly less susceptible than the parent. However, suboptimal dosing strategies lead to selective kill of the more susceptible population, which leaves the resistant isolates to flourish.*

In some instances, a single-step mutation results in a high degree of resistance. In other circumstances, however, sequential acquisition of more than 1 mutation leads to clinically significant resistance. As an example, the combination of pyrimethamine and sulfadoxine inhibits Plasmodium falciparum’s folate biosynthetic pathway via inhibition of dihydrofolate reductase (DHFR) by the pyrimethamine and inhibition of dihydropteroate synthetase (DHPS) by sulfadoxine. Clinically meaningful resistance occurs when there is a single point mutation in the DHPS gene accompanied by at least a double mutation in the DHFR gene.

**HYPERMUTABLE PHENOTYPES.** Protecting genetic information from disintegrating and also maintaining flexibility sufficient for genetic changes that lead to adaptation to the environment are essential to life. This is accomplished principally by the insertion of the correct base pair by DNA polymerase III, proofreading by the polymerase, and postreplicative repair. The development of a defect in any of these repair mechanisms leads to mutations in many genes; such isolates are termed *mutator (Mut) phenotypes* and may include mutations in genes causing antibiotic resistance.

This second-order selection of hypermutable (mutator) alleles based on
alterations in DNA repair genes has been implicated in the emergence of multidrug resistant strains of *M. tuberculosis* Beijing genotype.

**RESISTANCE BY EXTERNAL ACQUISITION OF GENETIC ELEMENTS.** Drug resistance may be acquired by mutation and selection, with passage of the trait *vertically* to daughter cells. For mutation and selection to be successful in generating resistance, the mutation cannot be lethal and should not appreciably alter virulence. For the trait to be passed on, the original mutant or its progeny also must disseminate and replicate.

Drug resistance more commonly is acquired by *horizontal transfer* of resistance determinants from a donor cell, often of another bacterial species, by *transduction, transformation, or conjugation*. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain or by subsequent transfers to other susceptible recipient strains. Horizontal transfer of resistance offers several advantages over mutation selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher; the gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells; and the resistance gene can be eliminated when it no longer offers a selective advantage.

**HORIZONTAL GENE TRANSFER.** Horizontal transfer of resistance genes is facilitated by mobile genetic elements that include plasmids and transducing phages. Other mobile elements—transposable elements, integrons, and gene cassettes—also participate in the process. *Transposable elements* are of 3 general types: insertion sequences, transposons, and transposable phages. Only insertion sequences and transposons are important for resistance.

*Insertion sequences* are short segments of DNA encoding enzymatic functions (e.g., transposase and resolvase) for site-specific recombination with inverted repeat sequences at either end. They can copy themselves and insert themselves into a chromosome or a plasmid. Insertion sequences do not encode resistance, but they function as sites for integration of other resistance-encoding elements
Transposons are insertion sequences that also code for other functions, 1 of which can be drug resistance. Because transposons move between chromosome and plasmid, the resistance gene can “hitchhike” with a transferable element out of the host and into a recipient. Transposons are mobile elements that excise and integrate in the bacterial genomic or plasmid DNA. Integrons are not formally mobile and do not copy themselves, but they encode an integrase and provide a specific site into which mobile gene cassettes integrate. Gene cassettes encode resistance determinants, usually lacking a promoter, with a downstream repeat sequence. The integrase recognizes this repeat sequence and directs insertion of the cassette into position behind a strong promoter that is present on the integron. Integrons may be located within transposons or in plasmids, and therefore may be mobilizable, or located on the chromosome.

Transduction is acquisition of bacterial DNA from a phage (a virus that propagates in bacteria) that has incorporated DNA from a previous host bacterium within its outer protein coat. If the DNA includes a gene for drug resistance, the newly infected bacterial cell may acquire resistance. Transduction is particularly important in the transfer of antibiotic resistance among strains of S. aureus. Transformation is the uptake and incorporation into the host genome by homologous recombination of free DNA released into the environment by other bacterial cells. Transformation is the molecular basis of penicillin resistance in pneumococci and Neisseria. Conjugation is gene transfer by direct cell-to-cell contact through a sex pilus or bridge. This mechanism for the spread of antibiotic resistance is important because multiple resistance genes can be transferred in a single event. Conjugation with genetic exchange between nonpathogenic and pathogenic microorganisms probably occurs in the GI tracts of humans and animals. The efficiency of transfer is low; however, antibiotics can exert a powerful selective pressure to allow emergence of the resistant strain. Genetic transfer by conjugation is common among gram-negative bacilli, and resistance is conferred on a susceptible cell as a single event. Enterococci also contain a broad range of host-range conjugative plasmids that are involved in the transfer and spread of resistance genes among gram-positive organisms.
Malaria affects about a quarter of a billion people and leads to almost 900,000 deaths annually. This disease is caused by infection with single-celled protozoan parasites of the genus *Plasmodium*. Five *Plasmodium* spp. are known to infect humans: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. *P. falciparum* and *P. vivax* cause most of the malarial infections worldwide. *P. falciparum* accounts for the majority of the burden of malaria in sub-Saharan Africa and is associated with the most severe disease. *P. vivax* accounts for half of the malaria burden in South and East Asia and 80% of the malarial infections in the America.

**BIOLOGY OF MALARIAL INFECTION**

*Plasmodium* sporozoites, which initiate infection in humans, are inoculated into the dermis and enter the bloodstream following the bite of a *Plasmodium*-infected female anopheline mosquito. Within minutes, sporozoites travel to the liver, where they infect hepatocytes via cell surface receptor-mediated events. This process initiates the asymptomatic prepatent period, or exoerythrocytic stage of infection, which typically lasts 1 week.

During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver stage *schizonts*. When the infected hepatocytes rupture, tens of thousands of *merozoites* are released into the bloodstream and infect red blood cells. After the initial exoerythrocytic stage, *P. falciparum* and *P. malariae* are no longer found in the liver. *P. vivax* and *P. ovale*, however, can maintain a quiescent hepatocyte infection as a dormant form of the parasite known as the hypnozoite and can reinitiate symptomatic disease long after the initial symptoms of malaria are recognized and treated. Erythrocytic forms cannot reestablish infection of hepatocytes. Transmission of human-infecting malarial parasites is maintained in human populations by the
persistence of hypnozoites (several months to few years for *P. vivax* and *P. ovale*), by antigenic variation in *P. falciparum* (probably months), and by the putative antigen variation in *P. malariae* (for as long as several decades).

The *asexual erythrocytic stages* of malarial parasites are responsible for the clinical manifestations of malaria. This part of the *Plasmodium* life cycle is initiated by merozoite recognition of red blood cells, mediated by cell surface receptors, followed by red blood cell invasion.

Once inside a red blood cell, the merozoite develops into a ring form, which becomes a trophozoite that matures into an asexually dividing blood stage schizont. Upon rupture of the infected erythrocyte, these schizonts release 8-32 merozoites that can establish new infections in nearby red blood cells. The erythrocytic replication cycle lasts for 24 h (for *P. knowlesi*), 48 h (for *P. falciparum, P. vivax*, and *P. ovale*), and 72 h (for *P. malariae*). Although most invading merozoites develop into schizonts, a small proportion become gametocytes, the form of the parasite that is infective to mosquitoes. Gametocytes are ingested into the mosquito midgut during an infectious blood meal and then transform into gametes that can fertilize to become zygotes. Zygotes mature into ookinetes, which penetrate the mosquito midgut wall and develop into oocysts. Numerous rounds of asexual replication occur in the oocyst to generate sporozoites over 10-14 days. Fully developed sporozoites rupture from oocysts and invade the mosquito salivary glands, from which they can initiate a new infection during subsequent mosquito blood meals (*Figure 49–1*).
Figure 49–1 Life cycle of malaria parasites.

*P. falciparum* has a family of binding proteins that can recognize a variety of host cell molecules; it invades all stages of erythrocytes and therefore can achieve high parasitemias. *P. vivax* selectively binds to the Duffy chemokine receptor protein as well as reticulocyte-specific proteins. *P. falciparum* assembles cytoadherence proteins (PfEMP1s, encoded by a highly variable family of *var* genes) into structures called knobs that are presented on the erythrocyte surface. Knobs allow the *P. falciparum*-parasitized erythrocyte to bind to postcapillary vascular endothelium, so as to avoid spleen-mediated clearance and allow the parasite to grow in a low O₂, high CO₂ environment.
The cardinal signs and symptoms of malaria are high, spiking fevers, chills, headaches, myalgias, malaise, and GI symptoms. The clinical manifestations of malaria are detailed in Chapter 49 of the 12th edition of the parent text.

CLASSIFICATION OF ANTIMALARIAL AGENTS

The various stages of the malarial parasite life cycle in humans differ in their drug sensitivity. Thus, antimalarial drugs can be classified based on their activities during this life cycle as well as by their intended use for either chemoprophylaxis or treatment. The spectrum of antimalarial drug activity leads to several generalizations.

The first relates to chemoprophylaxis: because no antimalarial drug kills sporozoites, it is not truly possible to prevent infection; drugs can only prevent the development of symptomatic malaria caused by the asexual erythrocytic forms.

The second relates to the treatment of an established infection: no single antimalarial is effective against all liver and intraerythrocytic stages of the life cycle that may coexist in the same patient. Complete elimination of the parasite infection, therefore, may require more than 1 drug.

The patterns of clinically useful activity fall into 3 general categories.

The first group of agents (artemisinins, chloroquine, mefloquine, quinine and quinidine, pyrimethamine, sulfadoxine, and tetracycline) are not reliably effective against primary or latent liver stages. Instead, their action is directed against the asexual blood stages responsible for disease. These drugs will treat, or prevent, clinically symptomatic malaria.

The second group of drugs (typified by atovaquone and proguanil) target not only the asexual erythrocytic forms but also the primary liver stages of P.
falciparum. This additional activity shortens to several days the required period for postexposure chemoprophylaxis.

The third category, comprised solely of primaquine, is effective against primary and latent liver stages as well as gametocytes. Primaquine is used most commonly to eradicate the intrahepatic hypnozoites of *P. vivax* and *P. ovale* that are responsible for relapsing infections.

Aside from their antiparasitic activity, the utility of antimalarials for chemoprophylaxis or therapy depends on their pharmacokinetics and their safety. Quinine and primaquine, which have significant toxicity and relatively short half-lives, generally are reserved for the treatment of established infection and are not used for chemoprophylaxis in a healthy traveler. By contrast, chloroquine is relatively free from toxicity and has a long $t_{1/2}$ that is convenient for chemoprophylactic dosing (in those few areas still reporting chloroquine-sensitive malaria) (see Tables 49–1 and 49–2).

</tbody>
</table>
For ease of reference, detailed information on the antimalarial drugs appears below in alphabetical order by drug name.

**ARTEMISININ AND DERIVATIVES**

Artemisinin and its 3 major semisynthetic derivatives in clinical use, dihydroartemisinin, artemether, and artesunate, are potent and fast-acting antimalarials. They are particularly well suited for the treatment of severe *P. falciparum* malaria and are also effective against the asexual erythrocytic stages of *P. vivax*. Increasingly, the standard treatment of malaria employs *artemisinin-based combination therapies* (ACTs) to increase treatment efficacy and reduce selection resistance.
pressure for the emergence of drug resistance.

![Artemisinin structure]

Artemisinins cause a significant reduction of the parasite burden, with a 4-log$_{10}$ reduction in the parasite population for each 48-h cycle of intraerythrocytic invasion, replication, and egress. Only 3 to 4 cycles (6-8 days) of treatment are required to remove all the parasites from the blood. Additionally, artemisinins possess some gametocytocidal activity, leading to a decrease in malarial parasite transmission.

**Mechanism of Action.** The activity of artemisinin and derivatives seems to result from cleavage of the drug’s peroxide bridge by reduced heme-iron, produced inside the highly acidic digestive vacuole (DV) of the parasite as it digests hemoglobin. The site of action of the putatively toxic heme-adducts is unclear. Additionally, activated artemisinin might in turn generate free radicals that alkylate and oxidize macromolecules in the parasite.

**ADME.** The semisynthetic artemisinins have been formulated for oral (dihydroartemisinin, artesunate, and artemether), intramuscular (artesunate and artemether), intravenous (artesunate), and rectal (artesunate) routes. Bioavailability after oral dosing typically is <30%. Peak serum levels occur rapidly with artemisinins and in 2-6 h with intramuscular artemether. Both artesunate and artemether have modest levels of Asexual malarial parasites flourish plasma protein binding, ranging from 43-82%. These derivatives are extensively metabolized and converted to dihydroartemisinin, which has a plasma $t_{1/2}$ of 1-2 h. Drug bioavailability via rectal administration is highly variable among individual patients. With repeated dosing, artemisinin and artesunate induce their own CYP-mediated metabolism, primarily via CYPs 2B6...
and 3A4. This may enhance clearance by up to 5-fold.

**Therapeutic Uses.** Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the treatment of severe *P. falciparum* malaria. The artemisinins generally are not used alone because of their limited ability to eradicate infection completely. Artemisinins are highly effective, when combined with other antimalarials, for the first-line treatment of malaria. Artemisinins should not be used for chemoprophylaxis because of their short *t*<sub>1/2</sub>.

**Toxicity and Contraindications.** In pregnant rats and rabbits, artemisinins can cause increased embryo lethality or malformations early postconception. Preclinical toxicity studies have identified the brain (and brainstem), liver, bone marrow, and fetus as the principal target organs. However, no systematic neurological changes were attributable to treatment in patients >5 years of age. Patients may develop dose-related and reversible decreases in reticulocyte and neutrophil counts and increases in transaminase levels. About 1 in 3000 patients develops an allergic reaction. Studies of artemisinin treatment during the first trimester have found no evidence of adverse effects on fetal development. Nonetheless, it is recommended that ACTs not be used for the treatment of children <5 kg or during the first trimester of pregnancy.

**ACT PARTNER DRUGS.** Current ACT regimens that are well tolerated in adults and children ≥5 kg include artemether/lumefantrine, artesunate-mefloquine, artesunate-amodiaquine, artesunate-sulfadoxine-pyrimethamine, and dihydroartemisinin-piperaquine.

**Lumefantrine** shares structural similarities with the arylamino alcohol drugs mefloquine and halofantrine and is formulated with artemether (Coartem). This combination is highly effective for the treatment of uncomplicated malaria and is the most widely used first-line antimalarial across Africa. The pharmacokinetic properties of lumefantrine include a large apparent volume of distribution and a terminal elimination *t*<sub>1/2</sub> of 4-5 days. Administration with a high-fat meal is recommended because it significantly increases absorption. A sweetened dispersible formulation of artemether-lumefantrine (Coartem Dispersible) has been approved for treatment of children.
Amodiaquine is a congener of chloroquine that is no longer recommended in the U.S. for chemoprophylaxis of \textit{P. falciparum} malaria because of its toxicity (hepatic and agranulocytosis) that were generally associated with its prophylactic use. Amodiaquine is rapidly converted by hepatic CYPs into monodesethyl-amodiaquine. This metabolite, which retains substantial antimalarial activity, has a plasma $t_{1/2}$ of 9-18 days and reaches a peak concentration of $\sim$500 nM 2 h after oral administration. By contrast, amodiaquine has a $t_{1/2}$ of $\sim$3 h, attaining a peak concentration of $\sim$25 nM within 30 min of oral administration. Clearance rates of amodiaquine ranges between individuals from 78-943 mL/min/kg.

\textbf{Piperaquine} is a potent and well-tolerated bisquinoline compound structurally related to chloroquine. Piperaquine has a large volume of distribution and reduced rates of excretion after multiple doses. It is rapidly absorbed, with a $T_{\text{max}}$ (time to reach the highest concentration) of 2 h after a single dose. Piperaquine has the longest plasma $t_{1/2}$ (5 weeks) of all ACT partner drugs, which might also be effective in reducing rates of reinfection following treatment.

\textbf{Pyronaridine} is an antimalarial structurally related to amodiaquine. It is well tolerated and highly potent against both \textit{P. falciparum} and \textit{P. vivax}, causing fever to subside in 1-2 days and parasite clearance in 2-3 days.

\textbf{ATOVAQUONE}

A fixed combination of atovaquone with proguanil hydrochloride (MALARONE) is available in the U.S. for malaria chemoprophylaxis and for the treatment of uncomplicated \textit{P. falciparum} malaria in adults and children.

\textbf{Antimalarial Action and Resistance.} Atovaquone is a lipophilic analog of ubiquinone, the electron acceptor for parasite dihydroorotate dehydrogenase, an enzyme essential for pyrimidine biosynthesis in the parasite. Atovaquone inhibits electron transport, collapses the mitochondrial membrane potential, and inhibits regeneration of ubiquinone. The drug is highly active against \textit{P. falciparum} asexual blood stage parasites and the liver stages of \textit{P. falciparum}, but not against \textit{P. vivax} liver stage hypnozoites. Synergy between proguanil and
Atovaquone results from the ability of nonmetabolized proguanil to enhance the mitochondrial toxicity of atovaquone. Resistance to atovaquone alone in *P. falciparum* develops easily and is conferred by single nonsynonymous nucleotide polymorphisms in the cytochrome b gene located in the mitochondrial genome. Addition of proguanil markedly reduces the frequency of appearance of atovaquone resistance. However, once atovaquone resistance is present, the synergy of the partner drug proguanil diminishes.

**ADME.** Atovaquone absorption is slow and variable after an oral dose due to its lipophilicity. Absorption improves when the drug is taken with a fatty meal. More than 99% of the drug is bound to plasma protein; cerebrospinal fluid levels are <1% of those in plasma. Profiles of drug concentration versus time often show a double peak; the first at 1-8 h, the second 1-4 days after a single dose; this pattern suggests an enterohepatic circulation. In the absence of a CYP-inducing second medication, humans do not metabolize atovaquone significantly. The drug is excreted in bile, and >94% of the drug is recovered unchanged in feces. Atovaquone has a reported elimination $t_{1/2}$ from plasma of 2-3 days in adults and 1-2 days in children.

**Therapeutic Uses.** A tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride, taken orally, is highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of chloroquine- or sulfadoxine-pyrimethamine-resistant *P. falciparum* malaria. The same regimen followed by a primaquine course is effective in treatment of *P. vivax* malaria. Atovaquone-proguanil is a standard agent for malaria chemoprophylaxis. Experience in prevention of non-*P. falciparum* malaria is limited. *P. vivax* infection may occur after drug discontinuation, indicating imperfect activity against exoerythrocytic stages of this parasite.

**Toxicity.** Atovaquone may cause side effects (abdominal pain, nausea, vomiting, diarrhea, headache, rash) that require cessation of therapy. Vomiting and diarrhea may decrease drug absorption, resulting in therapeutic failure. However, readministration of this drug within an hour of vomiting may still be effective in patients with *P. falciparum* malaria. Atovaquone occasionally causes transient elevations of serum transaminase or amylase.

**Precautions and Contraindications.** Although atovaquone is generally considered to be safe, it needs further evaluation in children <11 kg, pregnant
women, and lactating mothers. Atovaquone may compete with certain drugs for binding to plasma proteins, and therapy with rifampin, a potent inducer of CYP-mediated drug metabolism, can reduce plasma levels of atovaquone substantially, whereas atovaquone may raise plasma levels of rifampin. Coadministration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

**DIAMINOPYRIMIDINES**

*Sulfadoxine-pyrimethamine* (FANSIDAR) was a primary treatment for uncomplicated *P. falciparum* malaria, especially against chloroquine-resistant strains. Due to widespread resistance, it is no longer recommended for the treatment of uncomplicated malaria.

**Antimalarial Action and Resistance.** Pyrimethamine is a slow-acting blood schizontocide with antimalarial effects in vivo resulting from inhibition of folate biosynthesis in *Plasmodium*, similar to proguanil. The efficacy of pyrimethamine against hepatic forms of *P. falciparum* is less than that of proguanil, and at therapeutic doses pyrimethamine fails to eradicate *P. vivax* hypnozoites or gametocytes of any *Plasmodium* species. It increases the number of circulating *P. falciparum* mature infecting gametocytes, likely leading to increased transmission to mosquitoes during the period of treatment.

Synergy of pyrimethamine and the sulfonamides or sulfoxides results from inhibition of 2 metabolic steps in folate biosynthesis in the parasite:

- The utilization of *p*-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides
- The reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by pyrimethamine (see Figure 52–2).

Dietary *p*-aminobenzoic acid or folate may affect the therapeutic response to antifolates. Resistance to pyrimethamine has developed in regions of prolonged or extensive drug use and can be attributed to mutations in dihydrofolate reductase that decrease the binding affinity of pyrimethamine.

**ADME.** Oral pyrimethamine is slowly but completely absorbed, reaching peak
plasma levels in 2-6 h. The compound is significantly distributed in the tissues and is ~90% bound to plasma proteins. Pyrimethamine is slowly eliminated from plasma with a $t_{1/2}$ of 85-100 h. Concentrations that are suppressive for responsive *Plasmodium* strains remain in the blood for ~2 weeks. Pyrimethamine also enters the milk of nursing mothers.

**Therapeutic Uses.** Pyrimethamine-sulfadoxine is no longer recommended for the treatment of uncomplicated malaria or for chemoprophylaxis due to increasing drug resistance. However, for those living in malaria-endemic areas, some still recommend it for the intermittent preventive treatment of malaria in pregnancy.

**Toxicity, Precautions, and Contraindications.** Antimalarial doses of pyrimethamine alone cause minimal toxicity except for occasional skin rashes and reduced hematopoiesis. Excessive doses can produce a megaloblastic anemia, resembling that of folate deficiency, which responds readily to drug withdrawal or treatment with folinic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans the related combination, trimethoprim-sulfamethoxazole, may cause birth defects.

Sulfonamides or sulfones, rather than pyrimethamine, usually account for the toxicity associated with coadministration of these antifolate drugs. The combination of pyrimethamine and sulfadoxine causes severe and even fatal cutaneous reactions, such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. It has also been associated with serum sickness–type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine-sulfadoxine is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants <2 months of age.

Administration of pyrimethamine with dapsone (MALOPRIM), a drug combination unavailable in the U.S., has occasionally been associated with agranulocytosis.

**PROGUANIL**

The antimalarial activity of proguanil (chloroguanide) is ascribed to cycloguanil, a cyclic triazine metabolite (structurally related to pyrimethamine) and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase-thymidylate synthetase that is crucial for
parasite de novo purine and pyrimidine synthesis.

**Antimalarial Action and Resistance.** In drug-sensitive *P. falciparum* malaria, proguanil exerts activity against both the primary liver stages and the asexual red blood cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil is also active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after the drug is withdrawn. Proguanil treatment does not destroy gametocytes, but oocysts in the gut of the mosquito can fail to develop normally.

Cycloguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors. A series of amino acid changes near the dihydrofolate reductase–binding site have been identified that cause resistance to cycloguanil, pyrimethamine, or both. The presence of *Plasmodium* dihydrofolate reductase is not required for the intrinsic antimalarial activity of proguanil or chlorproguanil; however, the molecular basis for this alternative activity is unknown. Proguanil accentuates the mitochondrial membrane-potential-collapsing action of atovaquone against *P. falciparum* but displays no such activity by itself. In contrast to cycloguanil, resistance to the parent drug, proguanil, either alone or in combination with atovaquone, is not well documented.

**ADME.** Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak plasma concentrations are attained within 5 h. The mean plasma elimination half-life is ~180-200 h or longer. The drug’s metabolism and activation involves the CYP2C subfamily; ~3% of whites are deficient in this oxidation phenotype, contrasted with ~20% of Asians and Kenyans. Proguanil is oxidized to 2 major metabolites, cycloguanil and an inactive 4-chlorophenyl biguanide. On a 200-mg-daily dosage regimen, plasma levels of cycloguanil in extensive metabolizers exceed the therapeutic range, whereas cycloguanil levels in poor metabolizers do not. Proguanil itself does not accumulate appreciably in tissues during long-term administration, except in red blood cells where its concentration is about 3 times that in plasma. In humans, 40-60% of the absorbed proguanil is excreted in urine, either as the parent drug or as the active metabolite.
**Therapeutic Uses.** Proguanil as a single agent is not available in the U.S. but has been prescribed as chemoprophylaxis in England and Europe for individuals traveling to malarious areas in Africa. Strains of *P. falciparum* resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections may also result from deficient conversion of proguanil to its active antimalarial metabolite. Proguanil is effective and tolerated well in combination with atovaquone, once daily for 3 days, to treat drug-resistant strains of *P. falciparum* or *P. vivax* (see section on atovaquone). *P. falciparum* readily develops clinical resistance to monotherapy with either proguanil or atovaquone; however, resistance to the combination is uncommon unless the strain is initially resistant to atovaquone.

**Toxicity and Side Effects.** In chemoprophylactic doses of 200-300 mg daily, proguanil causes relatively few adverse effects, except occasional nausea and diarrhea. Large doses (≥1 g daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Doses as high as 700 mg twice daily have been taken for >2 weeks without serious toxicity. Proguanil is safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs.

**QUINOLINES AND RELATED COMPOUNDS**

Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree. Quinine and its many derivatives have been the mainstay of malarial treatment for 4 centuries. Structure-activity analysis of the cinchona alkaloids provided the basis for the discovery of more recent antimalarials such as mefloquine.
ANTIMALARIAL ACTION. Asexual malarial parasites flourish in host erythrocytes by digesting hemoglobin; this generates free radicals and iron-bound heme as highly reactive by-products. Heme is sequestered as an insoluble, chemically inert malarial pigment termed hemoglobin. Quinolines interfere with heme sequestration. Failure to inactivate heme and drug-heme complexes is thought to kill the parasites via oxidative damage to membranes, or other critical biomolecules.

CHLOROQUINE AND HYDROXYCHLOROQUINE

Chloroquine, a weak base, concentrates in the highly acidic digestive vacuoles of susceptible Plasmodium, where it binds to heme and disrupts its sequestration. Hydroxychloroquine, in which 1 of the N-ethyl substituents of chloroquine is β-hydroxylated, is essentially equivalent to chloroquine against P. falciparum malaria.

Resistance. Resistance of erythrocytic asexual forms of P. falciparum to antimalarial quinolines, especially chloroquine, now is common (Figure 49–2). Chloroquine resistance results from mutations in the polymorphic gene pfcr gene (pfcr, for P. falciparum chloroquine resistance transporter) that encodes a putative transporter that resides in the membrane of the acidic digestive vacuole, the site of hemoglobin degradation and chloroquine action. In addition to PfCRT, the P-glycoprotein transporter encoded by pfmdr1, and other transporters including PfMRP, may play a modulatory role in chloroquine resistance.
ADME. Chloroquine is well absorbed from the GI tract and rapidly from intramuscular and subcutaneous sites. This drug extensively sequesters in
tissues, particularly liver, spleen, kidney, lung, and, to a lesser extent, brain and spinal cord. Chloroquine binds moderately (60%) to plasma proteins and is transformed via hepatic CYPs to 2 active metabolites, desethylchloroquine and bisdesethylchloroquine. The renal clearance of chloroquine is about half of its total systemic clearance. Unchanged chloroquine and desethylchloroquine account for >50% and 25% of the urinary drug products, respectively, and their renal excretion is increased by urine acidification. To avoid potentially lethal toxicity, parenteral chloroquine is given either slowly by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. Chloroquine is safer when given orally because the rates of absorption and distribution are more closely matched. Peak plasma levels are achieved in ~3-5 h. The $t_{1/2}$ of chloroquine increases from a few days to weeks as plasma levels decline. The terminal $t_{1/2}$ ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

**Therapeutic Uses.** Chloroquine is highly effective against the erythrocytic forms of *P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi*, and chloroquine-sensitive strains of *P. falciparum*. For infections caused by *P. ovale* and *P. malariae*, it remains the agent of choice for chemoprophylaxis and treatment. For *P. falciparum* this drug has been largely replaced by ACTs.

The utility of chloroquine has declined across most malaria-endemic regions of the world because of the spread of chloroquine-resistant *P. falciparum*. Except in areas where resistant strains of *P. vivax* are reported, chloroquine is very effective in chemoprophylaxis or treatment of acute attacks of malaria caused by *P. vivax*, *P. ovale*, and *P. malariae*. Chloroquine has no activity against primary or latent liver stages of the parasite. To prevent relapses in *P. vivax* and *P. ovale* infections, primaquine can be given either with chloroquine or used after a patient leaves an endemic area. Chloroquine rapidly controls the clinical symptoms and parasitemia of acute malarial attacks. Most patients become completely afebrile within 24-48 h after receiving therapeutic doses. If patients fail to respond during the second day of chloroquine therapy, resistant strains should be suspected and therapy instituted with quinine plus tetracycline or doxycycline, or atovaquone-proguanil, or artemether-lumefantrine, or mefloquine if the others are not available. In comatose children, chloroquine is well absorbed and effective when given through a nasogastric tube. **Tables 49–1 and 49–2** provide information about recommended chemoprophylactic and
therapeutic dosage regimens involving chloroquine. Chloroquine and its analogs are also used to treat certain nonmalarial conditions, including hepatic amebiasis.

**Toxicity and Side Effects.** Taken in proper doses and for recommended total durations, chloroquine is very safe. However, its safety margin is narrow, and a single dose of 30 mg/kg may be fatal. Acute chloroquine toxicity is encountered most frequently when therapeutic or high doses are administered too rapidly by parenteral routes. Cardiovascular effects include hypotension, vasodilation, suppressed myocardial function, cardiac arrhythmias, and eventual cardiac arrest. Confusion, convulsions, and coma may also result from overdose. Chloroquine doses of >5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs most commonly among dark-skinned persons. Prolonged treatment with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes. This drug has also been reported to interfere with the immunogenicity of certain vaccines. Irreversible retinopathy and ototoxicity can result from high daily doses of chloroquine or hydroxychloroquine (>250 mg) leading to cumulative total doses of >1 g/kg. Retinopathy presumably is related to drug accumulation in melanin containing tissues and can be avoided if the daily dose is ≥250 mg. Prolonged therapy with high doses of chloroquine or hydroxychloroquine also can cause toxic myopathy, cardiopathy, and peripheral neuropathy. These reactions improve if the drug is withdrawn promptly. Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

**Precautions and Contraindications.** Chloroquine is not recommended for treating individuals with epilepsy or myasthenia gravis, and should be used cautiously if at all in the presence of advanced liver disease or severe GI, neurological, or blood disorders. The dose should be adjusted in renal failure. In rare cases, chloroquine can cause hemolysis in patients with G6PD deficiency. Chloroquine should not be prescribed for patients with psoriasis or other
exfoliative skin conditions. It should not be used to treat malaria in patients with porphyria cutanea tarda; however, it can be used in lower doses for treatment of manifestations of this form of porphyria. Chloroquine inhibits CYP2D6 and thus can interact with a variety of different drugs. It attenuates the efficacy of the yellow fever vaccine when administered at the same time. It should not be given with mefloquine because of increased risk of seizures. Chloroquine opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias when coadministered with amiodarone or halofantrine. By increasing plasma levels of digoxin and cyclosporine, chloroquine can increase the risk of toxicity from these agents. Patients receiving long-term, high-dose therapy should undergo ophthalmological and neurological evaluations every 3-6 months.

**QUININE AND QUINIDINE**

Oral quinine is FDA-approved for the treatment of uncomplicated *P. falciparum* malaria. Quinidine, a stereoisomer of quinine, is more potent as an antimalarial and more toxic than quinine.

**ANTIMALARIAL ACTION AND PARASITE RESISTANCE.** Quinine acts against asexual erythrocytic forms and has no significant effect on hepatic forms of malarial parasites. This drug is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. However, quinine, along with its stereoisomer quinidine, is especially valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*. Because of its toxicity and short $t_{1/2}$, quinine is generally not used for chemoprophylaxis. The antimalarial mechanism of quinine is presumably similar to that of chloroquine. The basis of *P. falciparum* resistance to quinine is complex. Patterns of *P. falciparum* resistance to quinine correlate in some strains with resistance to chloroquine yet in others correlate more closely with resistance to mefloquine and halofantrine. A number of transporter genes may confer resistance to quinine.

**Action on Skeletal Muscle.** Quinine increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but it also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive nerve stimulation and to acetylcholine
are reduced. Quinine can antagonize the actions of physostigmine on skeletal muscle. Quinine may also produce alarming respiratory distress and dysphagia in patients with myasthenia gravis.

**ADME.** Quinine is readily absorbed when given orally or intramuscularly. Oral absorption occurs mainly from the upper small intestine and is >80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels reach a maximum in 3-8 h and, after distributing into an apparent volume of ~1.5 L/kg, decline with a $t_{1/2}$ of 11 h. The pharmacokinetics of quinine may change according to the severity of malarial infection: the apparent volume of distribution and the systemic clearance of quinine decrease, such that the average elimination $t_{1/2}$ increases to 18 h. The high levels of plasma $\alpha_1$-acid glycoprotein produced in severe malaria may prevent toxicity by binding quinine and thereby reducing the free fraction of drug. Concentrations of quinine are lower in erythrocytes (33-40%) and CSF (2-5%) than in plasma, and the drug readily reaches fetal tissues. The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4; thus, only ~20% of an administered dose is excreted in an unaltered form in the urine. The major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of quinine itself is more rapid when the urine is acidic.

**THERAPEUTIC USES.** Quinine and quinidine have long been treatments of choice for drug-resistant and severe *P. falciparum* malaria. However, the advent of oral and intravenous artemisinin therapy is changing this situation. In severe illness, the prompt use of loading doses of intravenous quinine (or quinidine, where intravenous quinine is not available) can be lifesaving. Oral medication to maintain therapeutic concentrations is then given as soon as tolerated and is continued for 5-7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizonticides such as tetracyclines or clindamycin are given concurrently to enhance quinine efficacy. Formulations of quinine and quinidine and specific regimens for their use in the treatment of *P. falciparum* malaria are shown in Table 49–2. The therapeutic range for “free” quinine is 0.2 and 2.0 mg/L. Regimens needed to achieve this target vary based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. Dosage regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger
apparent volume of distribution, greater systemic clearance, and shorter terminal elimination $t_{1/2}$ than quinine. The CDC recommends a dose of quinidine of 10 mg salt/kg initially, followed by 0.02 mg salt/kg/min).

Nocturnal Leg Cramps. It is commonly believed that night cramps are relieved by quinine (200-300 mg) taken at bedtime. The FDA has required drug manufacturers to stop marketing over-the-counter quinine products for nocturnal leg cramps, stating that data supporting safety and efficacy of quinine for this indication were inadequate and that risks outweighed the potential benefits.

TOXICITY AND SIDE EFFECTS. The fatal oral dose of quinine for adults is ~2-8 g. Quinine is associated with a triad of dose-related toxicities when given at full therapeutic or excessive doses: cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism (consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension) occur frequently and disappear soon after the drug is withdrawn. Hypoglycemia is also common and can be life threatening if not treated promptly with intravenous glucose. Hypotension is rare and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and skin manifestations. GI symptoms (nausea, vomiting, abdominal pain, and diarrhea) result from the local irritant action of quinine, but the nausea and emesis also have a central basis. Cutaneous manifestations may include flushing, sweating, rash, and angioedema, especially of the face. Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells.

Quinine rarely causes cardiac complications unless therapeutic plasma concentrations are exceeded. QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. Acute overdosage also may cause serious and even fatal cardiac dysrhythmias such as sinus arrest, junctional rhythms, AV block, and ventricular tachycardia and fibrillation. Quinidine is even more cardiotoxic than quinine. Cardiac monitoring of patients on intravenous quinidine is advisable where possible.

Severe hemolysis can result from hypersensitivity to these cinchona alkaloids. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria
leading to anuria, renal failure, and in some instances death—is a rare hypersensitivity reaction to quinine therapy that can occur during treatment of malaria. Quinine occasionally may cause milder hemolysis, especially in people with G6PD deficiency. Thrombotic thrombocytopenic purpura also is rare but can occur even in response to ingestion of tonic water, which has ~4% the therapeutic oral dose per 12 oz (“cocktail purpura”). Other rare adverse effects include hypoprothrombinemia, leukopenia, and agranulocytosis.

**PRECAUTIONS, CONTRAINDICATIONS, AND INTERACTIONS.**
Quinine must be used with considerable caution, if at all, in patients who manifest hypersensitivity. Quinine should be discontinued immediately if evidence of hemolysis appears. This drug should be avoided in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine. Quinine appears to be safe in pregnancy and is used commonly for the treatment of pregnancy-associated malaria. However, glucose levels must be monitored because of the increased risk of hypoglycemia.

The drugs are highly irritating and should not be given subcutaneously. Concentrated solutions may cause abscesses when injected intramuscularly, or thrombophlebitis when infused intravenously. Antacids that contain aluminum can delay absorption of quinine from the GI tract. Quinine and quinidine can delay the absorption and elevate plasma levels of cardiac glycosides and warfarin and related anticoagulants. The action of quinine at neuromuscular junctions enhances the effect of neuromuscular blocking agents and opposes the action of acetylcholinesterase inhibitors. Prochlorperazine can amplify quinine’s cardiotoxicity, as can halofantrine. The renal clearance of quinine can be decreased by cimetidine and increased by urine acidification and by rifampin.

**MEFLOQUINE**
Mefloquine (LARIAM) emerged from the Walter Reed Malaria Research Program as safe and effective against drug-resistant strains of *P. falciparum*.

**MECHANISMS OF ACTION AND PARASITE RESISTANCE.** Mefloquine is a highly effective blood schizonticide. Mefloquine associates with
intraerythrocytic hemozoin, suggesting similarities to the mode of action of chloroquine. However, increased pfmdr1 copy numbers are associated with both reduced parasite susceptibility to mefloquine and increased PfMDR1-mediated solute import into the digestive vacuole of intraerythrocytic parasites, suggesting that the drug’s target resides outside of this vacuolar compartment. The (−)-enantiomer is associated with adverse CNS effects, whereas the (+)-enantiomer retains antimalarial activity with fewer side effects. Mefloquine can be paired with artesunate to reduce the selection pressure for resistance. This combination has proved efficacious for the treatment of *P. falciparum* malaria, even in regions with high prevalence of mefloquine-resistant parasites.

**ADME.** Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is absorbed rapidly but with marked variability. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of mefloquine rise in a biphasic manner to their peak in ~17 h. Mefloquine has a variable and long $t_{1/2}$, 13-24 days, reflecting its high lipophilicity, extensive tissue distribution, and extensive binding (~98%) to plasma proteins. The slow elimination of mefloquine fosters the emergence of drug-resistant parasites. Mefloquine is extensively metabolized in the liver by CYP3A4; this CYP can be inhibited by ketoconazole and induced by rifampicin. Excretion of mefloquine is mainly by the fecal route; only ~110% of mefloquine appears unchanged in the urine.

**Therapeutic Uses.** Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant *P. falciparum* and *P. vivax*; it is no longer considered first-line treatment of malaria. The drug is especially useful as a chemoprophylactic agent for travelers spending weeks to years in areas where these infections are endemic (*see Table 49–1*). In areas where malaria is due to multiply drug-resistant strains of *P. falciparum*, mefloquine is more effective when used in combination with an artemisinin compound.

**Toxicity and Side Effects.** At chemoprophylactic dosages, oral mefloquine is generally well tolerated. Vivid dreams are common; significant neuropsychiatric signs and symptoms can occur in ≥10% of people receiving treatment doses; serious adverse events (psychosis, seizures) are rare. Short-term adverse effects of treatment include nausea, vomiting, and dizziness. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within
the first hour. After treatment of malaria with mefloquine, CNS toxicity can be as high as 0.5%; symptoms include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms are reversible upon drug discontinuation. Mild-to-moderate toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at prophylactic dosages. Adverse effects usually manifest after the first to third doses and often abate even with continued treatment. Cardiac abnormalities, hemolysis, and agranulocytosis are rare.

**Contraindications and Interactions.** At very high doses, mefloquine is teratogenic in rodents. Studies have suggested an increased rate of stillbirths with mefloquine use, especially during the first trimester. Pregnancy should be avoided for 3 months after mefloquine use because of the prolonged $t_{1/2}$ of this agent. This drug is contraindicated for patients with a history of seizures, depression, bipolar disorder and other severe neuropsychiatric conditions, or adverse reactions to quinoline antimalarials. Although this drug can be taken safely 12 h after a last dose of quinine, taking quinine shortly after mefloquine can be very hazardous because the latter is eliminated so slowly. Treatment with or after halofantrine or within 2 months of prior mefloquine administration is contraindicated. Controlled studies suggest that mefloquine does not impair performance in persons who tolerate the drug; nonetheless, some advise against the use of mefloquine for patients in occupations that require focused concentration, dexterity, and cognitive function.

**PRIMAQUINE**

Primaquine, in contrast to other antimalarials, acts on exo-erythrocytic tissue stages of plasmodia in the liver to prevent and cure relapsing malaria. Patients should be screened for G6PD deficiency prior to therapy with this drug.
Antimalarial Action and Parasite Resistance. The mechanism of action of the 8-aminoquinolines has not been elucidated. Primaquine acts against primary and latent hepatic stages of *Plasmodium* spp. and prevents relapses in *P. vivax* and *P. ovale* infections. This drug and other 8-aminoquinolines also display gametocytocidal activity against *P. falciparum* and other *Plasmodium* species. However, primaquine is inactive against asexual blood stage parasites.

**ADME.** Absorption of primaquine from the GI tract approaches 100%. Peak plasma concentration occurs within 3 h and then falls with a variable $t_{1/2}$ averaging 7 h. Primaquine is metabolized rapidly; only a small fraction of a dose is excreted as the parent drug. Importantly, primaquine induces CYP1A2. The major metabolite, carboxyprimaquine, is inactive.

**Therapeutic Uses.** Primaquine is used primarily for terminal chemoprophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) infections because of its high activity against the latent tissue forms (hypnozoites) of these *Plasmodium* species. The compound is given together with a blood schizonticide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance. For terminal chemoprophylaxis, primaquine regimens should be initiated shortly before or immediately after a subject leaves an endemic area (see Table 49–1). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during an asymptomatic latent period of presumed infection or during an acute attack. Simultaneous administration of a schizonticidal drug plus primaquine is more effective than sequential treatment in promoting a radical cure. Limited studies have shown efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine is taken as chemoprophylaxis. Primaquine is generally well tolerated when taken for up to 1 year.

**Toxicity and Side Effects.** Primaquine has few side effects when given in the
usual therapeutic doses. Primaquine can cause mild to moderate abdominal distress in some individuals. Taking the drug at mealtime often alleviates these symptoms. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60-240 mg daily) worsen the abdominal symptoms. Methemoglobinemia can occur even with usual doses of primaquine and can be severe in individuals with congenital deficiency of NADH methemoglobin reductase. Chloroquine and dapsone may synergize with primaquine to produce methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Other rare adverse reactions are hypertension, arrhythmias, and symptoms referable to the CNS.

*Therapeutic or higher doses of primaquine may cause acute hemolysis and hemolytic anemia in humans with G6PD deficiency. Primaquine is the prototype of > 50 drugs, including antimalarial sulfonamides, that cause hemolysis in G6PD-deficient individuals.*

**Precautions and Contraindications.** G6PD deficiency should be ruled out prior to administration of primaquine. Primaquine has been used cautiously in subjects with the A form of G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks but should not be used in patients with more severe deficiency. If a daily dose of >30 mg primaquine base (>15 mg in potentially sensitive patients) is given, then blood counts should be followed carefully. Patients should be counseled to look for dark or blood-colored urine, which would indicate hemolysis. Primaquine should not be given to pregnant women; in treating lactating mothers, primaquine should be prescribed only after ascertaining that the breast-feeding infant has a normal G6PD level. Primaquine is contraindicated for acutely ill patients suffering from systemic disease characterized by a tendency to granulocytopenia (e.g., active forms of rheumatoid arthritis and lupus erythematosus). Primaquine should not be given to patients receiving drugs capable of causing hemolysis or depressing the myeloid elements of the bone marrow.

**SULFONAMIDES AND SULFONES**

The sulfonamides and sulfones are slow-acting blood schizonticides and more active against *P. falciparum* than *P. vivax.*
MECHANISM OF ACTION. Sulfonamides are \( p \)-aminobenzoic acid analogs that competitively inhibit *Plasmodium* dihydropteroate synthase. These agents are combined with an inhibitor of parasite dihydrofolate reductase to enhance their antimalarial action.

DRUG RESISTANCE. Sulfadoxine resistance is conferred by several point mutations in the dihydropteroate synthase gene. These sulfadoxine-resistance mutations, when combined with mutations of dihydrofolate reductase and conferring pyrimethamine resistance, greatly increase the likelihood of sulfadoxine-pyrimethamine treatment failure. Sulfadoxine-pyrimethamine, given intermittently during the second and third trimesters of pregnancy, is a routine component of antenatal care throughout Africa. Intermittent preventive treatment strategies may also benefit infants. Generally, one can anticipate that, in the absence of novel antifolates effective against existing drug-resistant strains, the use of these antimalarials for either prevention or treatment will continue to decline.

TETRACYCLINES AND CLINDAMYCIN

Tetracycline and doxycycline are useful in malaria treatment, as is clindamycin. These agents are slow-acting blood schizonticides that can be used alone for short-term chemoprophylaxis in areas with chloroquine- and mefloquine-resistant malaria (only doxycycline is recommended for malaria chemoprophylaxis).

These antibiotics act via a delayed death mechanism resulting from their inhibition of protein translation in the parasite plastid. This effect on malarial parasites manifests as death of the progeny of drug-treated parasites, resulting in slow onset of antimalarial activity. Their relatively slow mode of action makes these drugs ineffective as single agents for malaria treatment. Dosage regimens for tetracyclines and clindamycin are listed in Tables 49–1 and 49–2. Because of their adverse effects on bones and teeth, tetracyclines should not be given to pregnant women or to children <8 years of age.

PRINCIPLES AND GUIDELINES FOR CHEMOPROPHYLAXIS AND CHEMOTHERAPY OF MALARIA
Pharmacological prevention of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Chloroquine remains effective against malaria caused by *P. ovale, P. malariae, P. knowlesi*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* are now the rule, not the exception, in most malaria-endemic regions (see Figure 49–2). Extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine-sulfadoxine. Multidrug-resistant *P. falciparum* malaria is especially prevalent and severe in Southeast Asia and Oceania. These infections may not respond adequately even to mefloquine or quinine. The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. Current CDC recommendations for drugs and dosing regimens for the chemoprophylaxis and treatment of malaria in nonimmune individuals are shown in Tables 49–1 and 49–2.

*Drugs should not replace simple, inexpensive measures for malaria prevention.* Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites. One such measure is to avoid exposure to mosquitoes at dusk and dawn, usually the times of maximal feeding. Others include using insect repellents containing at least 30% *N, N’*-diethylmetatoluamide (DEET) and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin.

**MALARIA CHEMOPROPHYLAXIS.** Regimens for malaria chemoprophylaxis include primarily 3 drugs: *atovaquoneproguanil* and *doxycycline* that can both be used in all areas, and *mefloquine* that can be used in areas with mefloquine-sensitive malaria. Other available options are chloroquine or hydroxychloroquine (but their use is restricted to the few areas with chloroquine-sensitive malaria), and primaquine (for short duration travel to areas with principally *P.*
vivax). In general, dosing should be started before exposure, ideally before the traveler leaves home (see Table 49–1).

In those few areas where chloroquine-sensitive strains of *P. falciparum* are found, chloroquine is still suitable for chemoprophylaxis. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone-proguanil are the regimens of choice for chemoprophylaxis. For chemoprophylaxis in long-term travelers, chloroquine is safe at the doses used, but some recommend yearly retinal examinations, and there is a finite dose limit for which chemoprophylaxis with chloroquine is recommended because of ocular toxicity. Mefloquine and doxycycline are well tolerated. Mefloquine is the best documented drug for long-term travelers and, if well tolerated, can be used for prolonged periods. Atovaquone-proguanil has been studied for up to 20 weeks but probably is acceptable for years based on experience with the individual components.

**DIAGNOSIS AND TREATMENT OF MALARIA.** The diagnosis of malaria must be considered for patients presenting with acute febrile illness after returning from a malaria-endemic region. An organized, rational approach to diagnosis, parasite identification, and appropriate treatment is crucial. Guidelines for treatment of malaria in the U.S. are provided by the CDC and are shown in Table 49–2 and Figure 49–3.

Children and pregnant women are the most susceptible to severe malaria. The treatment of children generally is the same as for adults (pediatric dose should never exceed adult dose). However, tetracyclines should not be given to children <8 years of age except in an emergency, and atovaquone-proguanil as treatment has been approved only for children weighing >5 kg.

CHEMOPROPHYLAXIS AND TREATMENT DURING PREGNANCY.
Chemoprophylaxis during pregnancy is complex, and women should evaluate with expert medical staff the benefits and risks of different strategies with regard to their particular situation. Severe malaria during pregnancy should be treated with intravenous antimalarial treatment according to the general guidelines for severe malaria, taking into account the drugs that should be avoided during pregnancy. In lactating mothers, treatment with most compounds is acceptable, although chloroquine and hydroxychloroquine are the preferred agents. The use of atovaquone-proguanil is not recommended unless breast-feeding infants weigh >5 kg. Also, the breast-feeding infant should be shown to have a normal G6PD level before receiving primaquine.

**SELF-TREATMENT OF PRESumptIVE MALARIA FOR TRAVELERS.**

The CDC provides traveler’s guidelines for self-treatment of presumptive malaria (atovaquone-proguanil, as described in Table 49–2) when professional care is not available within 24 h. In such cases, medical care should be sought immediately after treatment. These recommendations may change over time and with specific locations. Consult the CDC Yellow Book or [www.cdc.gov/travel](http://www.cdc.gov/travel).
Humans host a wide variety of protozoal parasites that can be transmitted by insect vectors, directly from other mammalian reservoirs or from one person to another. The immune system plays a crucial role in protecting against the pathological consequences of protozoal infections. Thus, opportunistic infections with protozoa are prominent in infants, individuals with cancer, transplant recipients, those receiving immunosuppressive drugs or extensive antibiotic therapy, and persons with advanced human immunodeficiency virus (HIV) infection. Because effective vaccines are unavailable, chemotherapy has been the only practical way to both treat infected individuals and reduce transmission. Many effective antiprotozoal drugs are toxic at therapeutic doses, a problem exacerbated by increasing drug resistance.

INTRODUCTION TO PROTOZOAL INFECTIONS OF HUMANS

AMEBIASIS. Amebiasis affects ~10% of the world’s population, commonly individuals living in poverty, crowded conditions, and areas with poor sanitation. Three morphologically identical but genetically distinct species of Entamoeba (i.e., E. histolytica, E. dispar, and E. moshkovskii) have been isolated from infected persons, with E. histolytica responsible for ~10% of human infections. Only E. histolytica causes disease and requires treatment.

Humans are the only known hosts for these protozoa, which are transmitted almost exclusively by the fecal-oral route. Ingested E. histolytica cysts from contaminated food or water survive acid gastric contents and transform into trophozoites that reside in the large intestine. The outcome of E. histolytica
infection is variable. Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals, *E. histolytica* trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). In a smaller proportion of patients, *E. histolytica* trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess.

*The cornerstone of therapy for amebiasis is metronidazole or its analogs tinidazole and ornidazole.* Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen, and the drug is less effective against cysts. Hence patients with amebiasis (amebic colitis or amebic liver abscess) also should receive a luminal agent to eradicate any *E. histolytica* trophozoites residing within the gut lumen. Luminal agents are also used to treat asymptomatic individuals found to be infected with *E. histolytica*. The nonabsorbed aminoglycoside *paromomycin* and the 8-hydroxyquinoline compound *iodoquinol* are effective luminal agents. Diloxanide furate, previously considered the luminal agent of choice for amebiasis, is no longer available in the U.S. *Nitazoxanide* (*ALINIA*), approved in the U.S. for treatment of cryptosporidiosis and giardiasis, is also active against *E. histolytica*.

**GIARDIASIS.** Giardiasis, caused by the flagellated protozoan *Giardia intestinalis*, is prevalent worldwide and is the most commonly reported intestinal protozoal infection in the U.S. Infection results from ingestion of the cyst form of the parasite, which is found in fecally contaminated water or food.

Infection with *Giardia* results in 1 of 3 syndromes: an asymptomatic carrier state, acute self-limited diarrhea, or chronic diarrhea. Chemotherapy with a 5-day course of *metronidazole* usually is successful, although therapy may have to be repeated or prolonged in some instances. A single dose of *tinidazole* (*TINDAMAX*, others) probably is superior to metronidazole for the treatment of giardiasis. *Paromomycin* (*HUMATIN*, others) has been used to treat pregnant women to avoid any possible mutagenic effects of the other drugs. *Nitazoxanide* (*ALINIA*), N-(nitrothiazolyl) salicylamide, and tinidazole are approved for the treatment of giardiasis in immune-competent children <12 years of age. Furazolidone has been discontinued in the U.S.
TRICHOMONIASIS. Trichomoniasis is caused by the flagellated protozoan *Trichomonas vaginalis*. This organism inhabits the genitourinary tract of the human host, where it causes vaginitis in women and, uncommonly, urethritis in men. Trichomoniasis is a sexually transmitted disease and has been associated with an increased risk of acquiring HIV infection. Only *trophozoite* forms of *T. vaginalis* have been identified in infected secretions.

Metronidazole remains the drug of choice for the treatment of trichomoniasis. Tinidazole, another nitroimidazole, appears to be better tolerated than metronidazole and has been used successfully at higher doses to treat metronidazole-resistant *T. vaginalis*.

TOXOPLASMOSIS. Toxoplasmosis is a zoonotic infection caused by *Toxoplasma gondii*. Although cats and other feline species are the natural hosts, tissue cysts (*bradyzoites*) have been recovered from all mammalian species examined. Common routes of infection in humans are:

- Ingestion of undercooked meat containing tissue cysts
- Ingestion of contaminated vegetable matter containing infective *oocysts*
- Direct oral contact with feces of cats shedding oocysts
- Transplacental fetal infection with *tachyzoites* from acutely infected mothers

The acute illness is usually self-limiting, and treatment rarely is required. Individuals who are immunocompromised, however, are at risk of developing toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain. The primary treatment for toxoplasmic encephalitis consists of the antifolates *pyrimethamine* (*Daraprim*) and *sulfadiazine* along with *folinic acid* (*leucovorin*). Therapy must be discontinued in ~40% of cases because of toxicity owing primarily to the sulfa compound; *clindamycin* can be substituted for sulfadiazine without loss of efficacy. Alternative regimens combining azithromycin, clarithromycin, atovaquone, or dapsone with either trimethoprim-sulfamethoxazole or pyrimethamine and folinic acid are less toxic but also less effective. *Spiramycin*, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in pregnancy to prevent transmission.
to the fetus. If fetal infection is detected, the combination of pyrimethamine, sulfadiazine, and folic acid is administered to the mother (only after the first 12-14 weeks of pregnancy) and to the newborn in the postnatal period. Spiramycin is not available in the U.S.

CRYPTOSPORIDIOSIS. Cryptosporidia are coccidian protozoan parasites that can cause diarrhea. *Cryptosporidium parvum* and the newly named *C. hominis* appear to account for almost all infections in humans. Infectious oocysts in feces may be spread either by direct human-to-human contact or by contaminated water supplies.

After ingestion, the mature oocyte is digested, releasing *sporozoites* that invade host epithelial cells. In most individuals, infection is self-limited. However, in AIDS patients and other immunocompromised individuals, the severity of diarrhea may require hospitalization. The most effective therapy for cryptosporidiosis in AIDS patients is restoration of their immune function through highly active antiretroviral therapy (HAART) (*see Chapter 59*). *Nitazoxanide* has shown activity in treating cryptosporidiosis in immunocompetent children and is possibly effective in immunocompetent adults. Its efficacy in children and adults with HIV infection and AIDS is not clearly established.

TRYPANOSOMIASIS. African trypanosomiasis, or “sleeping sickness,” is caused by subspecies of the hemoflagellate *Trypanosoma brucei* that are transmitted by bloodsucking tsetse flies of the genus *Glossina*. Largely restricted to sub-Saharan Africa, the infection causes serious human illness and also threatens livestock (*nagana*), leading to protein malnutrition. In humans, the infection is fatal unless treated. An estimated 500,000 Africans carry the infection, and >50 million people are at risk for the disease.

The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream or lymph without CNS involvement (stage 1); stage 2 disease is characterized by CNS involvement. Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic
dissemination of the parasites. There are 2 types of African trypanosomiasis: the East African (Rhodesian; *T. brucei rhodesiense*) variety produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and frequent terminal cardiac failure; the West African type (Gambian; *T. brucei gambiense*) causes illness characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion, sensory deficits, psychiatric signs, disruption of the sleep cycle, and eventual progression into coma and death.

Standard therapy for early-stage disease is *pentamidine* for *T. brucei gambiense* and *suramin* for *T. brucei rhodesiense*. Both compounds must be given parenterally over long periods and are not effective against late-stage disease. The CNS phase has traditionally been treated with melarsoprol (available from the CDC), a highly toxic agent that causes a fatal reactive encephalopathy in 2-10% of treated patients. Moreover, lack of response to this agent is leading to increasing numbers of treatment failures. *Eflornithine*, an inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism, offers the only alternative for the treatment of late-stage disease. It has efficacy against both early and late stages of human *T. brucei gambiense* infection; however, it is ineffective as monotherapy for infections of *T. brucei rhodesiense*. Notably, eflornithine has significantly fewer side effects than melarsoprol and is more effective than melarsoprol for treatment of late-stage Gambian trypanosomiasis, suggesting that eflornithine is the best available first-line treatment for this form of the disease. *Nifurtimox-eflornithine combination therapy* (NECT) allows a shorter exposure to eflornithine with good efficacy and a reduction in adverse events.

*American trypanosomiasis*, or *Chagas disease*, a zoonotic infection caused by *Trypanosoma cruzi*, affects ~15 million people from Mexico to Argentina and Chile. The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megacolon, and death. Blood-sucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission also may occur in endemic areas. Two nitroheterocyclic drugs, *nifurtimox* (available from the CDC) and *benznidazole* are used to treat this infection. Both agents suppress parasitemia and can cure the acute phase of Chagas disease in 60-80% of cases;
both drugs are toxic and must be taken for long periods.

**LEISHMANIASIS.** Leishmaniasis is a complex vector-borne zoonosis caused by ~20 different species of intramacrophage protozoa of the genus *Leishmania*. Small mammals and canines generally serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of female phlebotomine sandflies.

In increasing order of systemic involvement and potential clinical severity, major syndromes of human leishmaniasis have been classified into *cutaneous*, *mucocutaneous*, *diffuse cutaneous*, and *visceral* (*kala azar*) forms. Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring in 3-18 months after infection. However, this form of the disease can leave disfiguring scars. The mucocutaneous, diffuse cutaneous, and visceral forms of the disease do not resolve without therapy. Visceral leishmaniasis caused by *L. donovani* is fatal unless treated. The classic therapy for all species of *Leishmania* is *pentavalent antimony* (sodium antimony gluconate; sodium stibogluconate; *Pentostam*); resistance to this compound is widespread in India, although it remains useful in other parts of the world. As an alternative, *liposomal amphotericin B* is a highly effective agent for visceral leishmaniasis, and it is currently the drug of choice for antimony-resistant disease. Treatment of leishmaniasis has undergone major changes owing to the success of the first orally active agent, *miltefosine*. The drug also appears to have promise for the treatment of the cutaneous disease and for the treatment of dogs, an important animal reservoir of the disease. Paromomycin has been used with success as a parenteral agent for visceral disease, and topical formulations of paromomycin have efficacy against cutaneous disease.

**OTHER PROTOZOAL INFECTIONS.** Just a few of the many less common protozoal infections of humans are highlighted here.

*Babesiosis*, caused by either *Babesia microti* or *B. divergens*, is a tick-borne zoonosis that superficially resembles malaria in that the parasites invade erythrocytes, producing a febrile illness, hemolysis, and hemoglobinuria. This infection usually is mild and self-limiting but can be severe or even fatal in asplenic or severely immunocompromised individuals. Currently recommended therapy is with a combination of *clindamycin and quinine* for severe disease, and
the combination of azithromycin and atovaquone for mild or moderate infections.

**Balantidiasis**, caused by the ciliated protozoan *Balantidium coli*, is an infection of the large intestine that may be confused with amebiasis. Unlike amebiasis, this infection usually responds to tetracycline therapy.

**Isospora belli**, a coccidian parasite, causes diarrhea in AIDS patients and responds to treatment with trimethoprim-sulfamethoxazole. *Cyclospora cayetanensis* causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in individuals with AIDS.

**Microsporidia** are spore-forming unicellular eukaryotic fungal parasites that can cause a number of disease syndromes, including diarrhea in immunocompromised individuals. Infections with microsporidia have been treated successfully with *albendazole*, an inhibitor of β-tubulin polymerization (see Chapter 51). Immunocompromised individuals with intestinal microsporidiosis due to *E. bieneusi* (which does not respond as well to albendazole) have been treated successfully with the antimicrobial *fumagillin*.

**ANTIPROTOZOAL DRUGS**

For ease of reference, the myriad agents used to treat nonmalarial protozoal diseases are presented alphabetically.

**AMPHOTERICIN B**

The pharmacology, formulation, and toxicology of amphotericin B are presented in Chapter 57.

Antiprotozoal Effects. *Amphotericin B (AMBISOME)* is a highly effective antileishmanial agent that cures >90% of the cases of visceral leishmaniasis and is the drug of choice for antimonial-resistant cases. It is a second-line drug for cutaneous or mucosal leishmaniasis, where it has been shown effective for the treatment of immunocompromised patients. The lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions.
**Mechanism of Action.** The basis of amphotericin B action against leishmania is similar to that for the drug’s antifungal activities (see Chapter 57). Amphotericin complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell. Leishmania has similar sterol composition to fungal pathogens, and the drug binds to these sterols preferentially over the host cholesterol. No significant resistance to the drug has been encountered after nearly 30 years of use as an antifungal agent.

**Therapeutic Uses.** Typical regimens of 10-20 mg/kg total dose given in divided doses over 10-20 days by intravenous infusion have yielded >95% cure rates. In the U.S., the FDA recommends 3 mg/kg intravenously on days 1-5, 14, and 21 for a total dose of 21 mg/kg. Recent data suggest that a single dose of 5 mg/kg followed by 7-14 days treatment with oral miltefosine was effective at curing visceral leishmaniasis, and this dosing scheme warrants additional study.

**CHLOROQUINE**

The pharmacology and toxicology of chloroquine are presented in Chapter 49 (antimalarials). Chloroquine does have an FDA-approved use for extra-intestinal amebiasis at a dose of 1 g (600 mg base) daily for 2 days, followed by 500 mg daily for at least 2-3 weeks. Treatment is usually combined with an effective intestinal amebicide.

**DILOXANIDE FUROATE**

Diloxanide furoate (FURAMIDE, others) is a derivative of dichloroacetamide. Diloxanide furoate is a very effective luminal agent for the treatment of *E. histolytica* infection but is no longer available in the U.S.

**EFLORNITHINE**

Eflornithine (α-D,L difluoromethylornithine, DFMO, ORNIDYL) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first and rate-limiting step in the biosynthesis of polyamines (putrescine, spermidine, and spermine) that are required for cell division and for normal cell differentiation. In trypanosomes, spermidine is required for the synthesis of
trypanothione, a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite.

Eflornithine currently is used to treat West African (Gambian) trypanosomiasis caused by \textit{T. brucei gambiense}; the drug is largely ineffective for East African trypanosomiasis. Eflornithine’s difficult treatment regimen limits its use. Eflornithine is no longer available for systemic use in the U.S. but is available for treatment of Gambian trypanosomiasis by special request from the CDC. Eflornithine is safer and more efficacious than melarsoprol for late-stage gambiense sleeping sickness, and is the recommended first-line treatment for this disease when adequate care can be provided for its administration.

\textit{Antitrypanosomal Effects.} Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion. The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity. \textit{T. brucei rhodesiense} cells are less sensitive to eflornithine inhibition than \textit{T. brucei gambiense} cells; studies \textit{in vitro} suggest that the effective doses are increased by 10-20 times in the refractory cells. The molecular basis for the higher dose requirement in \textit{T. brucei rhodesiense} is not understood.

\textit{ADME.} Eflornithine is given by intravenous infusion. The drug does not bind to plasma proteins but is well distributed and penetrates into the CSF, where estimated concentrations of at least 50 μM must be reached to clear well
distributed and penetrates into the CSF. Renal clearance after intravenous administration is rapid (2 mL/min/kg), with >80% of the drug cleared by the kidney largely in unchanged form. Some studies indicate that suramin enhances eflornithine uptake into the CNS and could lower the dose requirements for eflornithine.

**Therapeutic Uses.** Eflornithine is used for the treatment of late-stage West African trypanosomiasis caused by *T. brucei gambiense*. The preferred regimen for adult patients is 100 mg/kg given intravenously every 6 h as a 2-h infusion for 14 days. Response rates exceed 90% in the late-stage patients. Children (<12 years of age) receive higher doses of eflornithine (150 mg/kg given intravenously every 6 h for 14 days) based on prior findings that eflornithine trough concentrations in both the CSF and blood were significantly lower among children than in adults. The treatment course for eflornithine has been reduced to 7 days in combination with nifurtimox. This combination protocol, NECT, uses a shortened course of eflornithine with oral nifurtimox, with dosing as follows: 400 mg/kg/day given intravenously every 12 h by 2-h infusion for 7 days plus nifurtimox (orally at 15 mg/kg/day in 3 divided doses [every 8 h]) for 10 days. Eflornithine is less successful for treating AIDS patients with West African trypanosomiasis, presumably because host defenses play a critical role in clearing drug-treated *T. brucei gambiense* from the bloodstream.

**Toxicity and Side Effects.** Eflornithine causes adverse reactions that are generally reversible on withdrawal of the drug. Abdominal pain and headache are the predominant complaints, followed by reactions at the injection sites. Tissue infections and pneumonia are also observed. The most severe reactions reported include fever peaks (6%), seizures (4%), and diarrhea (2%). The case fatality rate for eflornithine (~1.2%) is significantly lower than for melarsoprol (4.9%), and overall eflornithine is superior to melarsoprol with respect to both safety and efficacy. Reversible hearing loss can occur after prolonged therapy with oral doses. Therapeutic doses of eflornithine are large and require coadministration of substantial volumes of intravenous fluid. This poses significant practical limitations in remote settings and can cause fluid overload in susceptible patients.

**FUMAGILLIN**
Fumagillin (FUMIDIL B, others) is an acyclic polyene macrolide. Fumagillin and its synthetic analog TNP-470 are toxic to microsporidia.

Fumagillin is used topically to treat keratoconjunctivitis caused by *E. hellem* at a dose of 3-10 mg/mL in a balanced salt suspension. For the treatment of intestinal microsporidiosis caused by *E. bieneusi*, fumagillin is used at a dose of 20 mg orally 3 times daily for 2 weeks. Adverse effects of fumagillin may include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported. Fumagillin has not been approved for the systemic treatment of microsporidia infection in the U.S.

Fumagillin is used widely to treat the microsporidian *Nosema apis*, a pathogen of honey bees. Fumagillin and TNP-470 also inhibit angiogenesis and suppress tumor growth. TNP-470 is undergoing clinical trials as an anticancer agent (see Chapter 61). Human methionine-aminopeptidase-2 (MetAP2) is the target for the drugs’ antitumor activity, and a gene encoding MetAP2 has been identified in the genome of the microsporidian parasite *E. cuniculi*.

8-HYDROXYQUINOLINES

The halogenated 8-hydroxyquinolines iodoquinol (diiodohydroxyquin) and clioquinol (iodochlorhydroxyquin) have been used as luminal agents to eliminate intestinal colonization with *E. histolytica*.

Iodoquinol (YODOXIN) is the safer and is the only one available for use as an oral agent in the U.S. When used at appropriate doses (never to exceed 2 g/day and duration of therapy not greater than 20 days in adults), adverse effects are unusual. However, the use of these drugs, especially at doses exceeding 2 g/day for long periods carries significant risk. The most important toxic reaction, ascribed primarily to clioquinol, is subacute myelo-optic neuropathy. Peripheral neuropathy is a less severe manifestation of neurotoxicity owing to these drugs. Administration of iodoquinol in high doses to children with chronic diarrhea has been associated with optic atrophy and permanent loss of vision.

Because of its superior adverse-event profile, paromomycin is preferred as the
luminal agent for amebiasis; however, iodoquinol is a reasonable alternative. Iodoquinol is used in combination with metronidazole to treat individuals with amebic colitis or amebic liver abscess but may be used as a single agent for asymptomatic individuals found to be infected with *E. histolytica*. For adults, the recommended dose of iodoquinol is 650 mg orally 3 times daily for 20 days, whereas children receive 10 mg/kg of body weight orally 3 times a day (not to exceed 1.95 g/day) for 20 days.

**MELARSOPROL**

Despite the fact that it causes an often fatal encephalopathy in 2-10% of the patients, melarsoprol is the only drug for the treatment of late (CNS) stages of East African trypanosomiasis caused by *T. brucei rhodesiense*. Although melarsoprol is also effective against late-stage West African trypanosomiasis caused by *T. brucei gambiense*, eflornithine has become the first-line treatment for this disease. The continued use of melarsoprol in the field is indicative of the paucity of alternative therapies for late-stage sleeping sickness.

![MELARSOPROL](image)

Melarsoprol (Mel B; ARSOBAL) is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

**Mechanism of Action; Antiprotozoal Effects.** Melarsoprol is metabolized to melarsen oxide, the active drug. Arsen-oxides react avidly and reversibly with vicinal sulfhydryl groups and thereby inactivate many enzymes. Melarsoprol reacts with trypanothione, the spermidine-glutathione adduct that substitutes for glutathione in these parasites. Binding of melarsoprol to trypanothione results in a melarsen oxide-trypanothione adduct that inhibits trypanothione reductase. Both the sequestering of trypanothione and the inhibition of trypanothione...
reductase would have lethal consequences to the cell; however, this mode of action remains unproven. Treatment failure owing to resistance of trypanosomes to melarsoprol has risen sharply and some of the resistant strains are an order of magnitude less sensitive to the drug. Resistance to melarsoprol likely involves transport defects. The adenine-adenosine transporter termed the P2 transporter is 1 example. It has activity on melarsoprol as well as pentamidine and berenil; point mutations in this transporter are found in melarsoprol-resistant isolates. Another transporter, HAPT1, has been identified, and the concomitant loss of both the P2 and HAPT transporters led to high-level cross-resistance to both melarsen and pentamidine.

**ADME.** Melarsoprol is always administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. Melarsoprol is a prodrug and is metabolized rapidly ($t_{1/2} = 30$ min) to melarsen oxide, the active form of the drug. A small but therapeutically significant amount of the drug enters the CSF and has a lethal effect on trypanosomes infecting the CNS. The compound is excreted rapidly, with 70-80% of the arsenic appearing in the feces.

**Therapeutic Uses.** Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis, which is 100% fatal if untreated. The drug is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. Patients infected with *T. brucei rhodesiense* who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with *T. brucei gambiense* who are not cured with melarsoprol rarely benefit from repeated treatment with this drug. Such patients often respond well to eflornithine.

For *T. brucei gambiense* a continuous 10-day course of 2.2 mg/kg/day is equivalent to the longer course treatment and is now recommended. For *T. brucei rhodesiense*, the CDC recommends 3 series of 3 daily doses with a 7-day rest period between series. The first series gives 1.8, 2.7, and 3.6 mg/kg on days 1, 2, and 3, respectively. The subsequent series are 3.6 mg/kg daily. Encephalopathy develops more frequently in patients with *T. brucei rhodesiense* compared to *T. brucei gambiense*. Concurrent administration of prednisolone is frequently employed throughout the treatment course.
**Toxicity and Side Effects.** Treatment with melarsoprol is associated with significant toxicity and morbidity. A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs 9-11 days after treatment starts in ~5-10% of patients, leading to death in about half of these. Peripheral neuropathy occurs in ~10% of patients receiving melarsoprol. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and evidence of renal or hepatic damage may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting melarsoprol slowly into the supine, fasting patient.

**Precautions and Contraindications.** Melarsoprol should be given only to patients under hospital supervision. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprous patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. The drug may be used in pregnancy.

**METRONIDAZOLE**

Metronidazole and related nitroimidazoles are active in vitro against a wide variety of anaerobic protozoal parasites and anaerobic bacteria. Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis, as well as in a variety of infections caused by obligate anaerobic bacteria, including *Bacteroides*, *Clostridium*, and microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp. Metronidazole manifests antibacterial activity against all anaerobic cocci and both anaerobic gram-negative bacilli, including *Bacteroides* spp., and anaerobic spore-forming gram-positive bacilli. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria.

**MECHANISM OF ACTION AND RESISTANCE.** Metronidazole is a prodrug requiring reductive activation of the nitro group by susceptible organisms.
Unlike their aerobic counterparts, anaerobic and microaerophilic pathogens (e.g., the amitochondriate protozoa *T. vaginalis, E. histolytica*, and *G. lamblia* and various anaerobic bacteria) contain electron transport components that have a sufficiently negative redox potential to donate electrons to metronidazole. The single electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA. Metronidazole is catalytically recycled; loss of the active metabolite’s electron regenerates the parent compound. Increasing levels of \( \text{O}_2 \) inhibit metronidazole-induced cytotoxicity because \( \text{O}_2 \) competes with metronidazole for electrons generated by energy metabolism. Thus, \( \text{O}_2 \) can both decrease reductive activation of metronidazole and increase recycling of the activated drug.

Anaerobic or microaerophilic organisms susceptible to metronidazole derive energy from the oxidative fermentation of ketoacids such as pyruvate. Pyruvate decarboxylation, catalyzed by pyruvate-ferredoxin oxidoreductase (PFOR), produces electrons that reduce ferredoxin, which, in turn, catalytically donates its electrons to biological electron acceptors or to metronidazole.

Clinical resistance to metronidazole is well documented for *T. vaginalis, G. lamblia*, and a variety of anaerobic and microaerophilic bacteria. Resistance correlates with impaired oxygen-scavenging capabilities, leading to higher local \( \text{O}_2 \) concentrations, decreased activation of metronidazole, and futile recycling of the activated drug. Other resistant strains have lowered levels of PFOR and ferredoxin, perhaps explaining why they may still respond to higher doses of metronidazole. In the case of *Bacteroides* spp., metronidazole resistance has been linked to a family of nitroimidazole (*nim*) resistance genes that can be encoded chromosomally or episomally. These *nim* genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminoimidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing.

**ADME.** Preparations of metronidazole are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake and distributed to a volume approximating total body water; less than 20% of the drug is bound to plasma proteins. A linear relationship between dose and plasma concentration pertains for doses of 200-2000 mg. Repeated doses every 6-8 h result in some accumulation of the drug. The \( t_{1/2} \) of metronidazole in plasma is \(~8\) h. With the exception of the placenta,
metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, breast milk, and CSF. After an oral dose, >75% of labeled metronidazole is eliminated in the urine, largely as metabolites formed by the liver from oxidation of the drug’s side chains, a hydroxy derivative and an acid; ~10% is recovered as unchanged drug. Two principal metabolites result. The hydroxy metabolite has a longer $t_{1/2}$ (~12 h) and has ~50% of the antitrichomonal activity of metronidazole. Formation of glucuronides also is observed. Small quantities of reduced metabolites are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of metronidazole is induced by phenobarbital, prednisone, rifampin, and possibly ethanol and is inhibited by cimetidine.

THERAPEUTIC USES. Metronidazole cures genital infections with *T. vaginalis* in both in >90% of cases. The preferred treatment regimen is 2 g metronidazole as a single oral dose for both males and females. Tinidazole, which has a longer $t_{1/2}$ than metronidazole, is also used at a 2-g single dose and appears to provide equivalent or better responses. When repeated courses or higher doses of the drug are required for uncured or recurrent infections, it is recommended that intervals of 4-6 weeks elapse between courses. Leukocyte counts should be carried out before, during, and after each course of treatment. Treatment failures owing to the presence of metronidazole-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a topical gel containing 0.75% metronidazole or a 500- to 1000-mg vaginal suppository may be beneficial in refractory cases.

Metronidazole is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscess. The recommended dose is 500-750 mg metronidazole taken orally 3 times daily for 7-10 days, or for children, 35-50 mg/kg/day given in 3 divided doses for 7-10 days. Amebic liver abscess has been treated successfully by short courses (2.4 g daily as a single oral dose for 2 days) of metronidazole or tinidazole. *E. histolytica* persist in most patients who recover from acute amebiasis after metronidazole therapy, so it is recommended that all such individuals also be treated with a luminal amebicide. Although effective for the therapy of giardiasis, metronidazole has yet to be approved for treatment of this infection in
the U.S. However, tinidazole is approved for the treatment of giardiasis as a single 2-g dose and is appropriate first-line therapy.

Metronidazole is a relatively inexpensive and versatile drug with efficacy against a broad spectrum of anaerobic and microaerophilic bacteria. It is used for the treatment of serious infections owing to susceptible anaerobic bacteria, including *Bacteroides, Clostridium, Fusobacterium, Peptococcus, Peptostreptococcus, Eubacterium*, and *Helicobacter*. The drug is also given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole achieves clinically effective levels in bones, joints, and the CNS. It can be given intravenously when oral administration is not possible. Metronidazole is used as a component of prophylaxis for colorectal surgery and is employed as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with *H. pylori* (see Chapter 45). Metronidazole is used as primary therapy for *Clostridium difficile* infection, the major cause of pseudomembranous colitis. Metronidazole is also used in the treatment of patients with Crohn disease who have perianal fistulas and colonic disease.

**Toxicity, Contraindications, and Drug Interactions.** Common side effects are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Dizziness, vertigo, and very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant discontinuation of metronidazole. The drug also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete. Urticaria, flushing, and pruritus are indicative of drug sensitivity that can require withdrawal of metronidazole. Metronidazole is a rare cause of Stevens-Johnson syndrome, which may be more common among individuals receiving high doses of metronidazole and concurrent therapy with the antihelminthic mebendazole. Dysuria, cystitis, and a sense of pelvic pressure have been reported. Metronidazole has a disulfiram-like effect, and some patients experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy with this drug. Metronidazole and disulfiram or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur. Metronidazole should be used cautiously in patients with active disease of the CNS because of potential
neurotoxicity. The drug also may precipitate CNS signs of lithium toxicity in patients receiving high doses of lithium. Metronidazole can prolong the prothrombin time of patients receiving therapy with warfarin (COUMADIN) anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease. Metronidazole use during the first trimester generally is not advised.

**MILTEFOSINE**

Miltefosine (IMPAVIDO) is an alkylphosphocholine (APC) analog developed originally as an anticancer agent. It is highly curative against visceral leishmaniasis and also appears to be effective against the cutaneous forms of the disease. Its main drawback is its teratogenicity; it must not be used in pregnant women.

![MILTEFOSINE](image)

**Antiprotozoal Effects.** Miltefosine is the first orally available therapy for leishmaniasis. It is a safe and effective treatment for visceral leishmaniasis and has shown >90% efficacy against some species of cutaneous leishmaniasis. The mechanism of action of miltefosine is not yet understood. Studies in *Leishmania* suggest that the drug may alter ether-lipid metabolism, cell signaling, or glycosylphosphatidylinositol anchor biosynthesis. Mutations in a P-type ATPase that belongs to the aminophospholipid translocase subfamily apparently decrease drug uptake and confer drug resistance.

**ADME.** Miltefosine is well absorbed orally and distributed throughout the human body. Detailed pharmacokinetic data are lacking, with the exception that miltefosine has a long $t_{1/2}$ (1-4 weeks). Plasma concentrations are proportional to the dose.

**Therapeutic Uses.** Oral miltefosine is registered for use in India for the treatment of visceral leishmaniasis: for adults $>25$ kg, 100 mg daily divided into 2 parts,
and for adults <25 kg, 50 mg daily in 1 dose for 28 days; for children, 2.5 mg/kg/day in 2 divided doses. In the U.S., the recommended dose for both visceral and cutaneous disease is 2.5 mg/kg/day (maximum dose of 150 mg/day) for 28 days, given in 2 divided doses. The compound cannot be given intravenously because it has hemolytic activity.

Toxicity and Side Effects. Vomiting and diarrhea have been reported as frequent side effects in up to 60% of the patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and reversible. Because of its teratogenic potential, miltefosine is contraindicated in pregnant women.

NIFURTIMOX AND BENZNIDAZOLE

Nifurtimox and benznidazole are used to treat American trypanosomiasis caused by *T. cruzi*. Nifurtimox (Bayer 2502, LAMPIT), a nitrofuran analog, and benznidazole (Roche 7-1051, ROCHAGAN), a nitroimidazole analog, can be obtained in the U.S. from the CDC.

Antiprotozoal Effects and Mechanisms of Action. Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi*. Nifurtimox also has activity against *T. brucei* and can be curative against both early- and late-stage disease (see earlier discussion on nifurtimox-eflornithine combination therapy). The trypanocidal effects of nifurtimox and benznidazole derive from their activation by a NADH-dependent mitochondrial nitroreductase to nitro radical anions that are thought to account for the trypanocidal effects. The generated nitro anion radicals form covalent attachments to macromolecules leading to cellular damage that includes lipid peroxidation and membrane injury, enzyme inactivation, and damage to DNA.

ADME. Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after ~3.5 h. Less than 0.5% of the dose is excreted in urine. The elimination $t_{1/2}$ is ~3 h. High concentrations of several unidentified metabolites are found, and nifurtimox undergoes rapid biotransformation, probably via a presystemic first-pass effect. Whether the metabolites have any trypanocidal activity is unknown.
**Therapeutic Uses.** Nifurtimox and benznidazole are employed in the treatment of American trypanosomiasis (Chagas disease) caused by *T. cruzi*. Because of toxicity, benznidazole is the preferred treatment. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas disease, with parasitological cures obtained in 80% of these cases. In the chronic form of the disease, parasitological cures are still possible in up to 50% of the patients, although the drug is less effective than in the acute stage. The clinical response of the acute illness to drug therapy varies with geographic region; parasite strains in Argentina, southern Brazil, Chile, and Venezuela appear to be more susceptible than those in central Brazil. The current recommendations are that patients <50 years of age with either acute- or recent chronic-phase disease, without advanced cardiomyopathy, should be treated. In patients >50 years of age, treatment is optional because of lowered drug tolerability. Therapy is strongly encouraged for patients who will receive immunosuppressive therapy or who are HIV positive. Therapy with nifurtimox or benznidazole should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or from blood transfusions.

Both drugs are given orally. For nifurtimox, adults (>17 years of age) with acute infection should receive 8-10 mg/kg/day in 3 to 4 divided doses for 90 days; children 1-10 years of age should receive 15-20 mg/kg/day in 3 to 4 divided doses for 90 days; for individuals 11-16 years old, the daily dose is 12.5-15 mg/kg given according to the same schedule. For benznidazole, the recommended treatment for adults (>13 years) is 5-7 mg/kg/day in 2 divided doses for 60 days, with children up to 12 years receiving 10 mg/kg/day. If gastric upset and weight loss occur during treatment, dosage should be reduced. The ingestion of alcohol should be avoided. Nifurtimox is used in combination with eflornithine in treating late stage *T.b. gambiense* sleeping sickness.

**Toxicity and Side Effects.** Side effects are common and range from hypersensitivity reactions (e.g., dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis) to dose- and age-dependent complications primarily referable to the GI tract and both the peripheral and central nervous systems. Nausea and vomiting are common, as are myalgia and weakness. Peripheral neuropathy and GI symptoms are especially common after prolonged treatment; the latter complication may lead to weight loss and preclude further therapy. Because of the seriousness of Chagas disease and the lack of superior drugs, there are few
NITAZOXANIDE

Nitazoxanide (N-[nitrothiazolyl] salicylamide, ALINA) is an oral synthetic broad-spectrum antiparasitic agent (see Chapter 51). Nitazoxanide is FDA-approved for the treatment of cryptosporidiosis and giardiasis in children.

Antimicrobial Effects. Nitazoxanide and its active metabolite, tizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites and oocytes of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis, E. histolytica,* and *T. vaginalis* in vitro. Nitazoxanide also demonstrated activity against intestinal helmiths.

Mechanism of Action. Nitazoxanide interferes with the PFOR enzyme-dependent electron-transfer reaction, which is essential to anaerobic metabolism in protozoan and bacterial species.

ADME. Following oral administration, nitazoxanide is hydrolyzed rapidly to its active metabolite, tizoxanide, which undergoes conjugation to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum plasma concentrations of the metabolites occur 1-4 h following administration. Tizoxanide is >99.9% bound to plasma proteins. Tizoxanide is excreted in the urine, bile, and feces; tizoxanide glucuronide is excreted in the urine and bile.

Therapeutic Uses. In the U.S., nitazoxanide is approved for the treatment of *G. intestinalis* infection (therapeutic efficacy of 85-90% for clinical response) and for the treatment of diarrhea caused by cryptosporidia (therapeutic efficacy, 56-88% for clinical response) in adults and children >1 year of age. The efficacy of nitazoxanide in children (or adults) with cryptosporidia infection and AIDS has not been clearly established. For children ages 12-47 months, the recommended dose is 100 mg nitazoxanide every 12 h for 3 days; for children ages 4-11 years, the dose is 200 mg nitazoxanide every 12 h for 3 days. A 500-mg tablet, suitable for adult dosing (every 12 h), is available. Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helmiths). Effective parasite clearance after nitazoxanide treatment was shown
for *G. intestinalis*, *E. histolytica/E. dispar*, *B. hominis*, *C. parvum*, *C. cayetanensis*, *I. belli*, *H. nana*, *T. trichiura*, *A. lumbricoides*, and *E. vermicularis*, although more than 1 course of therapy was required in some cases. Nitazoxanide has been used to treat infections with *G. intestinalis* that are resistant to metronidazole and albendazole.

**Toxicity and Side Effects.** Adverse effects appear are rare with nitazoxanide. A greenish tint to the urine is seen in most individuals taking nitazoxanide. Nitazoxanide is a pregnancy Category B agent, based on animal teratogenicity and fertility studies.

**PAROMOMYCIN**

Paromomycin (aminosidine, HUMATIN) is an aminoglycoside that is used as an oral agent to treat *E. histolytica* infection, cryptosporidiosis, and giardiasis. A topical formulation has been used to treat trichomoniasis; parenteral administration has been used for visceral leishmaniasis.

**Mechanism of Action; ADME.** Paromomycin shares the same mechanism of action as neomycin and kanamycin (binding to the 30S ribosomal subunit) and has the same spectrum of antibacterial activity. The drug is not absorbed from the GI tract and thus the actions of an oral dose are confined to the GI tract; 100% of the oral dose is recovered in the feces. Paromomycin is available only for oral use in the U.S.

**Antimicrobial Effects; Therapeutics Uses.** Paromomycin is the drug of choice for treating intestinal colonization with *E. histolytica* and is used in combination with metronidazole to treat amebic colitis and amebic liver abscess. Adverse effects are rare with oral usage but include abdominal pain and cramping, epigastric pain, nausea and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Dosing in adults is 500 mg orally 3 times daily for 10 days, whereas children have been treated with 25-30 mg/kg/day in 3 divided oral doses. Paromomycin formulated as a 6.25% cream has been used to treat vaginal trichomoniasis in patients in whom metronidazole therapy has failed. Cures have been reported, but vulvovaginal ulcerations and pain can complicate treatment. Paromomycin is also efficacious as a topical formulation containing
15% paromomycin in combination with 12% methylbenzonium chloride for the
treatment of cutaneous leishmaniasis. The drug has been administered
parenterally alone or in combination with antimony to treat visceral
leishmaniasis. Paromomycin has been advocated as a treatment for giardiasis in
pregnant women, when metronidazole is contraindicated and as an alternative
agent for metronidazole-resistant isolates of *G. intestinalis*.

**PENTAMIDINE**

Pentamidine is a positively charged aromatic diamine. It is a broad-
spectrum agent with activity against several species of pathogenic
protozoa and some fungi.

Pentamidine as the di-isethionate salt is marketed for injection (PENTAM 300,
others) or for use as an aerosol (NEBU-PENT). The di-isethionate salt is highly
water soluble; however, solutions should be used promptly because pentamidine
is unstable in solution.

*Antiprotozoal and Antifungal Effects.* Pentamidine is used for the treatment of
early-stage *T. brucei gambiense* infection but is ineffective in the treatment of
late-stage disease and has reduced efficacy against *T. brucei rhodesiense*.
Pentamidine is an alternative agent for the treatment of cutaneous leishmaniasis.
Pentamidine is an alternative agent for the treatment and prophylaxis of
Pneumocystis pneumonia caused by *Pneumocystis jiroveci*. *Diminazene*
(BERENIL) is a related diamidine that is used as an inexpensive alternative to
pentamidine for the treatment of early African trypanosomiasis.

*Mechanism of Action and Resistance.* The mechanism of action of the
diamidines is unknown. The compounds display multiple effects on any given
parasite and act by disparate mechanisms in different parasites. Multiple
transporters are responsible for pentamidine uptake, and this may account for the
fact that little resistance to this drug is observed in field isolates despite its years
of use as a prophylactic agent.

*ADME.* Pentamidine isethionate is fairly well absorbed from parenteral sites of
administration. Following a single intravenous dose, the drug disappears from
plasma with an apparent $t_{1/2}$ of several minutes to a few h and maximum plasma
concentrations after intramuscular injection occurring at 1 h. The $t_{1/2}$ of elimination is long (weeks to months); the drug is 70% bound to plasma proteins. This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining its ineffectiveness against late-stage trypanosomiasis. Inhalation of pentamidine aerosols is used for prophylaxis of *Pneumocystis* pneumonia; delivery of drug by this route results in little systemic absorption and decreased toxicity compared with intravenous administration.

**Therapeutic Uses.** Pentamidine isethionate is used for the treatment of early-stage *T. brucei gambiense* and is given by intramuscular injection in single doses of 4 mg/kg/day for 7 days. Pentamidine has been used successfully in courses of 15-20 intramuscular doses of 4 mg/kg every other day to treat visceral leishmaniasis. This compound provides an alternative to antimonials, lipid formulations of amphotericin B, or miltefosine but it is overall the least well tolerated.

Pentamidine is one of several drugs or drug combinations used to treat or prevent *Pneumocystis* infection. *Pneumocystis* pneumonia (PCP) is a major cause of mortality in individuals with AIDS and can occur in patients who are immunosuppressed by other mechanisms. Trimethoprim-sulfamethoxazole is the drug of choice for the treatment and prevention of PCP (see Chapter 52). Pentamidine is reserved for 2 indications: (1) as a 4 mg/kg single daily intravenous dose for 21 days to treat severe PCP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agents (e.g., atovaquone or the combination of clindamycin and primaquine); (2) as a “salvage” agent for individuals with PCP who fail to respond to initial therapy (usually trimethoprim-sulfamethoxazole; pentamidine may be less effective than the combination of clindamycin and primaquine or atovaquone for this indication).

Pentamidine administered as an aerosol preparation is used for the prevention of PCP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not deemed candidates for either dapsone (alone or in combination with pyrimethamine) or atovaquone. Candidates for PCP prophylaxis are individuals with HIV infection and a CD4 count of <200/mm$^3$ and individuals with HIV infection and persistent unexplained fever or oropharyngeal candidiasis. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5-
10% nebulized solution over 30-45 min. Although convenient, aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens, and a slightly increased risk for pneumothorax.

**Toxicity and Side Effects.** Approximately 50% of individuals receiving the drug at recommended doses show some adverse effect. Intravenous administration of pentamidine may be associated with hypotension, tachycardia, and headache. These effects are probably secondary to the binding of pentamidine to imidazoline receptors and can be ameliorated by slowing the infusion rate. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. Pentamidine is nephrotoxic (~25% of treated patients show signs of renal dysfunction), and if the serum creatinine concentration rises >1.0-2.0 mg/dL, it may be necessary to withhold the drug temporarily or change to an alternative agent. Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic enzymes. Intramuscular administration of pentamidine is associated with the development of sterile abscesses at the injection site, which can become infected secondarily; most authorities recommend intravenous administration. Aerosolized pentamidine is associated with few adverse events.

**SODIUM STIBOGLUCONATE**

Sodium stibogluconate (sodium antimony gluconate, PENTOSTAM) is a pentavalent antimonial compound that has been the mainstay of the treatment of leishmaniasis. Increasing resistance to antimonials has reduced their efficacy and they are no longer useful in India, where lipid-based amphotericin B and miltefosine are now recommended instead. In the U.S., sodium stibogluconate can be obtained from the CDC.

**Mechanism of Action.** The relatively nontoxic pentavalent antimonials act as prodrugs that are reduced to the more toxic Sb⁺ species that kill amastigotes within the phagolysosomes of macrophages. Following reduction, the drugs
seem to interfere with the trypanothione redox system, Sb+ induces a rapid efflux of trypanothione and glutathione from the cells, and also inhibits trypanothione reductase, thereby causing a significant loss of thiol reduction potential in the cells.

**ADME.** The drug is given intravenously or intramuscularly; it is not active orally. The agent is absorbed rapidly, distributed in an apparent volume of ~0.22 L/kg, and eliminated in 2 phases. The first has a $t_{1/2}$ of ~2 h, and the second is much slower ($t_{1/2} = 33-76$ h). The prolonged terminal elimination phase may reflect conversion of the Sb+ to the more toxic Sb+ that is concentrated and slowly released from tissues. The drug is eliminated in the urine.

**Therapeutic Uses.** Sodium stibogluconate is given parenterally. The standard course is 20 mg/kg/day for 21 days for cutaneous disease and for 28 days for visceral leishmaniasis. Increased resistance has greatly compromised the effectiveness of antimonials, and the stibogluconate is now obsolete in India. Liposomal amphotericin B is the recommended alternative for treatment of either visceral leishmaniasis (*kala azar*) in India or mucosal leishmaniasis in general; the orally effective compound miltefosine is likely to see much wider use. Intralesional treatment has also been advocated as a safer, alternative method for treating cutaneous disease. Children usually tolerate the drug well at the same dose per kilogram used for adults. Patients who respond favorably show clinical improvement within 1-2 weeks of initiation of therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals. Patients infected with HIV present a challenge because they usually relapse after successful initial therapy with either pentavalent antimonials or amphotericin B.

**Toxicity and Side Effects.** In general, high-dose regimens of sodium stibogluconate are fairly well tolerated; toxic reactions usually are reversible, and most subside despite continued therapy. Adverse effects noted most commonly include pain at the injection site; chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression manifested by decreased red cell, white cell, and platelet counts in the blood; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial
toxicity, as are shock and sudden death.

SURAMIN

*Suramin sodium* (BAYER 205, formerly GERMANIN, others) is a water-soluble trypanocide; solutions deteriorate quickly in air and only freshly prepared solutions should be used. In the U.S., suramin is available only from the CDC.

**Antiparasitic Effects.** Suramin is a relatively slow-acting trypanocide (>6 h in vitro) with high clinical activity against both *T. b. gambiense* and *T. b. rhodesiense*. Its mechanism of action is unknown. Selective toxicity is likely to result from the ability of the parasite to take up the drug by receptor-mediated endocytosis of the protein-bound drug, with low-density lipoproteins the most important interacting proteins for this event. Suramin inhibits many trypanosomal and mammalian enzymes and receptors unrelated to its antiparasitic effects. No consensus for the mechanism of action has emerged, and the lack of any significant field resistance points to multiple potential targets.

**ADME.** Because it is not absorbed after oral intake, suramin is given intravenously to avoid local inflammation and necrosis associated with subcutaneous or intramuscular injections. After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The drug is 99.7% serum protein bound and has a terminal elimination $t_{1/2}$ of 41-78 days. Suramin is not appreciably metabolized; renal clearance accounts for elimination of ~80% of the compound from the body. Very little suramin penetrates the CSF, consistent with its polar character and lack of efficacy once the CNS has been invaded by trypanosomes.

**Therapeutic Uses.** Suramin is the first-line therapy for early-stage *T. brucei rhodesiense* infection. Because only small amounts of the drug enter the brain, suramin is used only for the treatment of early-stage African trypanosomiasis (before CNS involvement). Treatment of active African trypanosomiasis should not be started until 24 h after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (i.e., pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia,
hypotension, and possibly permanent blindness). Suramin is given by slow intravenous injection as a 10% aqueous solution. The normal single dose for adults with *T. brucei rhodesiense* infection is 1 g. It is advisable to employ a test dose of 200 mg initially to detect sensitivity, after which the normal dose is given intravenously (e.g., on days 1, 3, 7, 14, and 21). The pediatric dose is 20 mg/kg, given according to the same schedule. Patients in poor condition should be treated with lower doses during the first week. Patients who relapse after suramin therapy should be treated with melarsoprol.

**Toxicity and Side Effects.** The most serious immediate reaction consisting of nausea, vomiting, shock, and loss of consciousness is rare (~1 in 2000 patients). Malaise, nausea, and fatigue are also common immediate reactions. The most common problem encountered after several doses of suramin is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. Other, less prevalent reactions include vomiting, diarrhea, stomatitis, chills, abdominal pain, and edema. Patients receiving suramin should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency.
Infections with helminths, or parasitic worms, affect more than 2 billion people worldwide (Figure 51–1). In regions of rural poverty in the tropics, where prevalence is greatest, simultaneous infection with more than 1 type of helminth is common.

![Relative incidence of helminth infections worldwide.](image)

Worms pathogenic for humans are *Metazoa* and can be classified into *roundworms* (*nematodes*) and 2 types of *flatworms*, *flukes* (*trematodes*) and *tapeworms* (*cestodes*). These biologically diverse eukaryotes vary with respect to life cycle, bodily structure, development, physiology, localization within the host, and susceptibility to chemotherapy. Immature forms invade humans via the skin or GI tract and evolve into well-differentiated adult worms with characteristic tissue distributions. With few exceptions, such as *Strongyloides* and *Echinococcus*, these organisms cannot complete their life cycle and replicate.
within the human host to produce mature offspring. Therefore, the extent of exposure to these parasites dictates the number of parasites infecting the host. Second, any reduction in the number of adult organisms by chemotherapy is sustained unless reinfection occurs. The burden of parasitic helminths within an infected population is not uniformly distributed, and it typically displays a negative binomial distribution whereby relatively few persons carry the heaviest parasite burden, resulting in increased morbidity in these individuals who also contribute disproportionately to transmission.

*Anthelmintics* are drugs that act either locally within the gut lumen to cause expulsion of worms from the GI tract, or systemically against helminths residing outside the GI tract. Therapy for many tissue-dwelling helminths, such as filarial parasites, is not fully effective. There is increasing appreciation of the impact of helminth infections on the health and education of school-aged children. In a massive public health effort, international health organizations are promoting the periodic and frequent use of anthelmintic drugs in schools as a means to control morbidity caused by soil-transmitted helminths and schistosomes in developing countries. Control programs employing anthelmintics rank among the world’s largest health efforts, and hundreds of millions of people receive treatment annually.

This chapter is divided into 2 main parts:

- Clinical presentation and recommended chemotherapy for common helminth infections
- Pharmacological properties of specific anthelmintics

**HELMINTH INFECTIONS AND THEIR TREATMENT**

**NEMATODES (ROUNDWORMS)**

The major nematode parasites of humans include the *soil-transmitted helminths* (STHs; sometimes referred to as “geohelminths”) and the *filarial nematodes*. The major STH infections (*ascariasis* [roundworm], *trichuriasis* [whipworm], and *hookworm infection*) are among the most prevalent infections in developing countries. The
agents most widely employed for reducing morbidity are the benzimidazole (BZ) anthelmintics, either albendazole (ALBENZA and ZENTEL) or mebendazole (VERMOX, others) (Figure 51–2).

Figure 51–2 Structure of the Benzimidazoles.

**ROUNDWORM: ASCARIS LUMBRICOIDES.** *Ascaris lumbricoides*, known as the “roundworm,” may affect from 70-90% of persons in some tropical regions; it is also seen in temperate climates. People become infected by ingesting food or soil contaminated with embryonated *A. lumbricoides* eggs.

The preferred anthelmintics are the BZs, mebendazole and albendazole, and the broad-spectrum drug pyrantel pamoate. Cure with any of these drugs can be achieved in nearly 100% of cases. Mebendazole and albendazole are preferred for therapy of asymptomatic to moderate ascariasis but should be used with caution to treat heavy *Ascaris* infections, alone or with hookworms. Some clinicians recommend the use of pyrantel for heavy *Ascaris* infections because this agent paralyzes the worms prior to their expulsion.

**TOXOCARIASIS: TOXOCARA CANIS.** This zoonotic infection, caused by the canine ascarid *Toxocara canis*, is a common helminthiasis in North America and Europe.

Three major syndromes are caused by *T. canis* infection: visceral larva migrans (VLM), ocular larva migrans (OLM), and covert toxocariasis (CTox). CTox may
represent an under-appreciated cause of asthma and seizures. Specific treatment of VLM is reserved for patients with severe, persistent, or progressive symptoms. Albendazole is the drug of choice. In contrast, anthelmintic therapies for OLM and CTox are controversial.

**HOOKWORM:** *Necator americanus, Ancylostoma duodenale.* These closely related hookworm species infect ~1 billion people in developing countries (see Figure 51–1).

*N. americanus* is the predominant hookworm worldwide, whereas *A. duodenale* is focally endemic in Egypt and in parts of northern India and China. Hookworm larvae live in the soils and penetrate exposed skin. After reaching the lungs, the larvae migrate to the oral cavity and are swallowed. After attaching to the small intestinal mucosa, the derived adult worms feed on host blood. There is a general relationship between the number of hookworms (hookworm burden) as determined by quantitative fecal egg counts and fecal blood loss. Unlike heavy *Ascaris* and *Trichuris* infections, which occur predominantly in children, heavy hookworm infections also occur in adults, including women of reproductive age. Although iron supplementation (and transfusion in severe cases) often is helpful in individuals with severe iron-deficiency anemia, the major goal of treatment is to remove blood-feeding adult hookworms from the intestines. Albendazole is the agent of first choice and is considered far superior to mebendazole at removing adult hookworms from the GI tract. Oral albendazole is the drug of choice for treating cutaneous larva migrans, or “creeping eruption,” which is due most commonly to skin migration by larvae of the dog hookworm, *A. braziliense*. Oral ivermectin or topical thiabendazole also can be used.

**WHIPWORM:** *Trichuris trichiura.* *Trichuris* (whipworm) infection is acquired by ingestion of embryonated eggs. In children, heavy *Trichuris* worm burdens can lead to colitis, *Trichuris* dysentery syndrome, and rectal prolapse. Mebendazole and albendazole are the most effective agents for treatment of whipworm. Both drugs provide significant reductions in host worm burdens even when used in a single dose. However, a “cure” (i.e., total worm burden removal) typically requires a 3-day course of therapy.
**THREADWORM: STRONGYLOIDES STERCORALIS.** *S. stercoralis* is distinctive among helminths in being able to complete its life cycle within the human host, infecting 30-100 million people worldwide, most frequently in the tropics and other hot, humid locales. In the U.S., strongyloidiasis is still endemic in the Appalachian region and in parts of the American South.

Infective larvae in fecally contaminated soil penetrate the skin or mucous membranes, travel to the lungs, and ultimately mature into adult worms in the small intestine, where they reside. Many infected individuals are asymptomatic, but some experience skin rashes, nonspecific GI symptoms, and cough. Life-threatening disseminated disease, known as the hyperinfection syndrome, can occur in immunosuppressed persons, even decades after the initial infection when parasite replication in the small intestine is unchecked by a competent immune response. Ivermectin is the drug of choice for treatment of strongyloidiasis.

**PINWORM: ENTEROBIUS VERMICULARIS.** *Enterobius* is one of the most common helminth infections in temperate climates, including the U.S.

Although this parasite rarely causes serious complications, pruritus in the perianal and perineal region can be severe, and scratching may cause secondary infection. In female patients, worms may wander into the genital tract and penetrate into the peritoneal cavity. Salpingitis or even peritonitis may ensue. Because the infection easily spreads throughout members of a family, a school, or an institution, the physician must decide whether to treat all individuals in close contact with an infected person. Pyrantel pamoate, mebendazole, and albendazole are highly effective. Single oral doses of each should be repeated after 2 weeks. When their use is combined with rigid standards of personal hygiene, a very high proportion of cures can be obtained.

**TRICHINOSIS: TRICHINELLA SPIRALIS.** *T. spiralis* is an ubiquitous zoonotic nematode parasite. Trichinosis in the U.S. and the developing world is usually caused by eating the under- or uncooked meat of deer and wild pigs.
When released by acid stomach contents, encysted larvae mature into adult worms in the intestine. Adults then produce infectious larvae that invade tissues, especially skeletal muscle and heart. Severe infection can be fatal, but more typically causes marked muscle pain and cardiac complications. Infection is readily preventable by cooking all pork products thoroughly before eating. The encysted larvae are killed by exposure to heat of 60°C for 5 min. Albendazole and mebendazole are effective against the intestinal forms of *T. spiralis* that are present early in infection. The efficacy of these agents or any anthelmintic agent on larvae that have migrated to muscle is questionable.

**LYMPHATIC FILARIASIS: WUCHERERIA BANCROFTI, BRUGIA MALAYI, AND B. TIMORI.** Adult worms that cause human lymphatic filariasis (LF) dwell in the lymphatic vessels. Transmission occurs through the bite of infected mosquitoes; ~90% of cases are due to *W. bancrofti*; most of the rest are due to *B. malayi*.

In LF, host reaction to the adult worms initially cause lymphatic inflymphangitis, and lymphadenitis. This can progress to lymphatic obstruction and is often exacerbated by secondary attacks of bacterial cellulitis, leading to lymphedema manifested by hydrocele and elephantiasis. All at-risk individuals should be treated once yearly with an oral 2-drug combination. For most countries, the WHO recommends diethylcarbamate (DEC) for its micro- and macrofilaricidal effect in combination with albendazole to enhance macrofilaricidal activity. The exceptions are in many parts of sub-Saharan Africa and Yemen, where either loiasis or onchocerciasis are co-endemic. In these regions, ivermectin is substituted for DEC. DEC and ivermectin clear circulating microfilariae from infected subjects, thereby reducing the likelihood that mosquitoes will transmit LF to other individuals. DEC is the drug of choice for specific therapy directed against adult worms. However, the anthelmintic effect on the adult worms is variable. In longstanding elephantiasis, surgical measures may be required to improve lymph drainage and remove redundant tissue.

**LOIASIS: LOA LOA.** *L. loa* is a tissue-migrating filarial parasite found in large river regions of Central and West Africa; the parasite is transmitted by deerflies. Adult worms reside in subcutaneous tissues, and infection may be recognized when these migrating worms cause
episodic and transient subcutaneous “Calabar” swellings. Adult worms may also pass across the sclera, causing “eyeworm.”

Rarely, encephalopathy, cardiopathy, or nephropathy occurs in association with heavy infection, particularly following chemotherapy. DEC currently is the best single drug for the treatment of loiasis. Glucocorticoids may be administered to ameliorate post-treatment acute reactions. In rare instances, life-threatening encephalopathy follows the treatment of loiasis, probably due to the inflammatory reaction to dead or dying microfilariae lodged in the cerebral microvasculature. Guidelines have been developed aimed at screening out populations with heavy infection so that they are not administered ivermectin, which has also been associated with fatal encephalopathy.

**RIVER BLINDNESS (ONCHOCERCIASIS).** *Onchocerca volvulus*, transmitted by blackflies near fast-flowing streams and rivers, infects 17-37 million people in 22 countries in sub-Saharan Africa and fewer people (<100,000) in 4 Latin American countries.

Inflammatory reactions, primarily to microfilariae rather than adult worms, affect the subcutaneous tissues, lymph nodes, and eyes. Onchocerciasis is a leading cause of infectious blindness. Ivermectin is the drug of choice for control and treatment of onchocerciasis. DEC is no longer recommended because ivermectin produces far milder systemic reactions and few if any ocular complications. Although suramin (see Chapter 50) kills adult *O. volvulus* worms, treatment with this relatively toxic agent is generally not advised.

**GUINEA WORM: DRACUNCULUS MEDINENSIS.** Known as the guinea, dragon, or Medina worm, this parasite causes dracunculiasis, an infection in decline (<5000 cases as of 2009, mostly in rural Sudan, Ghana, and Mali).

People become infected by drinking water containing copepods that carry infective larvae. After ~1 year, the adult female worms migrate and emerge through the skin, usually of the lower legs or feet. Strategies such as filtering drinking water and reducing contact of infected individuals with water have markedly reduced the transmission and prevalence of dracunculiasis in most endemic regions. There is no effective anthelmintic for treatment of *D.*
medinensis infection. Metronidazole, 250 mg given 3 times a day for 10 days, may provide symptomatic and functional relief.

CESTODES (FLATWORMS)

BEEF TAPEWORM: TAENIA SAGINATA. Humans are the definitive hosts for T. saginata.

Preventable by cooking beef to 60°C for >5 min, this infection rarely produces serious clinical disease, but it must be distinguished from that produced by Taenia solium. Praziquantel (BILTRICIDE) is the drug of choice for treatment of infection by T. saginata, although niclosamide can also be used.

PORK TAPEWORM: TAENIA SOLIUM. T. solium causes 2 types of infection. The intestinal form with adult tapeworms is caused by eating undercooked meat containing cysticerci, or more commonly by fecal-oral transmission of infective T. solium eggs from another infected human host. Cysticercosis, the far more dangerous systemic form that usually coexists with the intestinal form, is caused by invasive larval forms of the parasite.

Systemic infection results either from ingestion of fecally contaminated infectious material, or from eggs liberated from a gravid segment passing upward into the duodenum, where the outer layers are digested. In either case, larvae gain access to the circulation and tissues, exactly as in their cycle in the intermediate host, usually the pig. Invasion of the brain (neurocysticercosis) is common and dangerous. Niclosamide is preferred for treatment of intestinal infections with T. solium because it will have no effect on occult neurocysticercosis. Albendazole is the drug of choice for treating cysticercosis. The advisability of chemotherapy for neurocysticercosis is controversial, being appropriate only when it is directed at live cysticerci and not against dead or dying cysticerci. Pretreatment with glucocorticoids is strongly advised in this situation to minimize inflammatory reactions to dying parasites. Some experts advocate use of albendazole therapy for patients with multiple cysts or viable cysts.

FISH TAPEWORM: DIPHYLLOBOTHRIUM LATUM. D. latum is found most commonly in rivers and lakes of the Northern Hemisphere. In North America, the pike is the most common second intermediate host. The eating of
inadequately cooked infested fish introduces the larvae into the human intestine; the larvae can develop into adult worms up to 25 m long. Most infected individuals are asymptomatic. The most frequent manifestations include abdominal symptoms and weight loss; megaloblastic anemia develops due to a deficiency of vitamin B\textsubscript{12}. Therapy with praziquantel readily eliminates the worm and ensures hematological remission.

**DWARF TAPEWORM: HYMENOLEPIS NANA.** *H. nana* is the smallest and most common tapeworm parasitizing humans. *H. nana* is the only cestode that can develop from ovum to mature adult in humans without an intermediate host. Cysticerci develop in the villi of the intestine and then regain access to the intestinal lumen where larvae mature into adults. Praziquantel is effective against *H. nana* infections, but higher doses than used for other tapeworm infections usually are required. Albendazole is partially efficacious against *H. nana*.

**ECHINOCOCCUS SPECIES.** Humans are one of several intermediate hosts for larval forms of *Echinococcus* species that cause “cystic” (*E. granulosus*) and “alveolar” (*E. multilocularis* and *E. vogeli*) hydatid disease. Dogs and related canids are definitive hosts for these tapeworms.

Parasite eggs from canine stools are a major worldwide cause of disease in associated livestock (e.g., sheep and goats). Removal of the cysts by surgery is the preferred treatment, but leakage from ruptured cysts may spread disease to other organs. Prolonged regimens of albendazole, either alone or as an adjunct to surgery, are reportedly of some benefit. However, some patients are not cured despite multiple courses of therapy, especially in alveolar echinococcosis where lifelong therapy with albendazole may be required. Benzimidazole treatment should be administered in the perioperative period.

**TREMATODES (FLUKES)**

**SCHISTOSOMIASIS: SCHISTOSOMA HAEMATOBIIUM, S. MANSONI, S. JAPONICUM.** These are the main species of blood flukes that cause human schistosomiasis; less common species are *Schistosoma intercalatum* and *Schistosoma mekongi*. Infected
freshwater snails act as intermediate hosts for transmission of the infection, which continues to spread as agriculture and water resources increase.

The clinical manifestations of schistosomiasis generally correlate with the intensity of infection, with pathology primarily involving the liver, spleen, and GI tract (for *S. mansoni* and *S. japonicum*) or the urinary and genital tracts (*S. haematobium*). Heavy infection with *S. haematobium* predisposes to squamous cell carcinoma of the bladder. Chronic infections can cause porto-systemic shunting due to hepatic granuloma formation and periportal fibrosis in the liver.

Praziquantel is the drug of choice for treatment of schistosomiasis. Oxamniquine is effective for treatment of *S. mansoni* infections, particularly in South America, where the sensitivity of most strains may permit single-dose therapy; higher doses of the drug are required to treat African strains than to treat Brazilian strains of *S. mansoni*. Metrifonate (trichlorfon) is effective in the treatment of *S. haematobium* infections but not against *S. mansoni* and *S. japonicum*. Artemether (see Chapter 49) shows promise as an anti-schistosomal agent, targeting the larval schistosomula stages of the parasite.

**LUNG FLUKES: PARAGONIMUS WESTERMANI, ET AL.** Lung flukes, including several *Paragonimus* species, infect humans and carnivores; *P. westermani* is the most common. Humans become infected by eating raw or undercooked crabs or crayfish. Disease is caused by reactions to adult worms in the lungs or ectopic sites. Praziquantel is effective, as is triclabendazole (EGATEN). Bithionol is a second-line agent.

**CLONORCHIS SINENSIS, OPISTHORCHIS VIVERRINI, OPISTHORCHIS FELINEUS.** These closely related trematodes exist in the Far East (*C. sinensis*, “the Chinese liver fluke,” and *O. viverrini*) and parts of Eastern Europe (*O. felineus*). Metacercariae released from poorly cooked infected cyprinoid fish (carp) mature into adult flukes that inhabit the human biliary system. Heavy infections can cause obstructive liver disease, inflammatory gallbladder
pathology associated with cholangiocarcinoma, and obstructive pancreatitis. One-day therapy with praziquantel is highly effective against these parasites.

**FASCIOLA HEPATICA.** Humans are only accidentally infected with *F. hepatica*, the large liver fluke that exists worldwide and primarily affects herbivorous ruminants such as cattle and sheep. Triclabendazole, given as a single oral dose of 10 mg/kg, or in cases of severe infection 20 mg/kg divided into 2 doses, is the drug of choice for treatment of fascioliasis.

**FASCIOLOPSIS BUSKI, HETEROPHYES HETEROPHYES, METAGONIMUS YOKOGAWAI, NANOPHYETUS SALMINCOLA.** Obtained by eating contaminated water chestnuts and other caltrops in Southeast Asia, *F. buski* is one of the largest parasites causing human infection. Undercooked fish transmit infection with the other, much smaller GI trematodes that are widely distributed geographically. Abdominal symptoms produced by reactions to these flukes usually are mild, but heavy infections with *F. buski* can cause intestinal obstruction and peritonitis. Infections with all the intestinal trematodes respond well to single-day therapy with praziquantel.

**ANTHELMINTIC DRUGS**

**BENZIMIDAZOLES (BZS)**

Thiabendazole, mebendazole, and albendazole have been used extensively for the treatment of human helminth infections. The chemical structures of these drugs are shown in Figure 51–2.

Thiabendazole is active against a wide range of nematodes that infect the GI tract. However, its clinical value has declined markedly because of thiabendazole’s toxicity (CNS, liver, hypersensitivity, and visual side effects).
Mebendazole, the prototype benzimidazole carbamate, was introduced for the treatment of intestinal roundworm infections. Albendazole is a benzimidazole carbamate that is used worldwide for treatment of intestinal nematodes and cestodes; it is notable for the systemic bioavailability and efficacy of its sulfoxide metabolite against tissue-dwelling nematodes and cestodes. Albendazole is the drug of choice for treating cysticercosis and cystic hydatid disease. When used in single dose in conjunction with either ivermectin or DEC, it has shown additive effect in the control of LF and related tissue filarial infections. Of note, albendazole lacks activity against the liver fluke *F. hepatica*.

**ANTHELMINTIC ACTION.** The primary mechanism of action of action of BZ is thought to be inhibition of microtubule polymerization by binding to β-tubulin. The selective toxicity of these agents against helminths results from their higher affinity for parasite β-tubulin than for β-tubulin in humans.

Appropriate doses of mebendazole and albendazole are highly effective in treating most of the major STH infections (ascariasis, enterobiasis, trichuriasis, and hookworm) as well as less common human nematode infections. These drugs are active against both larval and adult stages of nematodes that cause these infections, and they are ovicidal for *Ascaris* and *Trichuris*. Immobilization and death of susceptible GI parasites occur slowly, and their clearance from the GI tract may not be complete until several days after treatment. Evidence for the emergence of β-tubulin gene mutations associated with resistance among human nematodes is confined to *T. trichiura* and *W. bancrofti*. Drug treatment failures have been reported in hookworm infections, but there is little evidence of widespread dissemination of resistant forms.

Albendazole is superior to mebendazole in curing hookworm and trichuriasis infections in children, especially when used as a single dose. Moreover, albendazole is more effective than mebendazole against strongyloidiasis and is superior to mebendazole against all tissue-dwelling helminths due to its active metabolite albendazole sulfoxide. It is therefore the drug of choice against cystic and alveolar hydatid disease caused by *Echinococcus granulosus* and *E. multilocularis*, and neurocysticercosis caused by larval forms of *Taenia solium*. The BZs probably are active against the intestinal stages of *Trichinella spiralis* in humans but probably do not affect the larval stages in tissues. Albendazole is
highly effective against the migrating forms of dog and cat hookworms that cause cutaneous larval migrans, although thiabendazole can be applied topically for this purpose. Microsporidial species that cause intestinal infections in HIV-infected individuals respond partially (*Enterocytozoon bieneusi*) or completely (*Encephalitozoon intestinalis* and related *Encephalitozoon* species) to albendazole. Albendazole also has efficacy against anaerobic protozoa such as *Trichomonas vaginalis* and *Giardia lamblia*. BZs exert antifungal activity in vitro but have no utility in human mycoses.

**ADME.** Thiabendazole is soluble in water; mebendazole and albendazole are poorly soluble in aqueous solution. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass hepatic metabolism. Absorbed mebendazole is ~95% bound to plasma proteins and is extensively metabolized. Mebendazole, rather than its metabolites, appears to be the active drug form. Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine. Coadministration of *cimetidine* will increase plasma levels of mebendazole, possibly due to inhibition of first-pass CYP-mediated metabolism.

Albendazole is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods and possibly by bile salts. Albendazole is rapidly metabolized in the liver and possibly in the intestine, to albendazole sulfoxide, which has potent anthelmintic activity. Albendazole sulfoxide is ~70% bound to plasma proteins and has a highly variable plasma *t*₁/₂ of 4-15 h. It is well distributed into various tissues including hydatid cysts, where it reaches a concentration of ~20% that in plasma. The bioavailability of the parent drug and activity of albendazole sulfoxide explain why albendazole is more effective than mebendazole for treatment of tissue-dwelling helminths. Oxidation of the sulfoxide derivatives to the nonchiral sulfone metabolite of albendazole, which is pharmacologically inactive, is probably rate limiting in determining the clearance and plasma *t*₁/₂ of the bioactive (+) sulfoxide metabolite. Albendazole metabolites are excreted mainly in the urine.

**Therapeutic Uses.** Thiabendazole remains a useful drug when applied topically for treatment of cutaneous larva migrans (creeping eruption). For treatment of strongyloidiasis, thiabendazole has been replaced by ivermectin.

Mebendazole is an effective drug for treatment of GI nematode infections. For
treatment of enterobiasis, a single 100-mg tablet is taken; a second dose should be given after 2 weeks. For control of ascariasis, trichuriasis, or hookworm infections, the recommended regimen is 100 mg of mebendazole taken in the morning and evening for 3 consecutive days (or a single 500-mg tablet administered once). If the patient is not cured 3 weeks after treatment, a second course should be given. A single dose of albendazole is superior to a single dose of mebendazole against hookworms and trichuriasis.

Albendazole is a safe and highly effective therapy for infections with GI nematodes, including A. lumbricoides, T. trichiura, and hookworms. For treatment of STH infections (enterobiasis, ascariasis, trichuriasis, and hookworm), albendazole is taken as a single oral 400-mg dose by adults and children >2 years of age. In children between the ages of 12 and 24 months, the WHO recommends a reduced dose of 200 mg. A 400-mg dose of albendazole appears to be superior to a 500-mg dose of mebendazole for curing hookworm infections and reducing egg counts.

Albendazole is the drug of choice for treating cystic hydatid disease due to Echinococcus granulosus. Although the drug provides only a modest cure rate when used alone, it is a useful adjunctive treatment in the perioperative period to reduce the risk of disseminated infection resulting from spillage of cyst contents at the time of surgery, or with nonoperative puncture, aspiration, injection, and re-aspiration (PAIR) procedures. A typical dosage regimen for adults is 400 mg given twice a day (for children, 15 mg/kg/day, maximum of 800 mg) for 1-6 months. Although it is the only drug available with useful activity against alveolar echinococcosis caused by E. multilocularis, it is parasiti-static rather than -cidal, and lifelong therapy with or without surgical intervention is usually required to control the infection. Albendazole, in the same regimen for 8-30 days, also is the preferred treatment of neurocysticercosis caused by larval forms of Taenia solium. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoid therapy is usually begun before initiating albendazole therapy and continued for several days after institution of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysticerci. Glucocorticoids increase plasma levels of albendazole sulfoxide.

Albendazole, 400 mg/day, also has shown efficacy for therapy of microsporidial intestinal infections in patients with AIDS. Infection with Capillaria
*philippinensis* can be treated with a 10-day treatment regimen with albendazole (400 mg/day). Albendazole is given with DEC to control LF in most parts of the world. The strategy is annual dosing with combination therapy for 4-6 years to maintain the microfilaremia at such low levels that transmission cannot occur. The period of therapy is estimated to correspond to the duration of fecundity of adult worms. To avoid serious reactions to dying microfilariae, the albendazole/ivermectin combination is recommended in locations where filariasis coexists with either onchocerciasis or loiasis.

**Toxicity, Side Effects, Precautions, and Contraindications.** Excluding thiabendazole, the BZs have excellent safety profiles. Overall, the incidence of side effects, primarily mild GI symptoms, occur in only 1% of treated children. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness. Mebendazole does not cause significant systemic toxicity in routine clinical use, due to its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infestation and expulsion of GI worms. Albendazole produces few side effects when used for short-term therapy of GI helminth infections, even in patients with heavy worm burdens. Even in long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is liver dysfunction, generally manifested by an increase in serum transaminase levels; rarely jaundice may be noted, but enzyme activities return to normal after therapy is completed. Liver function tests should be conducted during protracted albendazole therapy; the drug is not recommended for patients with cirrhosis. The safety of albendazole in children <2 years of age has not been established.

The BZs as a group display few clinically significant interactions with other drugs. Albendazole may induce its own metabolism; plasma levels of its sulfoxide metabolites can be increased by coadministration of glucocorticoids and possibly praziquantel. Caution is advised when using high doses of albendazole together with general inhibitors of hepatic CYPs. Coadministration of cimetidine can increase the bioavailability of mebendazole.

**Use in Pregnancy.** Neither albendazole nor mebendazole is recommended for use in human pregnancy. A review of the risk of congenital abnormalities from BZs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects; nonetheless, it is recommended that
treatment should be avoided during the first trimester of pregnancy. Hookworm occurs in many pregnant women in developing countries, including up to one-third of pregnant women in sub-Saharan Africa. Because some of these infected women may develop iron-deficiency anemia leading to adverse pregnancy outcomes, BZ treatment would be beneficial during the second and third trimesters of pregnancy. There is no evidence that maternal BZ therapy presents a risk to breast-fed infants.

**Use in Young Children.** The BZs have not been extensively studied in children <2 years of age. The WHO concluded that BZs may be used in children >1 year if the risks from adverse consequences caused by STHs are justified. The recommended dose is 200 mg of albendazole in children between the ages of 12 and 24 months.

**DIETHYLCARBAMAZINE (DEC)**

Diethylcarbamazine (DEC) (HETRAZAN) is a first-line agent for control and treatment of LF caused by *Wuchereria bancrofti* and *Brugia malayi* and for therapy of tropical pulmonary eosinophilia, an uncommon manifestation of lymphatic filarial infection. DEC is also the drug of choice for treatment of loiasis, caused by infection with the filarial parasite *L. loa*.

Caution must be used in treatment of high-grade *L. loa* infection because the rapid killing of large numbers of microfilariae can cause life-threatening post-treatment complications. Annual single-dose combination chemotherapy with both DEC and albendazole show considerable promise for the control of LF in geographic regions where onchocerciasis and loiasis are not endemic.

**Anthelmintic Action.** The mechanisms of action of DEC against filarial species are unknown. Microfilarial forms of susceptible filarial species are most affected by DEC. These developmental forms of *W. bancrofti*, *B. malayi*, and *L. loa* rapidly disappear from human blood after consumption of the drug. Microfilariae of *O. volvulus* rapidly disappear from skin after DEC administration, but the drug does not kill microfilariae in nodules that contain the adult (female) worms. The drug has some activity against the adult lifecycle stages of *W. bancrofti*, *B. malayi*, and *L. Loa* but negligible activity against adult
**O. volvulus.**

**ADME.** DEC is absorbed rapidly from the GI tract. Peak plasma levels occur within 1-2 h; the plasma $t_{1/2}$ varies from 2-10 h, depending on the urinary pH. Alkalining the urine can elevate plasma levels, prolong the plasma $t_{1/2}$, and increase both the therapeutic effect and toxicity of DEC. Dosage reduction may be required for people with renal dysfunction. Metabolism is rapid and extensive; a major metabolite, DEC-$N$-oxide, is active.

**Therapeutic Uses.** Recommended regimens differ according to whether the drug is used for population-based chemotherapy, treatment of confirmed filarial infection, or prophylaxis against infection.

**W. bancrofti, B. malayi, and B. timori.** The standard regimen for the treatment of LF traditionally has been a 12-day, 6 mg/kg/day course of DEC. In the U.S., it is common practice to administer small test doses of 50-100 mg (1-2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg reportedly has comparable macrofilaricidal and microfilaricidal efficacy to the standard regimen. Single-dose therapy may be repeated every 6-12 months, as necessary. Although DEC does not usually reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent new lymphatic damage. For mass treatment to interrupt transmission, effective strategies have included the introduction of DEC into table salt (0.2-0.4% by weight of the base). DEC, given annually as a single oral dose of 6 mg/kg, is most effective in reducing microfilaremia when coadministered with either albendazole (400 mg) or ivermectin (0.2-0.4 mg/kg). Therapy is usually well tolerated.

**O. volvulus and L. loa.** DEC is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions. Ivermectin is the preferred drug for this infection. DEC remains the best available drug for therapy of loiasis. Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2-3 days, escalating to maximally tolerated daily doses of 9 mg/kg in 3 doses for 2-3 weeks. In patients with high-grade microfilaremia, low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae. Albendazole may be useful in patients who either fail therapy with DEC or who cannot tolerate the drug. DEC is
clinically effective against microfilariae and adult worms of *D. streptocerca*. DEC is no longer recommended as a first-line drug for the treatment of toxocariosis.

**Toxicity and Side Effects.** Below a daily dose of 8-10 mg/kg, direct toxic reactions to DEC are rarely severe and usually disappear within a few days despite continuation of therapy. These reactions include anorexia, nausea, headache, and, at high doses, vomiting. Major adverse effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae. Delayed reactions to dying adult worms may result in lymphangitis, swelling, and lymphoid abscesses in bancroftian and brugian filariasis, and small skin wheals in loiasis. The drug occasionally causes severe side effects in heavy *L. loa* infections, including retinal hemorrhages and severe encephalopathy. In patients with onchocerciasis, the *Mazzotti reaction* typically occurs within a few hours after the first dose.

**Precautions and Contraindications.** Population-based therapy with DEC should be avoided where onchocerciasis or loiasis is endemic, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is undertaken to minimize indirect reactions to DEC that result from release of antigen by dying microfilariae. Dosage reduction may be appropriate for patients with impaired renal function or persistent alkaline urine.

**DOXYCYCLINE**

Filarial parasites, including *W. bancrofti* and *O. volvulus*, harbor bacterial symbionts of the genus *Wolbachia*, against which long courses of doxycycline (see Chapter 55) (>6 weeks) in bancroftian filariasis and onchocerciasis are effective. A 6-week regimen of doxycycline (100 mg daily), by killing the *Wolbachia*, leads to sterility of adult female *Onchocerca* worms.

**IVERMECTIN**

Ivermectin (MECTIZAN; STROMECTOL) is a semisynthetic analog of avermectin B₁₅ (abamectin), an insecticide developed for crop management. Ivermectin now is used extensively to control and treat a
broad spectrum of infections caused by parasitic nematodes (roundworms) and arthropods (insects, ticks, and mites) that plague livestock and domestic animals.

**MECHANISM OF ACTION.** Ivermectin immobilizes affected organisms by inducing a tonic paralysis of the musculature. Avermectins induce paralysis by activating a family of ligand-gated Cl⁻ channels, particularly glutamate-gated Cl⁻ channels found only in invertebrates. Ivermectin probably binds to glutamate-activated Cl⁻ channels found in nematode nerve or muscle cells, and causes hyperpolarization by increasing intracellular chloride concentration, resulting in paralysis. Avermectins also bind with high affinity to γ-aminobutyric acid (GABA)-gated and other ligand-gated Cl⁻ channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined.

**ANTI-PARASITIC ACTIVITY.** In humans infected with *O. volvulus*, ivermectin causes a rapid, marked decrease in microfilarial counts in the skin and ocular tissues that lasts for 6-12 months. The drug has little discernible effect on adult parasites, but affects developing larvae and blocks egress of microfilariae from the uterus of adult female worms. By reducing microfilariae in the skin, ivermectin decreases transmission to the *Simulium* black fly vector. Ivermectin also is effective against microfilaria but not against adult worms of *W. bancrofti*, *B. malayi*, *L. loa*, and *M. ozzardi*. The drug exhibits excellent efficacy in humans against *A. lumbricoides*, *S. stercoralis*, and cutaneous larva migrans.

**ADME.** Peak levels of ivermectin in plasma are achieved within 4-5 h after oral administration. The long $t_{1/2}$ (~57 h in adults) primarily reflects a low systemic clearance (~1-2 L/hour) and a large apparent volume of distribution. Ivermectin is ~93% bound to plasma proteins. The drug is extensively metabolized by hepatic CYP3A4. Virtually no ivermectin appears in human urine in either unchanged or conjugated form.

**THERAPEUTIC USES**

*Onchocerciasis.* Ivermectin, administered as a single oral dose (150-200 μg/kg) given every 6-12 months, is the drug of choice for onchocerciasis in adults and children >5 years of age. Marked reduction of microfilariae in the skin results in major relief of the intense pruritus that is a feature of onchocerciasis. Clearance of microfilariae from skin and ocular tissues occurs within a few days and lasts...
for 6-12 months; the dose then should be repeated. The drug is not curative, however, because ivermectin has little effect on adult *O. volvulus*. Annual doses of the drug are quite safe and substantially reduce transmission of this infection. Resistance to ivermectin and the related agent moxidectin have been reported in a variety of parasites of veterinary importance, suggesting the potential for development of similar resistance in human parasites, particularly in the setting of mass treatment campaigns.

**Lymphatic Filariasis.** Ivermectin is as effective as DEC for controlling LF, and unlike DEC, it can be used in regions where onchocerciasis, loiasis, or both are endemic. A single annual dose of ivermectin (200 μg/kg) and a single annual dose of albendazole (400 mg) are even more effective in controlling LF than either drug alone. The duration of treatment is at least 5 years, based on the estimated fecundity of the adult worms. This dual-drug regimen also reduces infections with intestinal nematodes.

**Strongyloidiasis.** Ivermectin administered as a single dose of 150 to 200 μg/kg is the drug of choice for human strongyloidiasis. It is generally recommended that a second dose be administered a week following the first dose. This regimen is more efficacious than a 3-day course of albendazole.

**Infections with Other Intestinal Nematodes.** Ivermectin is more effective in ascariasis and enterobiasis than in trichuriasis or hookworm infection. In the latter 2 infections, although it is not curative, it significantly reduces the intensity of infection.

**Other Indications.** Taken as a single 200-μg/kg oral dose, ivermectin is a first-line drug for treatment of cutaneous *larva migrans* caused by dog or cat hookworms, and for treatment of scabies. In uncomplicated scabies, 2 doses should be administered, 1-2 weeks apart. In severe (crusted) scabies, ivermectin should be used in repeated doses, with 1 recommended regimen entailing 7 doses of 200 μg/kg given with food, on days 1, 2, 8, 9, 15, 22, and 29. The drug appears to be effective against human head lice as well.

**Toxicity, Side Effects, and Precautions.** Ivermectin is well tolerated by uninfected humans. In filarial infection, ivermectin therapy frequently causes a Mazzotti-like reaction to dying microfilariae. The intensity and nature of these reactions relate to the microfilarial burden. After treatment of *O. volvulus*
infections, these side effects usually are limited to mild itching and swollen, tender lymph nodes, which occur in 5-35% of people, last just a few days, and are relieved by aspirin and antihistamines. Rarely, more severe reactions occur that include high fever, tachycardia, hypotension, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may respond to glucocorticoid therapy. Ivermectin induces milder side effects than does DEC, and unlike DEC, ivermectin seldom exacerbates ocular lesions in onchocerciasis. The drug can cause rare but serious side effects including marked disability and encephalopathies in patients with heavy *L. loa* microfilaria. *Loa* encephalopathy is associated with ivermectin treatment of individuals with *Loa* microfilaremia levels ≥30,000 microfilariae per milliliter of blood. Because of its effects on GABA receptors in the CNS, ivermectin is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). Ivermectin is not approved for use in children <5 years of age or in pregnant or lactating women (low levels of the drug appear in the mother’s milk).

**PRAZIQUANTEL**

Praziquantel (BILTRICIDE, DISTOCIDE) shows activity against most cestodes and trematodes that infect humans, whereas nematodes generally are unaffected. The drug is most commonly used for treatment of schistosomiasis.

*Mechanism of Anthelmintic Action.* Praziquantel has 2 major effects on adult schistosomes. At the lowest effective concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls and migrate from the mesenteric veins to the liver. At slightly higher concentrations, praziquantel causes tegumental damage and exposes a number of tegumental antigens. The clinical efficacy of this drug correlates better with tegumental action. The drug is ineffective against juvenile schistosomes and therefore is relatively ineffective in early infection. An intact immune response is believed to be important for the clinical efficacy of the drug.

*Absorption, Fate, and Excretion.* Praziquantel is readily absorbed after oral administration, reaching maximal levels in human plasma in 1-2 h. Extensive first-pass metabolism to many inactive hydroxylated and conjugated products
limits the bioavailability of this drug and results in plasma concentrations of metabolites at least 100-fold higher than that of praziquantel. The drug is ~80% bound to plasma proteins. Plasma $t_{1/2}$ is 0.8-3 h, depending on the dose, and 4-6 h for its metabolites; this may be prolonged in patients with severe liver disease, including those with hepatosplenic schistosomiasis. About 70% of an oral dose is recovered as metabolites in the urine within 24 h; most of the remainder is eliminated in the bile.

**Therapeutic Uses.** Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. A single oral dose of 40 mg/kg or 3 doses of 20 mg/kg each, given 4-6 h apart, generally produce cure rates of 70-95% and consistently high reductions (>85%) in egg counts. Three doses of 25 mg/kg taken 4-8 h apart result in high rates of cure for infections with the liver flukes *C. sinensis* and *O. viverrini*, or the intestinal flukes *F. buski*, *H. heterophyes*, and *M. yokogawai*. The same 3-dose regimen, used over 2 days, is highly effective against infections with the lung fluke, *P. westermani*. The liver fluke *F. hepatica* is resistant to praziquantel and should be treated with the BZ drug triclabendazole. Low doses of praziquantel can be used to treat intestinal infections with adult cestodes (a single oral dose of 25 mg/kg for *H. nana* and 10 to 20 mg/kg for *D. latum, T. saginata*, or *T. solium*). Retreatment after 7-10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent; its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be coadministered in this condition.

**Toxicity, Precautions, and Interactions.** Abdominal discomfort and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and may be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2-3 days, and respond to analgesics and anticonvulsants. Praziquantel is considered safe in children >4 years of age. Low levels of the drug appear in the breast milk, but there is no evidence that this compound is mutagenic or carcinogenic. The
bioavailability of praziquantel is reduced by inducers of hepatic CYPs. Dexamethasone reduces the bioavailability of praziquantel. Under certain conditions, praziquantel may increase the bioavailability of albendazole. Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Driving and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the $t_{1/2}$, requiring dosage adjustment.

**METRIFONATE**

Metrifonate (trichlorfon; Bilarcil) is an organophosphorus compound used first as an insecticide and later as an anthelmintic, especially for treatment of *S. haematobium*. Metrifonate is a prodrug; at physiological pH, it is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethyl phosphate [DDVP]), a potent cholinesterase inhibitor (see Chapter 10). However, inhibition of cholinesterase alone is unlikely to explain the antischistosomal properties of metrifonate.

**OXAMNIQUINE**. Oxamniquine is used as a second-line drug after praziquantel for the treatment of *S. mansoni* infection. *S. haematobium* and *S. japonicum* are refractory to this drug.

**NICLOSAMIDE**. Niclosamide, a halogenated salicylanilide derivative, was introduced for human use as a taeniacide. Niclosamide is no longer approved for use in the U.S.

**PIPERAZINE**. Piperazine has been superseded as a first-line anthelmintic by the better-tolerated BZ anthelmintics.

**PYRANTEL PAMOATE**

Pyrantel pamoate first was introduced into veterinary practice as a broad-spectrum anthelmintic against pinworm, roundworm, and hookworm infections. Its effectiveness and lack of toxicity led to its trial against related intestinal helminths in humans. *Oxantel pamoate*, an $m$-oxyphenol analog of pyrantel, is effective for single-dose treatment of trichuriasis.
Antihelmintic Action. Pyrantel and its analogs are depolarizing neuromuscular blocking agents. They open nonselective cation channels and induce persistent activation of nicotinic acetylcholine receptors and spastic paralysis of the worm. Pyrantel also inhibits cholinesterases. Pyrantel is effective against hookworm, pinworm, and roundworm but is ineffective against *T. trichiura*, which responds to the analog oxantel.

ADME. Pyrantel pamoate is poorly absorbed from the GI tract, a property that confines its action to intraluminal GI nematodes. Less than 15% is excreted in the urine as parent drug and metabolites. The major proportion of an administered dose is recovered in the feces.

Therapeutic Uses. Pyrantel pamoate is an alternative to mebendazole or albendazole in the treatment of ascariasis and enterobiasis. High cure rates are achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. Pyrantel also is effective against hookworm infections caused by *A. duodenale* and *N. americanus*, although repeated doses are needed to cure heavy infections by *N. americanus*. The drug should be used in combination with oxantel for mixed infections with *T. trichiura*. For pinworm, repeat the treatment after an interval of 2 weeks. In the U.S., pyrantel is sold as an over-the-counter pinworm treatment (PIN-x, others).

Precautions. Transient and mild GI symptoms occasionally occur, as do headache, dizziness, rash, and fever. Pyrantel pamoate has not been studied in pregnant women. Pyrantel pamoate and piperazine are mutually antagonistic with respect to their neuromuscular effects on parasites and should not be used together.
SULFONAMIDES

The sulfonamide drugs were the first effective chemotherapeutic agents to be employed systemically for the prevention and cure of bacterial infections in humans. The advent of penicillin and other antibiotics diminished the usefulness of the sulfonamides, but the introduction of the combination of trimethoprim and sulfamethoxazole has increased the use of sulfonamides for the prophylaxis and treatment of specific microbial infections. Sulfonamides are derivatives of para-aminobenzenesulfonamide (sulfanilamide; Figure 52–1) and are congeners of para-aminobenzoic acid. Most of them are relatively insoluble in water, but their sodium salts are readily soluble.

Figure 52–1 Sulfanilamide and para-aminobenzoic acid. Sulfonamides are derivatives of sulfanilamide and act by virtue of being congeners of para-aminobenzoate (PABA). The antimicrobial and dermatological anti-inflammatory agent dapsone (4,4’-diaminodiphenyl sulfone; see Figure 56–5 and Chapter 65) also bears a resemblance to PABA and sulfanilamide.

The minimal structural prerequisites for antibacterial action are all embodied in sulfanilamide itself. The sulfur must be linked directly to the benzene ring. The para-NH₂ group (the N of which has been designated as N4) is essential and can be replaced only by moieties that can be converted in vivo to a free amino group. Substitutions made in the amide NH₂ group (position N1) have variable effects on antibacterial activity of the molecule; substitution of heterocyclic aromatic...
nuclei at N1 yields highly potent compounds.

**MECHANISM OF ACTION.** Sulfonamides are competitive inhibitors of *dihydropteroate synthase*, the bacterial enzyme responsible for the incorporation of *para*-aminobenzoic acid (PABA) into *dihydropteroic acid*, the immediate precursor of *folic acid* (Figure 52–2). Sensitive microorganisms are those that must synthesize their own folic acid; bacteria that can use preformed folate are not affected. Toxicity is selective for bacteria because mammalian cells require preformed folic acid, cannot synthesize it, and are thus insensitive to drugs acting by this mechanism.

![Diagram of folate metabolism](image)

*Figure 52–2 Steps in folate metabolism blocked by sulfonamides and trimethoprim.* Coadministration of a sulfonamide and trimethoprim introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate; the combination is much more effective than either agent alone.

**SYNERGISTS OF SULFONAMIDES.** *Trimethoprim* exerts a synergistic effect with sulfonamides. It is a potent and selective
competitive inhibitor of microbial *dihydrofolate reductase*, the enzyme that reduces *dihydrofolate* to *tetrahydrofolate*, which is required for 1-carbon transfer reactions. Coadministration of a sulfonamide and trimethoprim introduces sequential blocks in the biosynthetic pathway for tetrahydrofolate (see Figure 52–2); the combination is much more effective than either agent alone.

**EFFECTS ON MICROBES**

Sulfonamides have a wide range of antimicrobial activity against both gram-positive and gram-negative bacteria. Resistant strains have become common and the usefulness of these agents has diminished correspondingly. Sulfonamides are *bacteriostatic*; cellular and humoral defense mechanisms of the host are essential for final eradication of the infection.

**ANTIBACTERIAL SPECTRUM.** Resistance to sulfonamides is increasingly a problem. Microorganisms that may be susceptible in vitro to sulfonamides include *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Haemophilus ducreyi*, *Nocardia*, *Actinomyces*, *Calymmatobacterium granulomatis*, and *Chlamydia trachomatis*. Minimal inhibitory concentrations (MICs) range from 0.1 µg/mL for *C. trachomatis* to 4-64 µg/mL for *Escherichia coli*. Peak plasma drug concentrations achievable in vivo are ~100-200 µg/mL. Isolates of *Neisseria meningitidis* and *Shigella* are generally resistant, as are many strains of *E. coli* isolated from patients with urinary tract infections (community acquired).

**ACQUIRED BACTERIAL RESISTANCE TO SULFONAMIDES.** Bacterial resistance to sulfonamides can originate by random mutation and selection or by transfer of resistance by plasmids (see Chapter 48); it usually does not involve cross-resistance to other classes of antibiotics. Resistance to sulfonamide can result from: (1) a lower affinity of dihydropteroate synthase for sulfonamides, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) an increased production of an essential metabolite or drug antagonist (e.g., PABA). Plasmid-mediated resistance is due to plasmid-encoded drug-resistant
dihydropteroate synthetase.

**ABSORPTION, DISTRIBUTION, METABOLISM, AND EXCRETION**

Except for sulfonamides especially designed for their local effects in the bowel (see Chapter 47), this class of drugs is absorbed rapidly from the GI tract. Approximately 70-100% of an oral dose is absorbed, and sulfonamide can be found in the urine within 30 min of ingestion. Peak plasma levels are achieved in 2-6 h, depending on the drug. The small intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. This is determined by the hydrophobicity of a particular drug and its pKa; at physiological pH, drugs with a high pKa exhibit a low degree of protein binding, and vice versa. Sulfonamides are distributed throughout all tissues of the body. The diffusible fraction of *sulfadiazine* is distributed uniformly throughout the total-body water, whereas *sulfisoxazole* is confined largely to the extracellular space. Because the protein content of such body fluids usually is low, the drug is present in the unbound active form. After systemic administration of adequate doses, sulfadiazine and sulfisoxazole attain concentrations in CSF that may be effective in meningitis. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis. Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues may cause both antibacterial and toxic effects.

Sulfonamides are metabolized in the liver. The major metabolite is the N4-acetylated sulfonamide. Acetylation results in products that have no antibacterial activity but retain the toxic potential of the parent substance. Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the t1/2 depends on
renal function. In acid urine, the older sulfonamides are insoluble and crystalline deposits may form. Small amounts are eliminated in the feces, bile, milk, and other secretions.

**PHARMACOLOGICAL PROPERTIES OF INDIVIDUAL SULFONAMIDES**

The sulfonamides may be classified on the basis of the rapidity with which they are absorbed and excreted (Table 52–1).

**RAPIDLY ABSORBED AND ELIMINATED SULFONAMIDES**

*Sulfisoxazole.* Sulfisoxazole is a rapidly absorbed and excreted sulfonamide with excellent antibacterial activity. Its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides. Sulfisoxazole is bound extensively to plasma proteins. Following an oral dose of 2-4 g, peak concentrations in plasma of 110-250 µg/mL are found in 2-4 h. Approximately 30% of sulfisoxazole in the blood and ~30% in the urine is in the acetylated form. The kidney excretes ~95% of a single dose in 24 h. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. The concentration in CSF is about a third of that in the blood. Sulfisoxazole acetyl is marketed in combination with erythromycin ethylsuccinate for use in children with otitis media.

The untoward effects of sulfisoxazole are similar to other sulfonamides. Because of its relatively high solubility in the urine as compared with sulfadiazine,
sulfisoxazole rarely produces hematuria or crystalluria (0.2-0.3%). Nonetheless, patients should still ingest an adequate quantity of water. Sulfisoxazole must be used with caution in patients with impaired renal function. Like all sulfonamides, sulfisoxazole may produce hypersensitivity reactions, some of which are potentially lethal.

_Sulfamethoxazole._ Sulfamethoxazole is a close congener of sulfisoxazole, but its rates of enteric absorption and urinary excretion are slower. It is administered orally and employed for both systemic and urinary tract infections. Precautions must be observed to avoid sulfamethoxazole crystalluria because of the high percentage of the acetylated, relatively insoluble form of the drug in the urine. The clinical uses of sulfamethoxazole are the same as those for sulfisoxazole. In the U.S., it is marketed only in fixed-dose combinations with trimethoprim.

_Sulfadiazine._ Sulfadiazine given orally is absorbed rapidly from the GI tract. Peak blood concentrations are reached within 3-6 h. About 55% of the drug is bound to plasma protein. Therapeutic concentrations are attained in CSF within 4 h of a single oral dose of 60 mg/kg. Both free and acetylated forms of sulfadiazine are readily excreted by the kidney; 15-40% of the excreted drug is in acetylated form. Alkalinization of the urine accelerates the renal clearance of both forms by diminishing their tubular reabsorption. Every precaution must be taken to ensure fluid intake adequate to produce a daily urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

**POORLY ABSORBED SULFONAMIDES**

**SULFASALAZINE.** Sulfasalazine (Azulfidine, others) is very poorly absorbed from the GI tract. It is used in the therapy of ulcerative colitis and regional enteritis. Intestinal bacteria break sulfasalazine down to 5-aminosalicylate (5-ASA, mesalamine; see Figures 47–2 through 47–4), the active agent in inflammatory bowel disease, and sulfapyridine, a sulfonamide that is absorbed and eventually excreted in the urine.

**SULFONAMIDES FOR TOPICAL USE**

_Sulfacetamide._ Sulfacetamide is the N1-acetyl-substituted derivative of sulfanilamide. Its aqueous solubility is ~90 times that of sulfadiazine. Solutions of the sodium salt of the drug are employed extensively in the management of ophthalmic infections. Very high aqueous concentrations are not irritating to the
eye and are effective against susceptible microorganisms. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to sulfacetamide are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. See Chapters 64 and 65 for ocular and dermatological uses.

**Silver Sulfadiazine.** Silver sulfadiazine (SILVADENE, others) is used topically to reduce microbial colonization and the incidence of infections from burns. Silver sulfadiazine should not be used to treat an established deep infection. Silver is released slowly from the preparation in concentrations that are selectively toxic to the microorganisms. However, bacteria may develop resistance to silver sulfadiazine. Although little silver is absorbed, the plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered an agent of choice for the prevention of burn infections.

**Mafenide.** This sulfonamide (α-amino-p-toluene-sulfonamide; SULFAMYLON) is applied topically to prevent colonization of burns by a large variety of gram-negative and gram-positive bacteria. It should not be used in treatment of an established deep infection. Adverse effects include intense pain at sites of application, allergic reactions, and loss of fluid by evaporation from the burn surface because occlusive dressings are not used. The drug and its primary metabolite inhibit carbonic anhydrase, and the urine becomes alkaline. Metabolic acidosis with compensatory tachypnea and hyperventilation may ensue; these effects limit the usefulness of mafenide. Mafenide is absorbed from the burn surface, reaching peak plasma concentrations in 2-4 h; the absorbed drug is converted to para-carboxybenzenesulfonamide.

**LONG-ACTING SULFONAMIDES**

**Sulfadoxine.** This agent has a particularly long plasma t½ (7-9 days). It is used in combination with pyrimethamine (500 mg sulfadoxine plus 25 mg pyrimethamine as FANSIDAR) for the prophylaxis and treatment of malaria caused by mefloquine-resistant strains of *Plasmodium falciparum* (see Chapter 49). However, because of severe and sometimes fatal reactions, including the Stevens-Johnson syndrome, and the emergence of resistant strains, the drug has limited usefulness for the treatment of malaria.
SULFONAMIDE THERAPY

URINARY TRACT INFECTIONS (UTIs). Because a significant percentage of UTIs are caused by sulfonamide-resistant microorganisms, sulfonamides are no longer a therapy of first choice. Trimethoprim-sulfamethoxazole, a quinolone, trimethoprim, fosfomycin, or ampicillin are the preferred agents. *Sulfisoxazole* may be used effectively in areas where the prevalence of resistance is not high. The usual dosage is 2-4 g initially followed by 1-2 g, orally 4 times a day for 5-10 days. Patients with acute pyelonephritis with high fever are at risk of bacteremia and shock and should not be treated with a sulfonamide.

NOCARDIOSIS. Sulfonamides are of value in the treatment of infections due to *Nocardia* spp. *Sulfisoxazole* or *sulfadiazine* may be given in dosages of 6-8 g daily and this schedule should be continued for several months after all manifestations have been controlled. Combination of sulfonamide with a second antibiotic has been recommended, especially for advanced cases; ampicillin, erythromycin, and streptomycin have been suggested but there are no clinical data to show that combination therapy is better than therapy with a sulfonamide alone. Trimethoprim-sulfamethoxazole also is effective; some authorities consider this combination to be the treatment of choice.

TOXOPLASMOSIS. The combination of pyrimethamine and sulfadiazine is the treatment of choice for toxoplasmosis (see Chapter 50). Pyrimethamine is given as a loading dose of 75 mg followed by 25 mg orally per day, with sulfadiazine 1 g orally every 6 h, plus folinic acid (leucovorin) 10 mg orally each day for at least 3-6 weeks. Patients should receive at least 2 L of fluid intake daily to prevent crystalluria.

USE OF SULFONAMIDES FOR PROPHYLAXIS. The sulfonamides are as efficacious as oral penicillin in preventing streptococcal infections and recurrences of rheumatic fever among susceptible subjects. Their toxicity and the possibility of infection by drug-resistant streptococci make sulfonamides less desirable than penicillin for this purpose; however, sulfonamides should be used in patients who are hypersensitive to penicillin. Untoward responses usually occur during the first 8 weeks of therapy. White blood cell counts should be carried out once weekly during the first 8 weeks.

UNTOWARD REACTIONS TO SULFONAMIDES
The untoward effects that follow the administration of sulfonamides are numerous and varied; the overall incidence of reactions is ~5%.

DISTURBANCES OF THE URINARY TRACT. The risk of crystalluria is very low with the more soluble agents such as sulfisoxazole. Crystalluria has occurred in dehydrated patients with acquired immunodeficiency syndrome (AIDS) who were receiving sulfadiazine for *Toxoplasma* encephalitis. Fluid intake should be sufficient to ensure a daily urine volume of at least 1200 mL (in adults). Alkalization of the urine may be desirable if urine volume or pH is unusually low because the solubility of sulfisoxazole increases greatly with slight elevations of pH.

DISORDERS OF THE HEMATOPOIETIC SYSTEM. Although rare, acute hemolytic anemia may occur. In some cases, it may be due to a sensitization phenomenon; in other instances, the hemolysis is related to an erythrocytic deficiency of glucose-6-phosphate dehydrogenase activity. Agranulocytosis occurs in ~0.1% of patients who receive sulfadiazine; it also can follow the use of other sulfonamides. Although return of granulocytes to normal levels may be delayed for weeks or months after sulfonamide is withdrawn, most patients recover spontaneously with supportive care. Aplastic anemia involving complete suppression of bone marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. Reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with AIDS or those receiving myelosuppressive chemotherapy).

HYPERSENSITIVITY REACTIONS. Among the skin and mucous membrane manifestations attributed to sensitization to sulfonamide are morbilliform, scarlatinal, urticarial, erysipeloid, pemphigoid, purpuric, and petechial rashes, as well as erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behçet syndrome, exfoliative dermatitis, and photosensitivity. These hypersensitivity reactions occur most often after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. The incidence of untoward dermal effects is ~2% with sulfisoxazole; patients with AIDS manifest a higher frequency of rashes with sulfonamide treatment than do other individuals. A
syndrome similar to serum sickness may appear after several days of sulfonamide therapy. Drug fever is a common untoward manifestation of sulfonamide treatment; the incidence approximates 3% with sulfisoxazole. Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in <0.1% of patients. Headache, nausea, vomiting, fever, hepatomegaly, jaundice, and laboratory evidence of hepatocellular dysfunction usually appear 3-5 days after sulfonamide administration is started, and the syndrome may progress to acute yellow atrophy and death.

MISCELLANEOUS REACTIONS. Anorexia, nausea, and vomiting occur in 1-2% of persons receiving sulfonamides. The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from plasma albumin, potentially causing an encephalopathy called kernicterus. Sulfonamides should not be given to pregnant women near term because these drugs cross the placenta and are secreted in milk.

DRUG INTERACTIONS. Drug interactions of the sulfonamides are seen with the oral anticoagulants, the sulfonylurea hypoglycemic agents, and the hydantoin anticonvulsants. In each case, sulfonamides can potentiate the effects of the other drug by inhibiting its metabolism or by displacing it from albumin. Dosage adjustment may be necessary when a sulfonamide is given concurrently.

TRIMETHOPRIM-SULFAMETHOXAZOLE
Trimethoprim inhibits bacterial dihydrofolate reductase, an enzyme downstream from the one that sulfonamides inhibit in the same biosynthetic sequence (see Figure 52–2). The combination of trimethoprim with sulfamethoxazole was an important advance in the development of clinically effective and synergistic antimicrobial agents. In much of the world, the combination of trimethoprim with sulfamethoxazole is known as cotrimoxazole. In addition to its combination with sulfamethoxazole (BACTRIM, SEPTRAM, others), trimethoprim also is available as a single-entity preparation.
ANTIBACTERIAL SPECTRUM. The antibacterial spectrum of trimethoprim is similar to that of sulfamethoxazole, although trimethoprim is 20-100 times more potent. Most gram-negative and gram-positive microorganisms are sensitive to trimethoprim, but resistance can develop when the drug is used alone. *Pseudomonas aeruginosa, Bacteroides fragilis,* and enterococci usually are resistant. There is significant variation in the susceptibility of *Enterobacteriaceae* to trimethoprim in different geographic locations because of the spread of resistance mediated by plasmids and transposons (see Chapter 48).

**Efficacy of Trimethoprim-Sulfamethoxazole in Combination.** *Chlamydia trachomatis* and *N. meningitidis* are susceptible to trimethoprim-sulfamethoxazole. Although most *S. pneumoniae* are susceptible, there has been a disturbing increase in resistance. From 50-95% of strains of *Staphylococcus aureus, Staphylococcus epidermidis, S. pyogenes,* the viridans group of streptococci, *E. coli, Proteus mirabilis, Proteus morganii, Proteus rettgeri, Enterobacter* spp., *Salmonella, Shigella, Pseudomonas pseudomallei, Serratia,* and *Alcaligenes* spp. are inhibited. Also sensitive are *Klebsiella* spp., *Brucella abortus, Pasteurella haemolytica, Yersinia pseudotuberculosis, Yersinia enterocolitica,* and *Nocardia asteroides.*

**MECHANISM OF ACTION.** The antimicrobial activity of the combination of trimethoprim and sulfamethoxazole results from actions on sequential steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid (see Figure 52–2). Tetrahydrofolate is essential for one-carbon transfer reactions (e.g., the synthesis of thymidylate from deoxyuridylate). Selective toxicity for microorganisms is achieved in 2 ways. Mammalian cells use preformed folates from the diet and do not synthesize the compound. Furthermore, trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms: ~100,000 times more drug is required to inhibit human reductase than the
bacterial enzyme. The optimal ratio of the concentrations of the 2 agents equals the ratio of the minimal inhibitory concentrations of the drugs acting independently. Although this ratio varies for different bacteria, the most effective ratio for the greatest number of microorganisms is 20:1, sulfamethoxazole:trimethoprim. The combination is thus formulated to achieve a sulfamethoxazole concentration in vivo that is 20 times greater than that of trimethoprim; sulfamethoxazole has pharmacokinetic properties such that the concentrations of the 2 drugs will thus be relatively constant in the body over a long period.

**BACTERIAL RESISTANCE.** Bacterial resistance to trimethoprim-sulfamethoxazole is a rapidly increasing problem. Resistance often is due to the acquisition of a plasmid that codes for an altered dihydrofolate reductase. Resistance to trimethoprim-sulfamethoxazole is reportedly formed in almost 30% of urinary isolates of *E. coli*.

**ADME.** The pharmacokinetic profiles of sulfamethoxazole and trimethoprim are closely but not perfectly matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. After a single oral dose of the combined preparation, trimethoprim is absorbed more rapidly than sulfamethoxazole. Peak blood concentrations of trimethoprim usually occur by 2 h in most patients, whereas peak concentrations of sulfamethoxazole occur by 4 h after a single oral dose. The half-lives of trimethoprim and sulfamethoxazole are ~11 and 10 h, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (the conventional 5:1 ratio) twice daily, the peak concentrations of the drugs in plasma are ~40 and 2 µg/mL, the optimal ratio. Peak concentrations are similar (46 and 3.4 µg/mL) after intravenous infusion of 800 mg sulfamethoxazole and 160 mg trimethoprim over a period of 1 h.

Trimethoprim is distributed and concentrated rapidly in tissues; ~40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost 9 times that of sulfamethoxazole. The drug readily enters CSF and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein. About 60% of administered trimethoprim and from 25-50% of administered sulfamethoxazole are excreted in the urine in 24 h. Two-thirds of
the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

THERAPEUTIC USES

**Urinary Tract Infections.** Treatment of uncomplicated lower UTI with trimethoprim-sulfamethoxazole often is highly effective for sensitive bacteria. Single-dose therapy (320 mg trimethoprim plus 1600 mg sulfamethoxazole in adults) has been effective in some cases for the treatment of acute uncomplicated UTI. Trimethoprim also is found in therapeutic concentrations in prostatic secretions, and trimethoprim-sulfamethoxazole is often effective for the treatment of bacterial prostatitis.

**Bacterial Respiratory Tract Infections.** Trimethoprim-sulfamethoxazole is effective for acute exacerbations of chronic bronchitis. Administration of 800-1200 mg sulfamethoxazole plus 160-240 mg trimethoprim twice a day appears to be effective in decreasing fever, purulence and volume of sputum, and sputum bacterial count. Trimethoprim-sulfamethoxazole should not be used to treat streptococcal pharyngitis because it does not eradicate the microorganism. It is effective for acute otitis media in children and acute maxillary sinusitis in adults caused by susceptible strains of *H. influenzae* and *S. pneumoniae*.

**GI Infections.** The combination is an alternative to a fluoroquinolone for treatment of shigellosis. Trimethoprim-sulfamethoxazole appears to be effective in the management of carriers of sensitive strains of *Salmonella typhi* and other *Salmonella* spp; however, failures have occurred. Acute diarrhea owing to sensitive strains of enteropathogenic *E. coli* can be treated or prevented with either trimethoprim or trimethoprim + sulfamethoxazole. However, antibiotic treatment of diarrheal illness owing to enterohemorrhagic *E. coli* O157:H7 may increase the risk of hemolytic-uremic syndrome, perhaps by increasing the release of Shiga toxin by the bacteria.

**Infection by Pneumocystis jiroveci.** High-dose therapy (trimethoprim 15-20
mg/kg/day plus sulfamethoxazole 75-100 mg/kg/day in 3 or 4 divided doses) is effective for this severe infection in patients with AIDS. Adjunctive corticosteroids should be given at the onset of anti-*Pneumocystis* therapy in patients with a PO$_2$ <70 mm Hg or an alveolar-arterial gradient >35 mm Hg. Prophylaxis with 800 mg sulfamethoxazole and 160 mg trimethoprim once daily or 3 times a week is effective in preventing pneumonia caused by this organism in patients with AIDS. Adverse reactions are less frequent with the lower prophylactic doses of trimethoprim-sulfamethoxazole. The most common problems are rash, fever, leukopenia, and hepatitis.

*Prophylaxis in Neutropenic Patients.* Low-dose therapy (150 mg/m$^2$ of body surface area of trimethoprim and 750 mg/m$^2$ of body surface area of sulfamethoxazole) is effective for the prophylaxis of infection by *P. jiroveci*. A regimen of 800 mg sulfamethoxazole and 160 mg trimethoprim twice daily to severely neutropenic patients provides significant protection against sepsis caused by gram-negative bacteria.

*Miscellaneous Infections.* *Nocardia* infections have been treated successfully with the combination, but failures also have been reported. Although a combination of doxycycline and streptomycin or gentamicin now is considered to be the treatment of choice for brucellosis, trimethoprim-sulfamethoxazole may be an effective substitute for the doxycycline combination. Trimethoprim-sulfamethoxazole also has been used successfully in the treatment of Whipple disease, infection by *Stenotrophomonas maltophilia*, and infection by the intestinal parasites *Cyclospora* and *Isospora*. Wegener granulomatosis may respond, depending on the stage of the disease.

**UNTOWARD EFFECTS.** The margin between toxicity for bacteria and that for humans may be relatively narrow when the patient is folate-deficient. In such cases, trimethoprim-sulfamethoxazole may cause or precipitate megaloblastosis, leukopenia, or thrombocytopenia. In routine use, the combination appears to exert little toxicity. About 75% of the untoward effects involve the skin. Trimethoprim-sulfamethoxazole reportedly causes up to 3 times as many dermatological reactions as does sulfisoxazole alone (5.9% vs. 1.7%). Exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis are rare, occurring primarily in older individuals. Nausea and vomiting constitute the bulk of GI reactions; diarrhea is rare. Glossitis and
stomatitis are relatively common. Mild and transient jaundice has been noted and appears to have the histological features of allergic cholestatic hepatitis. CNS reactions consist of headache, depression, and hallucinations, manifestations ascribed to sulfonamides. Hematological reactions include various anemias, coagulation disorders, granulocytopenia, agranulocytosis, purpura, Henoch-Schönlein purpura, and sulfhemoglobinemia. Permanent impairment of renal function may follow the use of trimethoprim-sulfamethoxazole in patients with renal disease, and a reversible decrease in creatinine clearance has been noted in patients with normal renal function. Patients with AIDS frequently have hypersensitivity reactions to trimethoprim-sulfamethoxazole (rash, neutropenia, Stevens-Johnson syndrome, Sweet syndrome, and pulmonary infiltrates). It may be possible to continue therapy in such patients following rapid oral desensitization.

**THE QUINOLONES**

Quinolones are derivatives of nalidixic acid. The fluorinated 4-quinolones, such as *ciprofloxacin* (CIPRO, others) and *moxifloxacin* (AVELOX), have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases (Table 52–2).

**Table 52–2**

| Structural Formulas of Selected Quinolones and Fluoroquinolones |
Rare and potentially fatal side effects, however, have resulted in the withdrawal from the U.S. market of lomefloxacin, sparfloxacin (phototoxicity, QTc prolongation), gatifloxacin (hypoglycemia), temafloxacin (immune hemolytic anemia), trovafloxacin (hepatotoxicity), grepafloxacin (cardiotoxicity), and clinafloxacin (phototoxicity).

MECHANISM OF ACTION. The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV. For many gram-positive bacteria, topoisomerase IV is the primary target. In contrast, DNA gyrase is the primary quinolone target in many gram-negative microbes. The gyrase introduces negative supercoils into the DNA to combat excessive positive supercoiling that can occur during DNA replication (Figure 52–3). The quinolones inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1-10 µg/mL). Mutations of the gene that encodes the A subunit of the gyrase can confer resistance to these drugs. Topoisomerase IV, which separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication, also is target for quinolones.
Figure 52–3 Model of the formation of negative DNA supercoils by DNA gyrase. DNA gyrase binds to 2 segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (−) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and, at higher concentrations, block the decatenating activity of topoisomerase IV. (From Cozzarelli NR. DNA gyrase and the supercoiling of DNA. Science, 1980;207:953-960. Reprinted with permission from AAAS.)

Eukaryotic cells do not contain DNA gyrase. They do contain a conceptually and mechanistically similar type II DNA topoisomerase but quinolones inhibit it only at concentrations (100-1000 µg/mL) much higher than those needed to inhibit the bacterial enzymes.

ANTIBACTERIAL SPECTRUM. The fluoroquinolones are potent bactericidal agents against *E. coli* and various species of *Salmonella*, *Shigella*, *Enterobacter*, *Campylobacter*, and *Neisseria* (MIC\textsubscript{90} usually are <0.2 µg/mL). Fluoroquinolones also have good activity against staphylococci, but not against methicillin-resistant strains (MIC\textsubscript{90} = 0.1-2 µg/mL). Activity against streptococci is limited to a subset of the quinolones, including levofloxacin (*LEVAQUIN*), gatifloxacin, and moxifloxacin (*VELOX*). Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of *Chlamydia*, *Mycoplasma*, *Legionella*, *Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*). Ciprofloxacin (*CIPRO*, others), ofloxacin (*FLOXIN*), and pefloxacin have MIC\textsubscript{90} values from 0.5-3 µg/mL for *M. fortuitum*, *M. kansasii*, and *M. tuberculosis*. Several fluoroquinolones, including garenoxacin (not available in U.S.) and gemifloxacin, have activity against anaerobic bacteria.

Resistance to quinolones may develop during therapy via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by
active transport of the drug out of the bacteria. Resistance has increased after the introduction of fluoroquinolones, especially in *Pseudomonas* and staphylococci. Increasing fluoroquinolone resistance also is being observed in *C. jejuni*, *Salmonella*, *N. gonorrhoeae*, and *S. pneumoniae*.

**ADME.** The quinolones are well absorbed after oral administration. Peak serum levels of the fluoroquinolones are obtained within 1-3 h of an oral dose of 400 mg. The volume of distribution of quinolones is high, with concentrations in urine, kidney, lung and prostate tissue, stool, bile, and macrophages and neutrophils higher than serum levels. Relatively low serum levels are reached with norfloxacin and limit its usefulness to the treatment of UTIs. Food may delay the time to peak serum concentrations. Oral doses in adults are 200-400 mg every 12 h for ofloxacin, 400 mg every 12 h for norfloxacin and pefloxacin, and 250 to 750 mg every 12 h for ciprofloxacin. Bioavailability of the fluoroquinolones is >50% for all agents and >95% for several. The serum $t_{1/2}$ is 3-5 h for norfloxacin and ciprofloxacin. Quinolone concentrations in CSF, bone, and prostatic fluid are lower than in serum. Pefloxacin and ofloxacin levels in ascites fluid are close to serum levels, and ciprofloxacin, ofloxacin, and pefloxacin have been detected in human breast milk. Most quinolones are cleared predominantly by the kidney, and dosages must be adjusted for renal failure. By contrast, pefloxacin and moxifloxacin are metabolized predominantly by the liver and should not be used in patients with hepatic failure. None of the agents is removed efficiently by peritoneal or hemodialysis.

**Pharmacokinetic Aspects.** The pharmacokinetic and pharmacodynamic parameters of antimicrobial agents are important in preventing the selection and spread of resistant strains and have led to description of the mutation-prevention concentration, which is the lowest concentration of antimicrobial that prevents selection of resistant bacteria from high bacterial inocula. β-Lactams are time-dependent agents without significant post-antibiotic effects, resulting in bacterial eradication when unbound serum concentrations exceed MICs of these agents against infecting pathogens for >40-50% of the dosing interval. By contrast, fluoroquinolones are concentration- and time-dependent agents, resulting in bacterial eradication when unbound serum area under the curve-to-MIC ratios exceed 25-30. An extended release formulation of ciprofloxacin (PROQUIN XR) exemplifies this principle (see Figure 48–4).

**THERAPEUTIC USES**
Urinary Tract Infections. Nalidixic acid is useful only for UTI caused by susceptible microorganisms. The fluoroquinolones are significantly more potent and have a much broader spectrum of antimicrobial activity. Norfloxacin and ciprofloxacin XR are approved for use in the U.S. only for UTIs. Fluoroquinolones are more efficacious than trimethoprim-sulfamethoxazole for the treatment of UTI.

Prostatitis. Norfloxacin, ciprofloxacin, and ofloxacin are effective in the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4-6 weeks appear to be effective in patients not responding to trimethoprim-sulfamethoxazole.

Sexually Transmitted Diseases. The quinolones are contraindicated in pregnancy. Fluoroquinolones lack activity for Treponema pallidum but have activity in vitro against C. trachomatis and H. ducreyi. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin is an alternative to a 7-day treatment with doxycycline or a single dose of azithromycin; other available quinolones have not been reliably effective. A single oral dose of a fluoroquinolone such as ofloxacin or ciprofloxacin had been effective treatment for sensitive strains of N. gonorrhoeae, but increasing resistance to fluoroquinolones has led to ceftriaxone being the first-line agent for this infection. Chancroid (infection by H. ducreyi) can be treated with 3 days of ciprofloxacin.

GI and Abdominal Infections. For traveler’s diarrhea (frequently caused by enterotoxigenic E. coli), the quinolones are equal to trimethoprim-sulfamethoxazole in effectiveness, reducing the duration of loose stools by 1-3 days. Norfloxacin, ciprofloxacin, and ofloxacin given for 5 days all have been effective in the treatment of patients with shigellosis. Ciprofloxacin and ofloxacin treatment cures most patients with enteric fever caused by S. typhi, as well as bacteremic nontyphoidal infections in AIDS patients, and clears chronic fecal carriage. The in vitro ability of the quinolones to induce the Shiga toxin stx2 gene (the cause of the hemolytic-uremic syndrome) in E. coli suggests that the quinolones should not be used for Shiga toxin–producing E. coli. Ciprofloxacin and ofloxacin are less effective in treating episodes of peritonitis occurring in patients on chronic ambulatory peritoneal dialysis (likely cause: coagulase-negative staphylococci).

Respiratory Tract Infections. Many newer fluoroquinolones, including
gatifloxacin (available only for ophthalmic use in U.S.) and moxifloxacin, have excellent activity against *S. pneumoniae*. The fluoroquinolones have in vitro activity against the rest of the commonly recognized respiratory pathogens. Either a fluoroquinolone (ciprofloxacin or levofloxacin) or azithromycin is the antibiotic of choice for *L. pneumophila*. Fluoroquinolones have been very effective at eradicating both *H. influenzae* and *M. catarrhalis* from sputum. Mild to moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis have responded to oral fluoroquinolone therapy.

**Bone, Joint, and Soft Tissue Infections.** The treatment of chronic osteomyelitis requires prolonged (weeks to months) antimicrobial therapy with agents active against *S. aureus* and gram-negative rods. The fluoroquinolones, with an appropriate antibacterial spectrum for these infections, may be used in some cases; recommended doses are 500 mg every 12 h or, if severe, 750 mg twice daily. Dosage should be reduced for patients with severely impaired renal function. Clinical cures are as high as 75% in chronic osteomyelitis in which gram-negative rods predominate. Failures are associated with the development of resistance in *S. aureus*, *P. aeruginosa*, and *Serratia marcescens*. In diabetic foot infections, the fluoroquinolones in combination with an agent with anti-anaerobic activity are a reasonable choice.

**Other Infections.** Ciprofloxacin is used for the prophylaxis of anthrax and is effective for the treatment of tularemia. The quinolones may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and atypical mycobacterial infections as well as *Myobacterium avium* complex infections in AIDS (see Chapter 56). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias. Levofloxacin is approved to treat and prevent anthrax as well as plague due to *Yersinia pestis*.

**ADVERSE EFFECTS.** Quinolones and fluoroquinolones generally are well tolerated. Common adverse reactions involve the GI tract, with 3-17% of patients reporting mild nausea, vomiting, and abdominal discomfort. Ciprofloxacin is the most common cause of *C. difficile* colitis. Gatifloxacin is associated with both hypo- and hyperglycemia in older adults. CNS side effects (1-11%) include mild headache and dizziness. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who were also receiving theophylline or NSAIDs. Ciprofloxacin and pefloxacin inhibit the metabolism of
theophylline, and toxicity from elevated concentrations of the methylxanthine may occur. NSAIDS may augment displacement of γ-aminobutyric acid (GABA) from its receptors by the quinolones. Rashes, including photosensitivity reactions, also can occur. Achilles tendon rupture or tendinitis is a recognized adverse effect, especially in those >60 years old, inpatients taking corticosteroids, and in solid organ transplant recipients. Ciprofloxacin should not be given to pregnant women and are generally not used in children.

Leukopenia, eosinophilia, and mild elevations in serum transaminases occur rarely. QT interval prolongation has been observed with sparfloxacin and to a lesser extent with gatifloxacin and moxifloxacin. Quinolones should be used with caution in patients on class III (amiodarone) and class IA (quinidine, procainamide) anti-arrhythmics (see Chapter 29).

ANTISEPTIC AND ANALGESIC AGENTS FOR URINARY TRACT INFECTIONS

Urinary tract antiseptics are concentrated in the renal tubules where they inhibit the growth of many species of bacteria. These agents cannot be used to treat systemic infections because effective concentrations are not achieved in plasma with safe doses; however, they can be administered orally to treat UTIs. Furthermore, effective antibacterial concentrations reach the renal pelves and the bladder.

METHENAMINE. Methenamine (hexamethylenamine) is a urinary tract antiseptic and prodrug that acts by generating formaldehyde via the following reaction:

\[
\text{NH}_4\text{(CH}_2\text{)}_6 + 6\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 4\text{NH}_4^+ + 6\text{HCHO}
\]

At pH 7.4, almost no decomposition occurs; the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes formaldehyde formation and the formaldehyde-dependent antibacterial action. The decomposition reaction is fairly slow, and 3 h are required to reach 90% completion. Nearly all bacteria are sensitive to free formaldehyde at concentrations of ~20 µg/mL. Microorganisms do not develop resistance to formaldehyde. Urea-splitting microorganisms (e.g., Proteus spp.) tend to raise
the pH of the urine and thus inhibit the release of formaldehyde.

**Pharmacology, Toxicology, and Therapeutic Uses.** Methenamine is absorbed orally, but 10-30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, methenamine is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000-1500 mL, a daily dose of 2 g will yield a urine concentration of 18-60 µg/mL of formaldehyde; this is more than the MIC for most urinary tract pathogens. Low pH alone is bacteriostatic, so acidification serves a double function. The acids commonly used are mandelic acid and hippuric acid (UREX, HIPREX). GI distress frequently is caused by doses >500 mg 4 times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/day given for longer than 3-4 weeks. Renal insufficiency is not a contraindication to the use of methenamine alone, but the acids given concurrently may be detrimental; methenamine mandelate is contraindicated in renal insufficiency. Methenamine combines with sulfamethizole and perhaps other sulfonamides in the urine, which results in mutual antagonism; therefore, these drugs should not be used in combination. Methenamine is not a primary drug for the treatment of acute UTIs but is of value for chronic suppressive treatment of UTIs. The agent is most useful when the causative organism is *E. coli*, but it usually can suppress the common gram-negative offenders and often *S. aureus* and *S. epidermidis* as well. *Enterobacter aerogenes* and *Proteus vulgaris* are usually resistant. The physician should strive to keep the pH <5.5.

**NITROFURANTOIN.** Nitrofurantoin (FURADANTIN, MACROBID, others) is a synthetic nitrofuran that is used for the prevention and treatment of UTIs.

**Antimicrobial Activity.** Nitrofurantoin is activated by enzymatic reduction, with the formation of highly reactive intermediates that seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce nitrofurantoin more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. Nitrofurantoin is active against many strains of *E. coli* and enterococci. However, most species of *Proteus* and *Pseudomonas* and many species of *Enterobacter* and *Klebsiella* are resistant.
Nitrofurantoin is bacteriostatic for most susceptible microorganisms at concentrations of <32 µg/mL or less and is bactericidal at concentrations of >100 µg/mL. The antibacterial activity is higher in acidic urine.

Pharmacology, Toxicity, and Therapy. Nitrofurantoin is absorbed rapidly and completely from the GI tract. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly. The plasma $t_{1/2}$ is 0.3-1 h; ~40% is excreted unchanged into the urine. The average dose of nitrofurantoin yields a concentration in urine of ~200 µg/mL. This concentration is soluble at pH >5, but the urine should not be alkalinized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance, so in patients with impaired glomerular function, the efficacy of the drug may be decreased and the systemic toxicity increased. Nitrofurantoin colors the urine brown.

The oral dosage of nitrofurantoin for adults is 50-100 mg 4 times a day with meals and at bedtime, less for the macrocrystalline formulation (100 mg every 12 h for 7 days). A single 50-100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5-7 mg/kg but may be as low as 1 mg/kg for long-term therapy. A course of therapy should not exceed 14 days; repeated courses should be separated by rest periods. Pregnant women, individuals with impaired renal function (creatinine clearance <40 mL/min), and children <1 month of age should not receive nitrofurantoin. Nitrofurantoin is approved for the treatment of UTIs. It is not recommended for treatment of pyelonephritis or prostatitis.

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated than traditional formulations. Various hypersensitivity reactions occur occasionally, including chills, fever, leukopenia, granulocytopenia, hemolytic anemia (associated with G6PD deficiency), cholestatic jaundice, and hepatocellular damage. Chronic active hepatitis is an uncommon. Acute pneumonitis with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. Interstitial pulmonary fibrosis can occur in patients (especially the elderly) taking the drug chronically. Megaloblastic anemia is rare. Headache, vertigo, drowsiness, muscular aches, and nystagmus occur
occasionally but are readily reversible. Severe polyneuropathies with
demyelination and degeneration of both sensory and motor nerves have been
reported; neuropathies are most likely to occur in patients with impaired renal
function and in persons on long-continued treatment.

PHENAZOPYRIDINE. Phenazopyridine hydrochloride (PYRIDIUM, others) is
not a urinary antiseptic. However, it does have an analgesic action on the urinary
tract and alleviates symptoms of dysuria, frequency, burning, and urgency. The
usual dose is 200 mg 3 times daily. The compound is an azo dye, which colors
urine orange or red. GI upset is seen in up to 10% of patients and can be reduced
by administering the drug with food; overdosage may result in
methemoglobinemia. OTC products containing phenazopyridine are under
review by the FDA for safety and efficacy.
The β-lactam antibiotics—penicillins, cephalosporins, and carbapenems—share a common structure and mechanism of action, inhibition of the synthesis of the bacterial peptidoglycan cell wall. Bacterial resistance against the β-lactam antibiotics continues to increase at a dramatic rate. β-Lactamase inhibitors such as clavulanate can extend the utility of these drugs against β-lactamase-producing organisms. Unfortunately, resistance includes not only production of β-lactamases but also alterations in or acquisition of novel penicillin-binding proteins (PBPs) and decreased entry and/or active efflux of the antibiotic. To a dangerous degree, we are re-entering the pre-antibiotic era, with many nosocomial gram-negative bacterial infections resistant to all available antibiotics.

**MECHANISM OF ACTION: INHIBITION OF PEPTIDOGLYCAN SYNTHESIS.** Peptidoglycan is a heteropolymeric component of the cell wall that provides rigid mechanical stability. The β-lactam antibiotics inhibit the last step in peptidoglycan synthesis (Figure 53–1).
Figure 53–1 *Action of β-lactam antibiotics in Staphylococcus aureus.* The bacterial cell wall consists of glycopeptide polymers (a NAM-NAG amino-hexose backbone) linked via bridges between amino acid side chains. In *S. aureus*, the bridge is (Gly)$_5$-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit.

In gram-positive microorganisms, the cell wall is 50-100 molecules thick; in gram-negative bacteria, it is only 1 or 2 molecules thick (Figure 53–2A). The peptidoglycan is composed of glycan chains, which are linear strands of 2 alternating amino sugars (*N*-acetylglucosamine and *N*-acetylmuramic acid) that are cross-linked by peptide chains. Peptidoglycan precursor formation takes place in the cytoplasm. The synthesis of UDP-*acetylmuramyl-pentapeptide* is completed with the addition of a dipeptide, D-alanyl-D-alanine (formed by racemization and condensation of *L*-alanine). UDP-*acetylmuramyl-pentapeptide* and UDP-*acetylglicosamine* are linked (with the release of the uridine nucleotides) to form a long polymer. The cross-link is completed by
transpeptidation reaction that occurs outside the cell membrane (Figure 53–2B). The β-lactam antibiotics inhibit this last step in peptidoglycan synthesis (see Figure 53–1), presumably by acylating the transpeptidase via cleavage of the —CO—N— bond of the β-lactam ring. There are additional, related targets for the actions of penicillins and cephalosporins; these are collectively termed *PBP*s. The transpeptidase responsible for synthesis of the peptidoglycan is 1 of these PBPs. The lethality of penicillin for bacteria appears to involve both lytic and nonlytic mechanisms.

---

**Figure 53–2** A. Structure and composition of gram-positive and gram-negative cell walls. (From Figure 4-11, p 83 of TORTORA, GERALD, MICROBIOLOGY: INTRODUCTION, 3rd Edition, © 1989. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ.) B. *Penicillin*
binding protein 2 (PBP2) from S. aureus. PBP2 has 2 enzymatic activities that are crucial to synthesis of the peptidoglycan layers of bacterial cell walls: a transpeptidase (TP) that cross-links amino acid side chains, and a glycosyltransferase (GT) that links subunits of the glycopeptide polymer (see Figure 53–1). The transpeptidase and glycosyltransferase domains are separated by a linker region. The glycosyltransferase is thought to be partially embedded in the membrane.

**MECHANISMS OF BACTERIAL RESISTANCE TO PENICILLINS AND CEPHALOSPORINS.** Bacteria can be resistant to β-lactam antibiotics by myriad mechanisms.

A sensitive strain may acquire resistance by mutations that decrease the affinity of PBPs for the antibiotic. Because the β-lactam antibiotics inhibit many different PBPs in a single bacterium, the affinity for β-lactam antibiotics of several PBPs must decrease for the organism to be resistant. Methicillin-resistant *Staphylococcus aureus* (MRSA) are resistant via acquisition of an additional high-molecular-weight PBP (via a transposon) with a very low affinity for all β-lactam antibiotics; this mechanism is responsible for methicillin resistance in the coagulase-negative staphylococci. Altered PBPs with decreased affinity for β-lactam antibiotics are acquired by homologous recombination between PBP genes of different bacterial species. Four of the 5 high-molecular-weight PBPs of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β-lactam antibiotics as a result of interspecies homologous recombination events (Figure 53–3). In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only 2 of the 5 high-molecular-weight PBPs because the other PBPs have inherently low affinity for the third-generation cephalosporins.
Bacterial resistance to the β-lactam antibiotics also results from the inability of the agent to penetrate to its site of action (Figure 53–4). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (see Figure 53–2) and small β-lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the PBPs. In gram-negative bacteria, the inner membrane is covered by the outer membrane, lipopolysaccharide, and capsule (see Figure 53–2). The outer membrane functions as an impenetrable barrier for some antibiotics. Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that are formed by proteins called porins. The number and size of pores in the outer membrane vary among different gram-negative bacteria, thereby providing greater or lesser access for antibiotics to the site of action. Active efflux pumps serve as another mechanism of resistance, removing the antibiotic from its site of action before it can act (see Figure 53–4).
Figure 53–4 Antibiotic efflux pumps of gram-negative bacteria. Multidrug efflux pumps traverse both the inner and outer membranes of gram-negative bacteria. The pumps are composed of a minimum of 3 proteins and are energized by the proton motive force. Increased expression of these pumps is an important cause of antibiotic resistance. (Reprinted with permission from Oxford University Press. Nikaido H. Antibiotic resistance caused by gram-negative multidrug efflux pumps. Clin Infect Dis, 1998;27[suppl 1]:S32–S41. © 1998 by the Infectious Diseases Society of America. All rights reserved.)

Bacteria also can destroy β-lactam antibiotics enzymatically via the action of β-lactamases (Figures 53–2 and 53–5). β-Lactamases are grouped into four classes: A through D. The substrate specificities of some of these classes are relatively narrow; these often are described as either penicillinases or cephalosporinases. Other “extended-spectrum” enzymes are less discriminant and can hydrolyze a variety of β-lactam antibiotics. In general, gram-positive bacteria produce and secrete a large amount of β-lactamase (see Figure 53–2A). Most of these enzymes are penicillinases. The information for staphylococcal penicillinase is encoded in a plasmid; this may be transferred by bacteriophage to other bacteria and is inducible by substrates. In gram-negative bacteria, β-lactamases are found in relatively small amounts but are located in the periplasmic space between the inner and outer cell membranes (see Figure 53–2A) for maximal protection of the microbe. β-Lactamases of gram-negative bacteria are encoded either in chromosomes or in plasmids, and may be constitutive or inducible. The plasmids can be transferred between bacteria by conjugation. These enzymes can hydrolyze penicillins, cephalosporins, or both.
OTHER FACTORS THAT INFLUENCE THE ACTIVITY OF β-LACTAM ANTIBIOTICS. Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart valves) produce biofilms. Bacteria in biofilms produce extracellular polysaccharides and, in part owing to decreased growth rates, are much less sensitive to antibiotic therapy. The β-lactam antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase. Similarly, bacteria that survive inside viable cells of the host generally are protected from the action of the β-lactam antibiotics.

THE PENICILLINS

Despite the emergence of microbial resistance, the penicillins are currently the drugs of choice for a large number of infectious diseases. Penicillins (Figure 53–5) consist of a thiazolidine ring (A) connected to a β-lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself is the chief structural requirement for biological activity. Side chains can be added that alter the susceptibility of the resulting compounds to inactivating enzymes (β-
lactamases) and that change the antibacterial activity and the pharmacological properties of the drug (Table 53–1).

**UNITAGE OF PENICILLIN.** The international unit of penicillin is the specific penicillin activity contained in 0.6 μg of the crystalline sodium salt of penicillin G. One milligram of pure penicillin G sodium thus equals 1667 units; 1.0 mg of pure penicillin G potassium represents 1595 units. The dosage and the antibacterial potency of the semisynthetic penicillins are expressed in terms of weight.

**CLASSIFICATION OF THE PENICILLINS AND SUMMARY OF THEIR PHARMACOLOGICAL PROPERTIES**

Penicillins are classified according to their spectra of antimicrobial activity.
• **Penicillin G** and its close congener **penicillin V** are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinase. Thus, they are *ineffective against most strains of S. aureus.*

• **The penicillinase-resistant penicillins** (*methicillin*, discontinued in U.S.), *nafcillin, oxacillin, cloxacillin* (not currently marketed in the U.S.), and *dicloxacillin* have less potent antimicrobial activity against microorganisms that are sensitive to penicillin G, but they are the *agents of first choice for treatment of penicillinase-producing S. aureus and Staphylococcus epidermidis that are not methicillin-resistant.*

• Ampicillin, amoxicillin, and others make up a group of **penicillins whose antimicrobial activity is extended to include gram-negative microorganisms** (e.g., *Haemophilus influenzae, Escherichia coli,* and *Proteus mirabilis*). These drugs are *frequently administered with a β-lactamase inhibitor* such as clavulanate or sulbactam to prevent hydrolysis by class A β-lactamases.

• **Agents with extended antimicrobial activity** that includes *Pseudomonas, Enterobacter,* and *Proteus* spp. [carbenicillin (discontinued in U.S.), its indanyl ester (carbenicillin indanyl), and ticarcillin (marketed with clavulanate in U.S.)] These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin against *Pseudomonas.*

• **Mezlocillin, azlocillin** (both discontinued in U.S.), and **piperacillin** have excellent antimicrobial activity against many isolates of *Pseudomonas, Klebsiella,* and certain other gram-negative microorganisms. Piperacillin retains the activity of ampicillin against gram-positive cocci and *L. monocytogenes.*

**General common properties:** Following absorption of an oral dose, penicillins are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in cerebrospinal fluid (CSF) are variable but are <1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly, particularly by glomerular
filtration and renal tubular secretion, such that their half-lives in the body are short, typically 30-90 min. As a consequence, concentrations of these drugs in urine are high.

**PENICILLIN G AND PENICILLIN V**

**ANTIMICROBIAL ACTIVITY.** The antimicrobial spectra of penicillin G (benzylpenicillin) and penicillin V (the phenoxyethyl derivative) are very similar for aerobic gram-positive microorganisms. However, penicillin G is 5-10 times more active than penicillin V against *Neisseria* spp. and certain anaerobes. Most streptococci (but not enterococci) are very susceptible. However, penicillin-resistant *viridans* streptococci and *S. pneumoniae* are becoming more common. Penicillin-resistant pneumococci are especially common in pediatric populations. Many penicillin-resistant pneumococci also are resistant to third-generation cephalosporins. More than 90% of strains of staphylococci isolates are now resistant to penicillin G, and nearly half are methicillin-resistant. Most strains of *S. epidermidis* and many strains of gonococci are also resistant. With rare exceptions, meningococci are quite sensitive to penicillin G.

Most anaerobic microorganisms, including *Clostridium* spp., are highly sensitive. *Bacteroides fragilis* is an exception, displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Some strains of *Prevotella melaninogenicus* also have acquired this trait. *Actinomyces israelii, Streptobacillus moniliformis, Pasteurella multocida,* and *L. monocytogenes* are inhibited by penicillin G. Most species of *Leptospira* are moderately susceptible to the drug. One of the most sensitive microorganisms is *Treponema pallidum. Borrelia burgdorferi,* the organism responsible for Lyme disease, also is susceptible. None of the penicillins is effective against amebae, plasmodia, rickettsiae, fungi, or viruses.

**ADME**

**Oral Administration of Penicillin G.** About one-third of an orally administered dose of penicillin G is absorbed from the GI tract. Gastric juice at pH 2 rapidly destroys the antibiotic. Absorption is rapid, and maximal concentrations in blood are attained in 30-60 min. Ingestion of food may interfere with enteric absorption of all penicillins. Thus, oral penicillin G should be administered at least 30 min before a meal or 2 h after. Despite the convenience of oral
administration of penicillin G, this route should be used only in infections in which clinical experience has proven its efficacy.

**Oral Administration of Penicillin V.** The virtue of penicillin V in comparison with penicillin G is that it is more stable in an acidic medium and therefore is better absorbed from the GI tract, yielding plasma concentrations 2-5 times those provided by penicillin G.

**Parenteral Administration of Penicillin G.** After intramuscular injection, peak concentrations in plasma are reached within 15-30 min, declining rapidly thereafter ($t_{1/2} \sim 30$ min). Repository preparations of penicillin G increase the duration of the effect. The compound currently favored is penicillin G benzathine (BICILLIN L-A, PERMAPEN), which releases penicillin G slowly from the area in which it is injected and produces relatively low but persistent concentrations in the blood. The average duration of demonstrable antimicrobial activity in the plasma is $\sim 26$ days. It is administered once monthly for rheumatic fever prophylaxis and can be given in a single injection to treat streptococcal pharyngitis. The persistence of penicillin in the blood after a suitable intramuscular dose of penicillin G benzathine reduces cost, need for repeated injections, and local trauma. The local anesthetic effect of penicillin G benzathine is comparable with that of penicillin G procaine.

**Distribution.** Penicillin G is distributed widely throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is $\sim 0.35$ L/kg. Approximately 60% of the penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine. Probenecid markedly decreases the tubular secretion of the penicillins and also produces a significant decrease in the apparent volume of distribution of the penicillins.

**Penetration into Cerebrospinal Fluid.** Penicillin does not readily enter the CSF but penetrates more easily when the meninges are inflamed. The concentrations are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms. Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. Probenecid competitively inhibits this transport and thus elevates the concentration of penicillin in CSF. In uremia, other organic acids accumulate in the CSF and compete with penicillin for secretion; the drug occasionally reaches
toxic concentrations in the brain and can produce convulsions.

**Excretion.** Approximately 60-90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid (see Figure 53–5). The \( t_{1/2} \) for elimination of penicillin G is \(~30\) min in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. Clearance values are considerably lower in neonates and infants; as a result penicillin persists in the blood several times longer in premature infants than in children and adults. The \( t_{1/2} \) of the antibiotic in children <1 week of age is 3 h; by 14 days of age it is 1.4 h. After renal function is fully established in young children, the rate of renal excretion of penicillin G is considerably more rapid than in adults. Anuria increases the \( t_{1/2} \) of penicillin G from 0.5 h to \(~10\) h. When renal function is impaired, 7-10% of the antibiotic may be inactivated each hour by the liver. The dose of the drug must be readjusted during dialysis and the period of progressive recovery of renal function. If hepatic insufficiency also is present, the \( t_{1/2} \) will be prolonged even further.

**THERAPEUTIC USES**

**Pneumococcal Infections.** Penicillin G remains the agent of choice for the management of infections caused by sensitive strains of *S. pneumoniae*, but resistance is an increasing problem.

**Pneumococcal Pneumonia.** Pneumococcal pneumonia should be treated with a third-generation cephalosporin or with 20-24 million units of penicillin G daily by constant intravenous infusion. If the organism is sensitive to penicillin, then the dose can be reduced. For parenteral therapy of sensitive isolates of pneumococci, penicillin G is favored. Therapy should be continued for 7-10 days, including 3-5 days after the patient’s temperature has returned to normal.

**Pneumococcal Meningitis.** Pneumococcal meningitis should be treated with a combination of vancomycin and a third-generation cephalosporin until it is established that the infecting pneumococcus is penicillin-sensitive. Dexamethasone given at the same time as antibiotics is associated with an improved outcome. The recommended therapy is 20-24 million units of
penicillin G daily by constant intravenous infusion or divided into boluses given every 2-3 h for 14 days.

**Streptococcal Infections.** *Streptococcal pharyngitis (including scarlet fever)* is the most common disease produced by *Streptococcus pyogenes* (group A β-hemolytic streptococcus). Penicillin-resistant isolates have yet to be observed. The preferred oral therapy is with penicillin V, 500 mg every 6 h for 10 days. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with penicillin.

*Streptococcal Toxic Shock and Necrotizing Fascitis.* These are life-threatening infections associated with toxin production and are treated optimally with penicillin plus clindamycin (to decrease toxin synthesis).

*Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis.* These uncommon conditions should be treated with penicillin G when they are caused by *S. pyogenes*; daily doses of 12-20 million units are administered intravenously for 2-4 weeks (4 weeks for endocarditis).

**Infections Caused by Other Streptococci.** The *viridans* group of streptococci is the most common cause of infectious endocarditis. These are nongroupable α-hemolytic microorganisms that are increasingly resistant to penicillin G. It is important to determine quantitative microbial sensitivities to penicillin G in patients with endocarditis. Patients with penicillin-sensitive viridans group streptococcal endocarditis can be treated successfully with daily doses of 12-20 million units of intravenous penicillin G for 2 weeks in combination with gentamicin 1 mg/kg every 8 h. The recommended therapy for penicillin- and aminoglycoside-sensitive enterococcal endocarditis is 20 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with a low dose of gentamicin. Therapy usually should be continued for 6 weeks.

**Infections with Anaerobes.** Many anaerobic infections are caused by mixtures of microorganisms. Most are sensitive to penicillin G. An exception is the *B. fragilis* group, in which up to 75% of strains may be resistant. Pulmonary and periodontal infections usually respond well to penicillin G; clindamycin may be
more effective than penicillin for therapy of lung abscess. Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 400,000 units [250 mg] 4 times daily). More severe infections should be treated with 12-20 million units of penicillin G intravenously. Brain abscesses also frequently contain several species of anaerobes, and most authorities recommend high doses of penicillin G (20 million units per day) plus metronidazole or chloramphenicol.

**Staphylococcal Infections.** Most staphylococcal infections are caused by microorganisms that produce penicillinase. Hospital-acquired methicillin-resistant staphylococci are resistant to penicillin G, all the penicillinase-resistant penicillins, and the cephalosporins. Isolates occasionally may appear to be sensitive to various cephalosporins in vitro, but resistant populations arise during therapy and lead to failure. Vancomycin, linezolid, quinupristin-dalfopristin, and daptomycin are active for infections caused by these bacteria, although reduced susceptibility to vancomycin has been observed. Community-acquired MRSA in many cases retains susceptibility to trimethoprim-sulfamethoxazole, doxycycline, and clindamycin.

**Meningococcal Infections.** Penicillin G remains the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously (see above). The occurrence of penicillin-resistant strains should be considered in patients who are slow to respond to treatment. Penicillin G does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure.

**Gonococcal Infections.** Gonococci gradually have become more resistant to penicillin G, and penicillins are no longer the therapy of choice. For uncomplicated gonococcal urethritis, a single intramuscular injection of 250 mg ceftriaxone is the recommended treatment. Gonococcal arthritis, disseminated gonococcal infections with skin lesions, and gonococcemia should be treated with ceftriaxone 1 g daily given either intramuscularly or intravenously for 7-10 days. Ophthalmia neonatorum also should be treated with ceftriaxone for 7-10 days (25-50 mg/kg/day intramuscularly or intravenously).

**Syphilis.** Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of <1-year duration may be treated with penicillin G procaine (2.4 million units per day intramuscularly) plus probenecid (1.0
g/day orally) for 10 days or with 1-3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine (3 doses in patients with HIV infection). Patients with neurosyphilis, or cardiovascular syphilis typically receive intensive therapy with 20 million units of penicillin G daily for 10 days. There are no proven alternatives for treating syphilis in pregnant women, so penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis. Infants with congenital syphilis discovered at birth or during the postnatal period should be treated for at least 10 days with 50,000 units/kg daily of aqueous penicillin G in 2 divided doses or 50,000 units/kg of procaine penicillin G in a single daily dose.

Most patients with secondary syphilis develop the Jarisch-Herxheimer reaction, including chills, fever, headache, myalgias, and arthralgias occurring several hours after the first dose of penicillin. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. Aspirin gives symptomatic relief, and therapy with penicillin should not be discontinued.

**Actinomycosis.** Penicillin G is the agent of choice for the treatment of all forms of actinomycosis (10-20 million units of penicillin G intravenously per day for 6 weeks). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

**Diphtheria.** Penicillin and other antibiotics do not alter the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. However, penicillin G eliminates the carrier state. The parenteral administration of 2-3 million units per day in divided doses for 10-12 days eliminates the diphtheria bacilli from the pharynx and other sites in practically 100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

**Anthrax.** Strains of *Bacillus anthracis* resistant to penicillin have been recovered from human infections. When penicillin G is used, the dose should be 12-20 million units per day.

**Clostridial Infections.** Penicillin G is the agent of choice for gas gangrene (12-20 million units per day given parenterally). Adequate debridement of the infected areas is essential. Antibiotics probably have no effect on the outcome of tetanus. Debridement and administration of human tetanus immune globulin may be
indicated.

**Fusospirochetal Infections.** Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and spirochetes that are present in the mouth, is readily treatable with penicillin. For simple “trench mouth,” 500 mg penicillin V given every 6 h for several days usually suffices.

**Rat-Bite Fever.** The 2 microorganisms responsible for this infection, *Spirillum minor* in the Far East and *Streptobacillus moniliformis* in the U.S. and Europe, are sensitive to penicillin G, the drug of choice. Because most cases due to *Streptobacillus* are complicated by bacteremia and, in many instances, by metastatic infections, especially of the synovia and endocardium, a daily dose of 12-15 million units given parenterally for 3-4 weeks is recommended.

**Listeria Infections.** Ampicillin (with gentamicin for immunosuppressed patients with meningitis) and penicillin G are the drugs of choice in the management of infections owing to *L. monocytogenes*. The recommended dose of penicillin G is 15-20 million units parenterally per day for at least 2 weeks. For endocarditis, the dose is the same, but the duration of treatment should be no less than 4 weeks.

**Lyme Disease.** Although a tetracycline is the usual drug of choice for early disease, amoxicillin is effective; the dose is 500 mg 3 times daily for 21 days. Severe disease is treated with a third-generation cephalosporin or up to 20 million units of intravenous penicillin G daily for 10-14 days.

**Erysipeloid.** The causative agent of this disease, *Erysipelothrix rhusiopathiae*, is sensitive to penicillin. The infection responds well to a single injection of 1.2 million units of penicillin G benzathine. When endocarditis is present, penicillin G, 12-20 million units per day, for 4-6 weeks is required.

**Pasteurella multocida.** *Pasteurella multocida* is the cause of wound infections after a cat or dog bite. It is susceptible to penicillin G and ampicillin and resistant to penicillinase-resistant penicillins and first-generation cephalosporins. When the infection causes meningitis, a third-generation cephalosporin is preferred.

**Prophylactic Uses of the Penicillins.** As prophylaxis has been investigated under
controlled conditions, it has become clear that penicillin is highly effective in some situations, useless and potentially dangerous in others, and of questionable value in still others (see Chapter 48).

**Streptococcal Infections.** The administration of penicillin to individuals exposed to *S. pyogenes* protects against infection. The oral ingestion of 200,000 units of penicillin G or penicillin V twice a day or a single injection of 1.2 million units of penicillin G benzathine is effective. Indications for this type of prophylaxis include outbreaks of streptococcal disease in closed populations (e.g., boarding schools or military bases).

**Recurrences of Rheumatic Fever.** The oral administration of 200,000 units of penicillin G or penicillin V every 12 h decreases the incidence of recurrences of rheumatic fever in susceptible individuals. The intramuscular injection of 1.2 million units of penicillin G benzathine once a month also yields excellent results. Prophylaxis must be continued throughout the year. Some suggest that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades, but the necessity of prolonged prophylaxis has not been established.

**Syphilis.** Prophylaxis for a contact with syphilis consists of a course of therapy as described for primary syphilis. A serological test for syphilis should be performed monthly for at least 4 months thereafter.

**Surgical Procedures in Patients with Valvular Heart Disease.** About 25% of cases of subacute bacterial endocarditis follow dental extractions. Since transient bacterial invasion of the bloodstream occurs occasionally after surgical procedures (e.g., tonsillectomy and genitourinary and GI procedures) and during childbirth, these, too, are indications for prophylaxis in patients with valvular heart disease. Whether the incidence of bacterial endocarditis actually is altered by this type of chemoprophylaxis remains to be determined.

**THE PENICILLINASE-RESISTANT PENICILLINS**

These penicillins are resistant to hydrolysis by staphylococcal penicillinase. Their appropriate use should be restricted to the treatment of infections that are known or suspected to be caused by
staphylococci that elaborate the enzyme, including the vast majority of strains that are encountered clinically. These drugs are much less active than penicillin G against other penicillin-sensitive microorganisms.

The role of the penicillinase-resistant penicillins for most staphylococcal disease is changing with the increasing incidence of isolates of so-called **methicillin-resistant microorganisms**. This term denotes resistance of these bacteria to all the penicillinase-resistant penicillins and cephalosporins. Vancomycin is considered the drug of choice for such infections. Vancomycin also is the drug of choice for serious infection caused by methicillin-resistant *S. epidermidis*; rifampin is given concurrently when a foreign body is involved.

**THE ISOXAZOLYL PENICILLINS: OXACILLIN, CLOXACILLIN, AND DICLOXACILLIN.** These semisynthetic congeners are relatively stable in an acidic medium and absorbed adequately after oral administration. All are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of diseases amenable to it and are not active against enterococci or *Listeria*. Oral administration is not a substitute for the parenteral route in the treatment of serious staphylococcal infections.

**Pharmacological Properties.** The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci. Dicloxacillin is the most active and many strains of *S. aureus* are inhibited by concentrations of 0.05-0.8 μg/mL. These agents are, in general, less effective against microorganisms susceptible to penicillin G, and they are not useful against gram-negative bacteria. These agents are absorbed rapidly but incompletely (30-80%) from the GI tract. These drugs are absorbed more efficiently when administered 1 h before or 2 h after meals. Peak concentrations in plasma are attained by 1 h. All these congeners are bound to plasma albumin to a great extent (~90-95%); none is removed from the circulation to a significant degree by hemodialysis. The isoxazolyl penicillins are excreted by the kidney; there is also significant hepatic degradation and elimination in the bile. The half-lives for all are between 30 and 60 min. Intervals between doses do not have to be altered for patients with renal failure.

**NAFCILLIN.** This semisynthetic penicillin is highly resistant to penicillinase
and has proven effective against infections caused by penicillinase-producing strains of \textit{S. aureus}.

\textit{Pharmacological Properties.} Nafcillin is slightly more active than oxacillin against penicillin G–resistant \textit{S. aureus} (most strains are inhibited by 0.06-2 μg/mL). Although it is the most active of the penicillinase-resistant penicillins against other microorganisms, it is not as potent as penicillin G. The peak plasma concentration is ~8 μg/mL 60 min after a 1-g intramuscular dose. Nafcillin is ~90% bound to plasma protein. Peak concentrations of nafcillin in bile are well above those found in plasma. Concentrations of the drug in CSF appear to be adequate for therapy of staphylococcal meningitis.

\textbf{THE AMINOPENICILLINS: AMPICILLIN, AMOXICILLIN, AND CONGENERS}

These agents have similar antibacterial activity and a spectrum that is broader than the antibiotics already discussed. They all are destroyed by β-lactamase (from both gram-positive and gram-negative bacteria).

\textit{Antimicrobial Activity.} Ampicillin and the related aminopenicillins are bactericidal for both gram-positive and gram-negative bacteria. The meningococci and \textit{L. monocytogenes} are sensitive to this class of drugs. Many pneumococcal isolates have varying levels of resistance to ampicillin. Penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. \textit{H. influenzae} and the \textit{viridans} group of streptococci exhibit varying degrees of resistance. Enterococci are about twice as sensitive to ampicillin as they are to penicillin G. From 30-50% of \textit{E. coli}, a significant number of \textit{P. mirabilis}, and practically all species of \textit{Enterobacter} presently are insensitive. Resistant strains of \textit{Salmonella} are recovered with increasing frequency. Most strains of \textit{Shigella}, \textit{Pseudomonas}, \textit{Klebsiella}, \textit{Serratia}, \textit{Acinetobacter}, and indole-positive \textit{Proteus} also are resistant to this group of penicillins; these antibiotics are less active against \textit{B. fragilis} than penicillin G. Concurrent administration of a β-lactamase inhibitor such as clavulanate or \textit{sulbactam} markedly expands their spectrum of activity.

\textbf{ADME}

\textit{Ampicillin.} Ampicillin (\textsc{principen}, others) is stable in acid and is well absorbed
after oral administration. An oral dose of 0.5 g produces peak concentrations in plasma of ~3 μg/mL at 2 h. Intake of food prior to ingestion of ampicillin diminishes absorption. Intramuscular injection of 0.5-1 g sodium ampicillin yields peak plasma concentrations of ~7-10 μg/mL, respectively, at 1 h. Plasma levels decline with a $t_{1/2}$ of ~80 min. Severe renal impairment markedly prolongs the $t_{1/2}$. Peritoneal dialysis is ineffective in removing the drug from the blood, but hemodialysis removes ~40% of the body store in ~7 h. Adjustment of the dose of ampicillin is required in the presence of renal dysfunction. Ampicillin appears in the bile, undergoes enterohepatic circulation, and is excreted in the feces.

**Amoxicillin.** This drug, a penicillinase-susceptible semi-synthetic penicillin (see Table 53–1), is a close chemical and pharmacological relative of ampicillin. Amoxicillin is stable in acid, designed for oral use, and absorbed more rapidly and completely from the GI tract than ampicillin. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, except that amoxicillin is less effective than ampicillin for shigellosis. Peak plasma concentrations of amoxicillin (AMOXIL, others) are 2-2.5 times greater for amoxicillin than for ampicillin after oral administration of the same dose. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with amoxicillin is less than that following administration of ampicillin. The incidence of other adverse effects appears to be similar. Although the $t_{1/2}$ of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin because of the more complete absorption. About 20% of amoxicillin is protein bound in plasma, a value similar to that for ampicillin. Most of a dose of the antibiotic is excreted in an active form in the urine. Probenecid delays excretion of the drug.

**THERAPEUTIC INDICATIONS**

**Upper Respiratory Infections.** Ampicillin and amoxicillin are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*. The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β-lactam antibiotics against both penicillin-sensitive and penicillin-resistant *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase
in dose of oral amoxicillin (from 40-45 up to 80-90 mg/kg/day) for empirical treatment of acute otitis media in children is recommended. Ampicillin-resistant *H. influenzae* is a problem in many areas. The addition of a β-lactamase inhibitor (amoxicillin-clavulanate or ampicillin-sulbactam) extends the spectrum to β-lactamase-producing *H. influenzae* and Enterobacteriaceae. Bacterial pharyngitis should be treated with penicillin G or penicillin V because *S. pyogenes* is the major pathogen.

**Urinary Tract Infections.** Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and *E. coli* is the most common species; ampicillin often is an effective agent, although resistance is increasingly common. Enterococcal urinary tract infections are treated effectively with ampicillin alone.

**Meningitis.** Acute bacterial meningitis in children is frequently due to *S. pneumoniae* or *Neisseria meningitidis*. Because 20-30% of strains of *S. pneumoniae* now may be resistant to ampicillin, it is not indicated for single-agent treatment of meningitis. Ampicillin has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. The combination of ampicillin and vancomycin plus a third-generation cephalosporin is a rational regimen for empirical treatment of suspected bacterial meningitis.

**Salmonella Infections.** Disease associated with bacteremia, disease with metastatic foci, and the enteric fever syndrome (including typhoid fever) respond favorably to antibiotics. A fluoroquinolone or ceftriaxone is considered by some to be the drug of choice, but the administration of trimethoprim-sulfamethoxazole or high doses of ampicillin (12 g/day for adults) also is effective. The typhoid carrier state has been eliminated successfully in patients without gallbladder disease with ampicillin, trimethoprim-sulfamethoxazole, or ciprofloxacin.

**ANTI-PSEUDOMONAL PENICILLINS:** THE CARBOXYPENICILLINS AND THE UREIDOPENICILLINS

**ANTIMICROBIAL ACTIVITY.** The carboxypenicillins, carbenicillin (discontinued in the U.S.) and ticarcillin (marketed in combination with clavulanate in the U.S.) and their close relatives, are active against some isolates of *P. aeruginosa* and certain indole-positive...
Proteus spp. that are resistant to ampicillin and its congeners. They are ineffective against most strains of S. aureus, Enterococcus faecalis, Klebsiella, and L. monocytogenes. B. fragilis is susceptible to high concentrations of these drugs, but penicillin G is actually more active. The ureidopenicillins, mezlocillin (discontinued in the U.S.) and piperacillin, have superior activity against P. aeruginosa compared with carbenicillin and ticarcillin. Mezlocillin and piperacillin are useful for treatment of infections with Klebsiella. The carboxypenicillins and the ureidopenicillins are sensitive to destruction by β-lactamases.

PHARMACOLOGICAL PROPERTIES

Carbenicillin. Carbenicillin was the first penicillin with activity against P. aeruginosa and some Proteus strains that are resistant to ampicillin. Preparations of carbenicillin may cause adverse effects in addition to those that follow the use of other penicillins. Congestive heart failure may result from the administration of excessive Na+. Hypokalemia may occur because of obligatory excretion of cation with the large amount of nonreabsorbable anion (carbenicillin) presented to the distal renal tubule. The drug interferes with platelet function, and bleeding may occur because of abnormal aggregation of platelets.

Carbenicillin Indanyl Sodium. This indanyl ester of carbenicillin is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to carbenicillin by hydrolysis of the ester linkage. The antimicrobial spectrum of the drug is therefore that of carbenicillin. The active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus, the only use of this drug is for the management of urinary tract infections caused by Proteus spp. other than P. mirabilis and by P. aeruginosa.

Piperacillin. Piperacillin extends the spectrum of ampicillin to include most strains of P. aeruginosa, Enterobacteriaceae (non-β-lactamase-producing), many Bacteroides spp., and E. faecalis. Combined with a β-lactamase inhibitor (piperacillin-tazobactam, ZOSYN) it has the broadest antibacterial spectrum of the penicillins. Pharmacokinetic properties are reminiscent of the other ureidopenicillins. High biliary concentrations are achieved.

THERAPEUTIC INDICATIONS. Piperacillin and related agents are important
agents for the treatment of patients with serious infections caused by gram-negative bacteria, including infections often acquired in the hospital. Therefore, these penicillins find their greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to penicillin G and ampicillin; the bacteria especially responsible include \textit{P. aeruginosa}, indole-positive strains of \textit{Proteus}, and \textit{Enterobacter} spp. Because \textit{Pseudomonas} infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β-lactam antibiotic such as piperacillin with good activity against these microorganisms.

**RELATED AGENTS**

\textit{Ticarcillin.} This semisynthetic penicillin is very similar to carbenicillin, but it is 2 to 4 times more active against \textit{P. aeruginosa}. Ticarcillin is inferior to piperacillin for the treatment of serious infections caused by \textit{Pseudomonas}. Ticarcillin is only marketed in combination with clavulanate (Timentin) in the U.S.

\textit{Mezlocillin.} This ureidopenicillin is more active against \textit{Klebsiella} than is carbenicillin; its activity against \textit{Pseudomonas} in vitro is similar to that of ticarcillin. It is more active than ticarcillin against \textit{E. faecalis}. Mezlocillin sodium has been discontinued in the U.S.

**UNTOWARD REACTIONS TO PENICILLINS**

**HYPERSENSITIVITY REACTIONS.** Hypersensitivity reactions are by far the most common adverse effects noted with the penicillins, and these agents probably are the most common cause of drug allergy.

Allergic reactions (overall incidence, 0.7-10%) can complicate treatment courses. Manifestations of allergy to penicillins include maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens-Johnson syndrome, and anaphylaxis. Hypersensitivity to penicillins generally extends to the other β-lactams (e.g., cephalosporins, some carbapenems). Hypersensitivity reactions may occur with any dosage form of penicillin; allergy to 1 penicillin exposes the patient to a greater risk of reaction if another is given but does not necessarily imply repetition on subsequent
exposures. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (e.g., in foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1-2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. In a few instances, it is necessary to interdict the future use of penicillin because of the risk of death, and the patient should be so warned.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety (major determinant moiety [MDM]), which is formed when the β-lactam ring is opened (see Figure 53–5). A large percentage of immunoglobulin (Ig)E-mediated reactions are to the MDM, but at least 25% of reactions are to other breakdown products. The terms *major* and *minor determinants* refer to the frequency with which antibodies to these haptens appear to be formed. They do not describe the severity of the reaction that may result. In fact, anaphylactic reactions to penicillin usually are mediated by IgE antibodies against the minor determinants. Anti-penicillin antibodies are detectable in virtually all patients who have received the drug and in many who have never knowingly been exposed to it. Immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant–specific skin-sensitizing antibodies. Some reactions may be due to toxic antigen-antibody complexes of major-determinant–specific IgM antibodies. Skin rashes of all types may be caused by allergy to penicillin. The incidence of skin rashes appears to be highest following the use of ampicillin, at ~9%; rashes follow the administration of ampicillin in nearly all patients with infectious mononucleosis.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004-0.04%. About 0.001% of patients treated with these agents die from anaphylaxis. Anaphylaxis most often
has followed the injection of penicillin, although it also has been observed after oral or intradermal administration. The most dramatic reaction is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes. Serum sickness of variable intensity and severity, mediated by IgG antibodies, is rare; when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed until 1 or 2 weeks after the drug has been stopped and may persist for a week or longer. Vasculitis may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy, but hemolytic anemia is rare. Reversible neutropenia has been noted, occurring in up to 30% of patients treated with 8-12 g nafcillin for >21 days. The bone marrow shows an arrest of maturation. Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. Penicillins rarely cause interstitial nephritis; methicillin has been implicated most frequently. Fever may be the only evidence of a hypersensitivity reaction to the penicillins. The febrile reaction usually disappears within 24-36 h after administration of the drug is stopped but may persist for days.

Management of the Patient Potentially Allergic to Penicillin. Evaluation of the patient’s history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Occasionally, desensitization is recommended for penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care setting. When full doses are reached, penicillin should not be discontinued and then restarted because immediate reactions may recur. The efficacy of this procedure is unproven. Patients with life-threatening infections (e.g., endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antimicrobial agents should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. Rarely, exfoliative dermatitis with or without vasculitis develops in these patients if therapy with penicillin is continued.

OTHER ADVERSE REACTIONS. The penicillins have minimal direct toxicity. Apparent toxic effects include bone marrow depression, granulocytopenia, and
hepatitis; the latter effect is rare but is seen most commonly following the administration of oxacillin and nafcillin. The administration of penicillin G, carbenicillin, piperacillin, or ticarcillin has been associated with impaired hemostasis due to defective platelet aggregation. Most common among the irritative responses to penicillin are pain and sterile inflammatory reactions at the sites of intramuscular injections. In some individuals who receive penicillin intravenously, phlebitis or thrombophlebitis develops. Adverse responses to oral penicillin preparations may include nausea, vomiting, and mild to severe diarrhea.

When penicillin is injected accidentally into the sciatic nerve, severe pain occurs and dysfunction in the area of distribution of this nerve develops and persists for weeks. Intrathecal injection of penicillin G may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins should be avoided. When the concentration of penicillin G in CSF exceeds 10 μg/mL, significant dysfunction of the CNS is frequent. The rapid intravenous administration of 20 million units of penicillin G potassium, which contains 34 mEq of K⁺, may lead to severe or even fatal hyperkalemia in persons with renal dysfunction. Injection of penicillin G procaine may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of toxic concentrations of procaine.

**REACTIONS UNRELATED TO HYPERSENSITIVITY OR TOXICITY.**
Penicillin changes the composition of the microflora in the GI tract by eliminating sensitive microorganisms. Normal microflora are typically reestablished shortly after therapy is stopped; however, in some patients, superinfection results. Pseudomembranous colitis, related to overgrowth and production of a toxin by *Clostridium difficile*, has followed oral and, less commonly, parenteral administration of penicillins.

**THE CEPHALOSPORINS**
Cephalosporin antibiotics are produced from 7-aminocephalosporanic acid by the addition of different side chains (Table 53–2).

| Table 53–2 |
Compounds containing 7-aminocephalosporanic acid are relatively stable in dilute acid and relatively resistant to penicillinase regardless of the nature of their side chains and their affinity for the enzyme. Modifications at position 7 of the β-lactam ring are associated with alteration in antibacterial activity; substitutions at position 3 of the dihydrothiazine ring alter the metabolism and pharmacokinetic properties of the drugs. The cephamycins are similar to the cephalosporins but have a methoxy group at position 7 of the β-lactam ring of the 7-aminocephalosporanic acid nucleus.

**MECHANISM OF ACTION.** Cephalosporins and cephamycins
inhibit bacterial cell wall synthesis in a manner similar to that of penicillin.

**CLASSIFICATION.** *Classification is by generations*, based on general features of antimicrobial activity ([Table 53–3](#)).

<sup>a</sup> All cephalosporins lack activity against *enterococci*, *Listeria monocytogenes*, *Legionella* spp., *methicillin-resistant S. aureus*, *Xanthomonas maltophilia*, and *Acinetobacter species*.  
<sup>b</sup> Except for *penicillin-resistant strains*.  
<sup>c</sup> Except for *methylpenicillin-resistant strains*.  
<sup>d</sup> Resistance to cephalosporins may be induced rapidly during therapy by derepression of bacterial chromosomal β-lactamases, which destroy the cephalosporins.  
<sup>e</sup> Cefazidime only.  
<sup>f</sup> Cefazidime lacks significant gram-positive activity. Cefotaxime is most active in class against *S. aureus* and *S. pyogenes*.

The **first-generation** cephalosporins (e.g., cephalothin and cefazolin) have good activity against gram-positive bacteria and relatively modest activity against gram-negative microorganisms. Most gram-positive cocci (with the exception of enterococci, MRSA, and *S. epidermidis*) are susceptible. Most oral cavity
anaerobes are sensitive, but the *B. fragilis* group is resistant. Activity against *Moraxella catarrhalis, E. coli, K. pneumoniae, and P. mirabilis* is good.

The **second-generation** cephalosporins have somewhat increased activity against gram-negative microorganisms but are much less active than the third-generation agents. A subset of second-generation agents (cefoxitin, cefotetan, and cefmetazole, which have been discontinued in the U.S.) also is active against *B. fragilis*.

**Third-generation** cephalosporins generally are less active than first-generation agents against gram-positive cocci; these agents are much more active against the Enterobacteriaceae, although resistance is dramatically increasing due to β-lactamase-producing strains. A subset of third-generation agents (ceftazidime and cefoperazone) also is active against *P. aeruginosa* but less active than other third-generation agents against gram-positive cocci.

**Fourth-generation** cephalosporins, such as cefepime, have an extended spectrum of activity compared with the third generation and have increased stability from hydrolysis by plasmid and chromosomally mediated β-lactamases (but not the KPC class A β-lactamases). Fourth-generation agents are useful in the empirical treatment of serious infections in hospitalized patients when gram-positive microorganisms, Enterobacteriaceae, and *Pseudomonas* all are potential etiologies.

None of the cephalosporins has reliable activity against the following bacteria: penicillin-resistant *S. pneumoniae*, MRSA, methicillin-resistant *S. epidermidis* and other coagulase-negative staphylococci, *Enterococcus, L. monocytogenes, Legionella pneumophila, L. micdadei, C. difficile, Xanthomonas maltophilia, Campylobacter jejuni*, KPC-producing *Enterobacteriaceae*, and *Acinetobacter* spp.

**MECHANISMS OF BACTERIAL RESISTANCE.** Resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the PBPs that are targets of the cephalosporins. Alterations in 2 PBPs (1A and 2X) that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other 3 PBPs have inherently
The most prevalent mechanism of resistance to cephalosporins is destruction of the cephalosporins by hydrolysis of the β-lactam ring. The cephalosporins have variable susceptibility to β-lactamase. Of the first-generation agents, cefazolin is more susceptible to hydrolysis by β-lactamase from *S. aureus* than is cephalothin (no longer marketed). Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β-lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins are susceptible to hydrolysis by inducible, chromosomally encoded (type I) β-lactamases. Induction of type I β-lactamases by treatment of infections owing to aerobic gram-negative bacilli with second- or third-generation cephalosporins or imipenem may result in resistance to all third-generation cephalosporins. The fourth-generation cephalosporins, such as cefepime, are poor inducers of type I β-lactamases and are less susceptible to hydrolysis by type I β-lactamases than are the third-generation agents. They are, however, susceptible to degradation by KPC and metallo-β-lactamases.

**GENERAL PHARMACOLOGY**

Many cephalosporins (cephalexin, cephradine, cefaclor, cefadroxil, loracarbef, cefprozil, cefpodoxime proxetil, ceftibuten, cefuroxime axetil, cefdinir, and cefditoren) are absorbed readily after oral administration; others can be administered intramuscularly or intravenously. Cephalosporins are excreted primarily by the kidney; thus the dosage should be reduced in patients with renal insufficiency. Probenecid slows the tubular secretion of most cephalosporins. Exceptions are cefpiramide and cefoperazone, which are excreted predominantly in the bile. Cefotaxime is deacetylated to a metabolite with less antimicrobial activity than the parent compound that is excreted by the kidneys. The other cephalosporins do not undergo appreciable metabolism. Several cephalosporins penetrate into the CSF in sufficient concentration to be useful for the treatment of meningitis. Cephalosporins also cross the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. Concentrations in bile usually are high, especially with cefoperazone and cefpiramide.
SPECIFIC AGENTS

FIRST-GENERATION CEPHALOSPORINS

Cefazolin has an antibacterial spectrum that is typical of other first-generation cephalosporins except that it also has activity against some Enterobacter spp. Cefazolin is relatively well tolerated after either intramuscular or intravenous administration; it is excreted by glomerular filtration and is ~85% bound to plasma proteins. Cefazolin usually is preferred among the first-generation cephalosporins because it can be administered less frequently owing to its longer $t_{1/2}$.

Cephalexin has the same antibacterial spectrum as the other first-generation cephalosporins. It is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalexin (usually 0.5 g) results in peak concentrations in plasma adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and 70-100% is excreted in the urine.

Cephradine is similar in structure to cephalexin, and its activity in vitro is almost identical. Cephradine is not metabolized and, after rapid absorption from the GI tract, is excreted unchanged in the urine. Because cephradine is so well absorbed, the concentrations in plasma are nearly equivalent after oral or intramuscular administration.

Cefadroxil is the para-hydroxy analog of cephalexin. Concentrations of cefadroxil in plasma and urine are at somewhat higher levels than are those of cephalexin. The drug is given orally once or twice a day for the treatment of urinary tract infections. Its activity in vitro is similar to that of cephalexin.

SECOND-GENERATION CEPHALOSPORINS. Second-generation cephalosporins have a broader spectrum than do the first-generation agents and are active against sensitive strains of Enterobacter spp., indole-positive Proteus spp., and Klebsiella spp.

Cefoxitin is resistant to some β-lactamases produced by gram-negative rods. This antibiotic is less active than the first-generation cephalosporins against gram-positive bacteria, but is more active against anaerobes, especially B. fragilis. Cefoxitin’s special role seems to be for treatment of certain anaerobic
and mixed aerobic-anaerobic infections, such as pelvic inflammatory disease and lung abscess.

**Cefaclor**’s concentration in plasma after oral administration is \(~50\%\) of that achieved after an equivalent oral dose of cephalaxin. However, cefaclor is more active against *H. influenzae* and *M. catarrhalis*, although some \(\beta\)-lactamase-producing strains of these organisms may be resistant.

**Loracarbef** is similar in activity to cefaclor and more stable against some \(\beta\)-lactamases.

**Cefuroxime** is similar to loracarbef with broader gram-negative activity against some *Citrobacter* and *Enterobacter* spp. Unlike cefoxitin, cefmetazole, and cefotetan, cefuroxime lacks activity against *B. fragilis*. The drug can be given every 8 h. Concentrations in CSF are \(~10\%\) of those in plasma, and the drug is effective (but inferior to ceftriaxone) for treatment of meningitis owing to *H. influenzae* (including strains resistant to ampicillin), *N. meningitidis*, and *S. pneumoniae*.

**Cefuroxime axetil** is the 1-acetyloxyethyl ester of cefuroxime. Between 30\% and 50\% of an oral dose is absorbed, and the drug then is hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

**Cefprozil** is an orally administered agent that is more active than first-generation cephalosporins against penicillin-sensitive streptococci, *E. coli*, *P. mirabilis*, *Klebsiella* spp., and *Citrobacter* spp; serum \(t_{1/2}\) is \(~1.3\) h.

**THIRD-GENERATION CEPHALOSPORINS**

**Cefotaxime** is highly resistant to many \(\beta\)-lactamases and has good activity against many gram-positive and gram-negative aerobic bacteria. However, activity against *B. fragilis* is poor compared with agents such as clindamycin and metronidazole. Cefotaxime has a \(t_{1/2}\) in plasma of \(~1\) h and should be administered every 4–8 h for serious infections. The drug is metabolized in vivo to desacetylceffotaxime, which is less active than is the parent compound. Cefotaxime has been used effectively for meningitis caused by *H. influenzae*, penicillin-sensitive *S. pneumoniae*, and *Neisseria meningitides*.

**Ceftizoxime** has a spectrum of activity in vitro that is very similar to that of
Cefotaxime, except that it is less active against *S. pneumoniae* and more active against *B. fragilis*. The \( t_{1/2} \) is 1.8 h, and the drug thus can be administered every 8-12 h for serious infections. Ceftizoxime is not metabolized; 90% is recovered in urine.

**Ceftriaxone** has activity very similar to that of ceftizoxime and cefotaxime but a longer \( t_{1/2} \) (≈8 h). Administration of the drug once or twice daily has been effective for patients with meningitis. About half the drug can be recovered from the urine; the remainder is eliminated by biliary secretion. A single dose of ceftriaxone (125-250 mg) is effective in the treatment of urethral, cervical, rectal, or pharyngeal gonorrhea, including disease caused by penicillinase-producing microorganisms.

**Cefpodoxime proxetil** is an orally administered third-generation agent that is very similar in activity to the fourth-generation agent cefepime except that it is not more active against *Enterobacter* or *Pseudomonas* spp.

**Cefditoren pivoxil** is a prodrug that is hydrolyzed by esterases during absorption to the active drug, cefditoren. Cefditoren is eliminated unchanged in the urine. The drug is active against methicillin-susceptible strains of *S. aureus*, penicillin-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, and *M. catarrhalis*. Cefditoren pivoxil is only indicated for the treatment of mild-to-moderate pharyngitis, tonsillitis, uncomplicated skin and skin structure infections, and acute exacerbations of chronic bronchitis.

**Cefixime** is orally effective against urinary tract infections caused by *E. coli* and *P. mirabilis*, otitis media caused by *H. influenza* and *S. pyogenes*, pharyngitis due to *S. pyogenes*, and uncomplicated gonorrhea. It is available as an oral suspension (suprax, others). Cefixime has a plasma \( t_{1/2} \) of 3-4 h and is both excreted in the urine and eliminated in the bile. The standard dose for adults is 400 mg/day for 5-7 days, and for a longer interval in patients with *S. pyogenes*. Doses must be reduced in patients with renal impairment. Pediatric dosing varies with patient weight.

**Ceftibuten** is an orally effective cephalosporin that is less active against gram-positive and gram-negative organisms than cefixime, with activity limited to *S. pneumonia* and *S. pyogenes*, *H. influenzae*, and *M. catarrhalis*. Ceftibuten is only indicated for acute bacterial exacerbations of chronic bronchitis, acute
bacterial otitis media, pharyngitis, and tonsillitis.

**Cefdinir** is effective orally; it is eliminated primarily unchanged in the urine. Cefdinir has activity against facultative gram-negative bacteria but lacks anaerobic activity. It is also inactive against *Pseudomonas* and *Enterobacter* spp.

*Third-Generation Cephalosporins with Good Anti-Pseudomonal Activity.*

**Ceftazidime** is one-quarter to one-half as active against gram-positive microorganisms as is cefotaxime. Its activity against the Enterobacteriaceae is very similar, but its major distinguishing feature is excellent activity against *Pseudomonas* and other gram-negative bacteria. Ceftazidime has poor activity against *B. fragilis*. Its $t_{1/2}$ in plasma is $\sim 1.5$ h; the drug is not metabolized.

*FOURTH-GENERATION CEPHALOSPORINS: CEFEPIME AND CEFPIROME*

Only cefepime is available for use in the U.S. Cefepime resists hydrolysis by many of the plasmid-encoded β-lactamases. It is a poor inducer of, and is relatively resistant to, the type I chromosomally encoded and some extended-spectrum β-lactamases. Thus, it is active against many Enterobacteriaceae that are resistant to other cephalosporins via induction of type I β-lactamases. Cefepime is susceptible hydrolysis by many bacteria expressing extended-spectrum plasmid-mediated β-lactamases. Cefepime is excreted renally; doses should be adjusted for renal failure. Cefepime has excellent penetration into the CSF in animal models of meningitis. The recommended dosage for adults is 2 g intravenously every 12 h. The serum $t_{1/2}$ is 2 h.

Against the fastidious gram-negative bacteria (*H. influenzae*, *Neisseria gonorrhoeae*, and *N. meningitidis*), cefepime has comparable or greater in vitro activity than cefotaxime. For *P. aeruginosa*, cefepime has comparable activity to ceftazidime, although it is less active than ceftazidime for other *Pseudomonas* spp. and *X. maltophilia*. Cefepime has higher activity than ceftazidime and comparable activity to cefotaxime for streptococci and methicillin-sensitive *S. aureus*. It is not active against MRSA, penicillin-resistant pneumococci, enterococci, *B. fragilis*, *L. monocytogenes, Mycobacterium avium* complex, or *Mycobacterium tuberculosis*.

**ADVERSE REACTIONS**

Hypersensitivity reactions to the cephalosporins are the most common
side effects; they are identical to those caused by the penicillins. Patients who are allergic to 1 class of β-lactam antibiotics may manifest cross-reactivity to a member of the other class.

Immediate reactions such as anaphylaxis, bronchospasm, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia. Patients with a history of a mild or a temporally distant reaction to penicillin appear to be at low risk of allergic reaction following the administration of a cephalosporin. However, patients who have had a recent severe, immediate reaction to a penicillin should be given a cephalosporin with great caution, if at all. A positive Coombs reaction appears frequently in patients who receive large doses of a cephalosporin, but hemolysis is rare. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia.

The cephalosporins are potentially nephrotoxic. Renal tubular necrosis has followed the administration of cephalaridine in doses >4 g/day; this agent is no longer available in the U.S. Other cephalosporins when used by themselves in recommended doses rarely produce significant renal toxicity. High doses of cephalothin (no longer available in the U.S.) have produced acute tubular necrosis in certain instances, and usual doses (8-12 g/day) have caused nephrotoxicity in patients with preexisting renal disease. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. Intolerance to alcohol has been noted with cephalosporins that contain the methylthiotetrazole (MTT) group. Serious bleeding related either to hypoprothrombinemia owing to the MTT group, thrombocytopenia, and/or platelet dysfunction has been reported.

**THERAPEUTIC USES**

The *first-generation cephalosporins* are excellent agents for skin and soft tissue infections owing to *S. pyogenes* and methicillin-susceptible *S. aureus*. A single dose of cefazolin just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens. For colorectal surgery, where prophylaxis for intestinal anaerobes is desired, the second-generation agent cefoxitin is preferred.
Second-generation cephalosporins generally have been displaced by third-generation agents. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are suboptimal (compared with oral amoxicillin) for treatment of penicillin-resistant *S. pneumoniae* pneumonia and otitis media. In situations where facultative gram-negative bacteria and anaerobes are involved, such as intra-abdominal infections, pelvic inflammatory disease, and diabetic foot infection, cefoxitin and cefotetan both are effective.

The third-generation cephalosporins are the drugs of choice for serious infections caused by *Klebsiella, Enterobacter, Proteus, Providencia, Serratia*, and *Haemophilus* spp. Ceftriaxone is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. Third-generation cephalosporins cefotaxime or ceftriaxone are used for the initial treatment of meningitis in nonimmunocompromised adults and children >3 months of age (in combination with vancomycin and ampicillin pending identification of the causative agent). They are the drugs of choice for the treatment of meningitis caused by *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria. Cefotaxime has failed in the treatment of meningitis owing to resistant *S. pneumoniae*; thus vancomycin should be added. Ceftazidime plus an aminoglycoside is the treatment of choice for *Pseudomonas* meningitis. Third-generation cephalosporins lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectra of cefotaxime and ceftriaxone are excellent for the treatment of community-acquired pneumonia.

The fourth-generation cephalosporins are indicated for the empirical treatment of nosocomial infections where antibiotic resistance owing to extended-spectrum β-lactamases or chromosomally induced β-lactamases are anticipated. For example, cefepime has superior activity against nosocomial isolates of *Enterobacter, Citrobacter*, and *Serratia* spp. compared with ceftazidime and piperacillin. KPC- or metallo-β-lactamase expressing strains are resistant to cefepime.

OTHER β-LACTAM ANTIBIOTICS

CARBAPENEMS
Carbapenems are β-lactams that contain a fused β-lactam ring and a 5-member ring system that differs from the penicillins because it is unsaturated and contains a carbon atom instead of the sulfur atom. This class of antibiotics has a broader spectrum of activity than most other β-lactam antibiotics.

**IMIPENEM.** Imipenem is marketed in combination with cilastatin, a drug that inhibits the degradation of imipenem by a renal tubular dipeptidase.

**Antimicrobial Activity.** Imipenem, like other β-lactam antibiotics, binds to PBPs, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β-lactamases. The activity of imipenem is excellent in vitro for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant *S. pneumoniae*), enterococci (excluding *E. faecium* and non-β-lactamase-producing penicillin-resistant strains), staphylococci (including penicillinase-producing strains), and *Listeria* all are susceptible. Some strains of methicillin-resistant staphylococci are susceptible: many strains are not. Activity was excellent against the Enterobacteriaceae until the emergence of KPC carbapenemase-producing strains. Most strains of *Pseudomonas* and *Acinetobacter* are inhibited. Anaerobes, including *B. fragilis*, are highly susceptible.

**Pharmacokinetics and Adverse Reactions.** Imipenem is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal tubule. To prolong drug activity, imipenem is combined with cilastatin, an inhibitor of the dehydropeptidase; the combined preparation is available as PRIMAXIN. Both imipenem and cilastatin have a $t_{1/2}$ of ~1 h. When administered concurrently with cilastatin, ~70% of administered imipenem is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency. Nausea and vomiting are the most common adverse reactions (1-20%). Seizures have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with renal insufficiency. Patients who are allergic to other β-lactam antibiotics may have hypersensitivity reactions when given imipenem.
**Therapeutic Uses.** Imipenem–cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The drug combination appears to be especially useful for the treatment of infections caused by cephalosporin-resistant nosocomial bacteria. It is prudent to use imipenem for empirical treatment of serious infections in hospitalized patients who have recently received other β-lactam antibiotics. Imipenem should not be used as monotherapy for infections owing to *P. aeruginosa* because of the risk of resistance developing during therapy.

**MEROPENEM.** Meropenem (Merrem IV) is a derivative of thienamycin. It does not require coadministration with cilastatin because it is not sensitive to renal dipeptidase. Its toxicity is similar to that of imipenem except that it may be less likely to cause seizures.

**DORIPENEM.** Doripenem (Doribax) has a spectrum of activity that is similar to that of imipenem and meropenem, with greater activity against some resistant isolates of Pseudomonas.

**ERTAPENEM.** Ertapenem (Invanz) differs from imipenem and meropenem by having a longer $t_{1/2}$ that allows once-daily dosing and by having inferior activity against *P. aeruginosa* and *Acinetobacter* spp. Its activity against gram-positive organisms, Enterobacteriaceae, and anaerobes makes it useful in intra-abdominal and pelvic infections.

**AZTREONAM.** Aztreonam (Azactam) is resistant to many of the β-lactamases elaborated by most gram-negative bacteria, including the metallo-β-lactamases but not the KPC β-lactamases.

The antimicrobial activity of aztreonam differs from those of other β-lactam antibiotics and more closely resembles that of an aminoglycoside. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. Activity against Enterobacteriaceae is excellent, as is that against *P. aeruginosa*. It is also highly active in vitro against *H. influenzae* and gonococci. Aztreonam is administered either intramuscularly or intravenously. The $t_{1/2}$ for elimination is 1.7 h; most of the drug is recovered unaltered in the urine. The $t_{1/2}$ is prolonged to ~6 h in anephric patients. The
usual dose of aztreonam for severe infections is 2 g every 6-8 h (reduced in patients with renal insufficiency). A notable feature is little allergic cross-reactivity with β-lactam antibiotics, with the possible exception of ceftazidime with which it has considerable structural similarity. Aztreonam is therefore useful for treating gram-negative infections that normally would be treated with a β-lactam antibiotic were it not for a prior allergic reaction. Aztreonam generally is well tolerated.

**β-LACTAMASE INHIBITORS**

Certain molecules can inactivate β-lactamases and prevent the destruction of β-lactam antibiotic substrates. β-Lactamase inhibitors are most active against plasmid-encoded β-lactamases (including those that hydrolyze ceftazidime and cefotaxime), but they are inactive at clinically achievable concentrations against the type I chromosomal β-lactamases induced in gram-negative bacilli (e.g., *Enterobacter, Acinetobacter, and Citrobacter*) by 2nd and 3rd generation cephalosporins.

**Clavulanic acid** has poor intrinsic antimicrobial activity but is a “suicide” inhibitor that irreversibly binds β-lactamases produced by a wide range of gram-positive and gram-negative microorganisms. Clavulanic acid is well absorbed by mouth and also can be given parenterally. It is combined with amoxicillin as an oral preparation (AUGMENTIN, others) and with ticarcillin as a parenteral preparation (TIMENTIN).

Amoxicillin plus clavulanate is effective for β-lactamase-producing strains of staphylococci, *H. influenzae*, gonococci, and *E. coli*. It is effective in the treatment of acute otitis media in children, sinusitis, animal or human bite wounds, cellulitis, and diabetic foot infections. Addition of clavulanate to
ticarcillin extends its spectrum to aerobic gram-negative bacilli, *S. aureus*, and *Bacteroides* spp. There is no increased activity against *Pseudomonas* spp. The combination is especially useful for mixed nosocomial infections, often with an aminoglycoside. Dosage should be adjusted in renal insufficiency.

**Sulbactam** is a β-lactamase inhibitor similar in structure to clavulanic acid. It is available for intravenous or intramuscular use combined with ampicillin (UNASYN, others). Dosage must be adjusted for patients with impaired renal function. The combination has good activity against gram-positive cocci, including β-lactamase-producing strains of *S. aureus*, gram-negative aerobes (but not resistant strains of *E. coli* or *Pseudomonas*), and anaerobes; it also has been used effectively for the treatment of mixed intra-abdominal and pelvic infections.

**Tazobactam** is a β-lactamase inhibitor with good activity against many of the plasmid β-lactamases, including some of the extended-spectrum class. It is combined with piperacillin as a parenteral preparation (ZOSYN) that should be equivalent in antimicrobial spectrum to ticarcillin plus clavulanate.
chapter 54
Aminoglycosides

Aminoglycosides \((\text{gentamicin, tobramycin, amikacin, netilmicin, kanamycin, streptomycin, paromomycin, and neomycin})\) are used primarily to treat infections caused by aerobic gram-negative bacteria. Streptomycin is an important agent for the treatment of tuberculosis, and paromomycin is used orally for intestinal amebiasis and in the management of hepatic coma. Aminoglycosides are \textit{bactericidal inhibitors} of protein synthesis. Mutations affecting proteins in the bacterial ribosome can confer marked resistance to their action. Most commonly resistance is due to acquisition of plasmids or transposon-encoding genes for aminoglycoside-metabolizing enzymes or from impaired transport of drug into the cell. Thus, there can be cross-resistance between members of the class.

Aminoglycosides are natural products or semisynthetic derivatives of compounds produced by a variety of soil actinomycetes. Amikacin, a derivative of kanamycin, and netilmicin, a derivative of sisomicin, are semisynthetic products. These agents contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (\textbf{Figure 54–1}). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in cerebrospinal fluid (CSF), and all are excreted relatively rapidly by the normal kidney. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.
Figure 54–1 Sites of activity of various plasmid-mediated enzymes capable of inactivating aminoglycosides. The red X indicates regions of the molecules that are protected from the designated enzyme. In gentamicin C₁, R₁R₂CH₃; in gentamicin C₂, R₁CH₃, R₂H; in gentamicin C₁a, R₁R₂H. (Reproduced with permission from Moellering RC Jr. Microbiological considerations in the use of tobramycin and related aninoglycosidic aminocyclitol antibiotics. Med J Aust, 1977;2S:4–8. Copyright 1977. The Medical Journal of Australia.)

GENERAL PROPERTIES
MECHANISM OF ACTION. The aminoglycoside antibiotics are
rapidly bactericidal. Bacterial killing is concentration dependent: the higher the concentration, the greater the rate of bacterial killing. The bactericidal activity persists after the serum concentration has fallen below the *minimum inhibitory concentration* (MIC). These properties probably account for the efficacy of high-dose, extended-interval dosing regimens.

Aminoglycosides diffuse through aqueous channels formed by *porin* proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on a transmembrane electrical gradient coupled to electron transport to drive permeation of these antibiotics. This energy-dependent phase is rate-limiting and can be blocked or inhibited by divalent cations (e.g., Ca$^{2+}$ and Mg$^{2+}$), hyperosmolarity, a reduction in pH, and anaerobic conditions. Thus, the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess and in hyperosmolar acidic urine.

Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination of mRNA translation ([Figure 54–2](#)). The primary intracellular site of action of the aminoglycosides is the 30S ribosomal subunit. At least 3 of these ribosomal proteins, and perhaps the 16S ribosomal RNA as well, contribute to the streptomycin-binding site. Aminoglycosides interfere with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes; the drugs also can cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains. The resulting aberrant proteins may be inserted into the cell membrane, leading to altered permeability and further stimulation of aminoglycoside transport.
**Figure 54–2 Effects of aminoglycosides on protein synthesis.**

A. Aminoglycoside (represented by red circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S-50S ribosomal complex at the start codon (AUG) of mRNA. As 30S-50S complexes downstream complete translation of mRNA and detach, the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to B, premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or C, incorporation of incorrect amino acids (indicated by the red X), resulting in the production of abnormal or nonfunctional proteins.

**MICROBIAL RESISTANCE TO THE AMINOGLYCOSIDES.**

Bacteria may be resistant to aminoglycosides because of:

- Inactivation of the drug by microbial enzymes
- Failure of the antibiotic to penetrate intracellularly
- Low affinity of the drug for the bacterial ribosome

Clinically, drug inactivation is the most common mechanism for acquired microbial resistance. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids (see Chapter 48). These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (see Figure 54–1). Amikacin is a suitable substrate for only a few of these inactivating enzymes (see Figure 54–1); thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to amikacin. However, a significant percentage of clinical isolates of *Enterococcus faecalis*...
and *E. faecium* are highly resistant to all aminoglycosides. Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures of streptomycin and other aminoglycosides, this enzyme does not modify streptomycin, which is inactivated by another enzyme; consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Transport of aminoglycosides across the cytoplasmic membrane is an active process that depends on oxidative metabolism. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

Missense mutations in *Escherichia coli* that substitute a single amino acid in a crucial ribosomal protein may prevent binding of streptomycin. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, 5% of strains of *Pseudomonas aeruginosa* exhibit such ribosomal resistance to streptomycin. Because ribosomal resistance usually is specific for streptomycin, these strains of enterococci remain sensitive to a combination of penicillin and gentamicin in vitro.

**ANTIBACTERIAL SPECTRUM OF THE AMINOGLYCOSIDES.** The antibacterial activity of gentamicin, tobramycin, kanamycin, netilmicin, and amikacin is directed primarily against aerobic gram-negative bacilli. Kanamycin, like streptomycin, has a more limited spectrum. The aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides (see Table 54–1).

### Table 54–1

*Typical Minimal Inhibitory Concentrations of Aminoglycosides That Will Inhibit 90% (MIC$_{90}$) of Clinical Isolates for Several Species*
Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. Their action against most gram-positive bacteria is limited, and they should not be used as single agents to treat infections caused by gram-positive bacteria. In combination with a cell wall–active agent, such as a penicillin or vancomycin, an aminoglycoside produces a synergistic bactericidal effect in vitro. Clinically, the superiority of aminoglycoside combination regimens over β-lactams alone is not proven except in relatively few infections (discussed later).

**ADME AND DOSING**

**ABSORPTION.** The aminoglycosides are polar cations and therefore are poorly absorbed from the GI tract. Less than 1% of a dose is absorbed after either oral or rectal administration. The drugs are eliminated quantitatively in the feces. Nonetheless, long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of gentamicin from the GI tract may be increased by GI disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into
body cavities with serosal surfaces also may result in rapid absorption and unexpected toxicity (i.e., neuromuscular blockade). Intoxication may occur when aminoglycosides are applied topically for long periods to large wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency.

All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30-90 min. These concentrations range from 4-12 μg/mL following a 1.5-2 mg/kg dose of gentamicin, tobramycin, or netilmicin and from 20-35 μg/mL following a 7.5 mg/kg dose of amikacin or kanamycin. There is increasing use of aminoglycosides administered via inhalation, primarily for the management of patients with cystic fibrosis who have chronic P. aeruginosa pulmonary infections. Amikacin and tobramycin solutions for injection have been used, as well as a commercial formulation of tobramycin designed for inhalation (TOBI, others).

**DISTRIBUTION.** Because of their polar nature, the aminoglycosides do not penetrate into most cells, the CNS, or the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid. The aminoglycosides distribute poorly into adipose tissue, which must be considered when using weight-based dosing regimens in obese patients.

Concentrations of aminoglycosides in secretions and tissues are low. High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contribute to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities. Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic. Treatment of meningitis
with intravenous administration is generally suboptimal. Intrathecal or intraventricular administration of aminoglycosides has been used to achieve therapeutic levels, but the availability of third- and fourth-generation cephalosporins has generally made this unnecessary.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; therefore, these agents should be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.

**ELIMINATION.** The aminoglycosides are excreted almost entirely by glomerular filtration, achieving urine concentrations of 50-200 μg/mL. The half-lives of the aminoglycosides in plasma are 2-3 h in patients with normal renal function. Because the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the \( t_{1/2} \) of all aminoglycosides in patients with moderately compromised renal function. Because the incidence of nephrotoxicity and ototoxicity is likely related to the overall drug exposure to aminoglycosides, it is critical to reduce the maintenance dosage of these drugs in patients with impaired renal function.

Although excretion of aminoglycosides is similar in adults and children >6 months of age, half-lives of aminoglycosides may be prolonged significantly in the newborn: 8-11 h in the first week of life in newborns weighing <2 kg and ~5 h in those weighing >2 kg. Thus, it is critically important to monitor plasma concentrations of aminoglycosides during treatment of neonates. Aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis. Larger doses of aminoglycosides may likewise be required in burn patients because of more rapid drug clearance, possibly because of drug loss through burn tissue. Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis.
Aminoglycosides can be inactivated by various penicillins in vitro and thus should not be admixed in solution. Some reports indicate that this inactivation may occur in vivo in patients with end-stage renal failure, making monitoring of aminoglycoside plasma concentrations even more necessary in such patients. Amikacin appears to be the aminoglycoside least affected by this interaction; penicillins with more nonrenal elimination (such as piperacillin) may be less prone to cause this interaction.

**DOSING.** High-dose, extended-interval administration of aminoglycosides is the preferred means of administering aminoglycosides for most indications and patient populations. Administering once daily higher doses at extended intervals is likely to be at least equally efficacious and potentially less toxic than administration of divided doses. Because of the post-antibiotic effect of aminoglycosides, good therapeutic response can be attained even when concentrations of aminoglycosides fall below inhibitory concentrations for a substantial fraction of the dosing interval. High-dose, extended-interval dosing schemes for aminoglycosides may also reduce the characteristic oto- and nephro-toxicity of these drugs. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. High-dose, extended-interval regimens, despite the higher peak concentration, provide a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (compare the 2 dosage regimens shown in Figure 54–3).
Figure 54–3 Comparison of single dose and divided dose regimens for gentamicin. In a hypothetical patient, a dose of gentamicin (5.1 mg/kg) is administered intravenously as a single bolus (red line) or in 3 portions, a third of the dose every 8 h (purple line), such that the total drug administered is the same in the 2 cases. The threshold for toxicity (green dashed line) is the plasma concentration of 2 μg/mL, the maximum recommended for prolonged exposure. The single-dose regimen produces a higher plasma concentration than the every-8-h regimen; this higher peak provides efficacy that otherwise might be compromised due to prolonged sub-threshold concentrations later in the dosing interval or that is provided by the lower peak levels achieved with the every-8-h regimen. The once-daily regimen also provides a 13-h period during which plasma concentrations are below the threshold for toxicity. The every-8-h regimen, by contrast, provides only 3 short (~1 h) periods in 24 h during which plasma concentrations are below the threshold for toxicity. The single high-dose, extended interval is generally preferred for aminoglycosides, with a few exceptions (during pregnancy, in neonates, etc.), as noted in the text. On the other hand, a divided-dose regimen can be useful for maximizing the time above a threshold (e.g., MIC) for some antibiotics (see Figure 48–4).

Exceptions to the high-dose/extended-interval dosing include pregnancy, neonates, and in pediatric infections, and combination therapy for endocarditis. In these infections, multiple daily doses (with a lower total daily dose) are preferred because data documenting equivalent safety and efficacy of extended-
interval dosing are inadequate. Extended-interval dosing should also be avoided in patients with significant renal dysfunction (i.e., creatinine clearance <25 mL/min). Aminoglycoside doses must be adjusted for patients with creatinine clearances of <80 mL/min (Table 54–2), and plasma concentrations must be monitored. Concentrations of aminoglycosides achieved in plasma after a given dose vary widely among patients.

*The maximum adult daily dose for amikacin, kanamycin, and streptomycin is 15 mg/kg; for gentamicin and tobramycin, 5.5 mg/kg; and for netilmicin, 6.5 mg/kg.

For twice- or thrice-daily dosing regimens, both peak and trough plasma concentrations are determined. The peak concentration documents that the dose produces therapeutic concentrations, while the trough concentration is used to avoid toxicity. Trough concentrations should be <1-2 μg/mL for gentamicin, netilmicin, and tobramycin and <10 μg/mL for amikacin and streptomycin. Monitoring of aminoglycoside plasma concentrations also is important when using an extended-interval dosing regimen. The most accurate method for monitoring plasma levels for dose adjustment is to measure the concentration in 2 plasma samples drawn several hours apart (e.g., at 2 and 12 h after a dose). The clearance then can be calculated and the dose adjusted to achieve the desired target range.

UNTOWARD EFFECTS. All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity.
OTOTOXICITY. Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides, and ototoxicity may become a dose-limiting adverse effect. Aminoglycoside-induced ototoxicity results in irreversible, bilateral high-frequency hearing loss and temporary vestibular hypofunction. Degeneration of hair cells and neurons in the cochlea correlates with the loss of hearing. Accumulation within the perilymph and endolymph occurs predominantly when aminoglycoside concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are 5 to 6 times longer in the otic fluids than in plasma. Drugs such as ethacrynic acid and furosemide potentiate the ototoxic effects of the aminoglycosides in animals, but data from humans implicating furosemide are less convincing. Streptomycin and gentamicin produce predominantly vestibular effects, whereas amikacin, kanamycin, and neomycin primarily affect auditory function; tobramycin affects both equally. The incidence of ototoxicity is difficult to determine. Audiometric data suggest that the incidence could be as high as 25%. The incidence of vestibular toxicity is particularly high in patients receiving streptomycin; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage. Because the initial symptoms may be reversible, patients receiving high doses and/or prolonged courses of aminoglycosides should be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued.

Clinical Symptoms of Cochlear Toxicity. A high-pitched tinnitus often is the first symptom of toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Because perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected except by careful audiometric examination. If the hearing loss progresses, the lower sound ranges
are affected.

Clinical Symptoms of Vestibular Toxicity. Moderately intense headache lasting 1-2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1-2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement (“mental past-pointing”), and difficulty in sitting or standing without visual cues. The acute stage ends suddenly and is followed by chronic labyrinthitis, in which, the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for ~2 months. Recovery from this phase may require 12-18 months, and most patients have some permanent residual damage. Early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

Nephrotoxicity. Approximately 8-26% of patients who receive an aminoglycoside for several days develop mild renal impairment that is almost always reversible. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells. The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border followed by mild proteinuria, and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days. The non-oliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity of the collecting-duct epithelium to vasopressin. Although severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate. Toxicity correlates with the total amount of drug administered and with longer courses of therapy. High-dose, extended-interval dosing approaches lead to less nephrotoxicity at the same level of total drug exposure (as measured by area under the curve) than divided-dose approaches (see Figure 54–3). Neomycin, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. Streptomycin does not concentrate in the renal cortex and is the least nephrotoxic. Drugs such as amphotericin B, vancomycin, angiotensin-converting enzyme inhibitors, cisplatin, and cyclosporine may potentiate aminoglycoside-induced nephrotoxicity.
NEUROMUSCULAR BLOCKADE. Acute neuromuscular blockade and apnea have been attributed to the aminoglycosides; patients with myasthenia gravis are particularly susceptible. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even oral administration of these agents. Neuromuscular blockade may be reversed by intravenous administration of a Ca\(^+\) salt.

OTHER UNTOWARD EFFECTS. In general, the aminoglycosides have little allergenic potential. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported as cross-hypersensitivity among drugs in this class.

THERAPEUTIC USES OF AMINOGLYCOSIDES

Gentamicin is an important agent for the treatment of many serious gram-negative bacillary infections. It is the aminoglycoside of first choice because of its lower cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin preparations are available for parenteral, ophthalmic, and topical administration. Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for the treatment of most of the following infections. For most indications, gentamicin is preferred because of long experience with its use and its lower cost. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less toxic agent is contraindicated or less effective.

Aminoglycosides frequently are used in combination with a cell wall–active agent (β-lactam or glycopeptide) for the therapy of serious proven or suspected bacterial infections. The 3 rationales for this approach are: to expand the empiric spectrum of activity of the antimicrobial regimen; to provide synergistic bacterial killing; and to prevent the emergence of resistance to the individual agents.
Combination therapy is used in infections such as healthcare-associated pneumonia or sepsis, where multidrug-resistant gram-negative organisms such as *P. aeruginosa, Enterobacter, Klebsiella,* and *Serratia* may be causative and the consequences of failing to provide initially active therapy are dire. The use of aminoglycosides to achieve synergistic bacterial killing and improve clinical response is most well established for the treatment of endocarditis due to gram-positive organisms, most importantly *Enterococcus.* Clinical data do not support the use of combination therapy for synergistic killing of gram-negative organisms, with the possible exceptions of serious *P. aeruginosa* infections.

**GENTAMICIN**

**DOSING.** The typical recommended intramuscular or intravenous dose of gentamicin sulfate when used for the treatment of known or suspected gram-negative organisms as a single agent or in combination therapy for adults with normal renal function is 5-7 mg/kg daily given over 30-60 min. For patients with renal dysfunction, the interval may be extended. For patients who are not candidates for extended-interval dosing, a loading dose of 2 mg/kg and then 3-5 mg/kg per day, one-third given every 8 h is recommended. Dosages at the upper end of this range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, patients with cystic fibrosis, and others in whom drug clearance is more rapid or volume of distribution is larger than normal. Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns <35 weeks of gestation; 4 mg/kg once daily for newborns >35 weeks of gestation; 5 mg/kg daily in 2 divided doses for neonates with severe infections; and 2-2.5 mg/kg every 8 h for children up to 2 years of age. Peak plasma concentrations range from 4-10 μg/mL (dosing: 1.7 mg/kg every 8 h) and 16-24 μg/mL (dosing: 5.1 mg/kg once daily). It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of the plasma concentration of aminoglycosides are recommended strongly.

**THERAPEUTIC USES**
Urinary Tract Infections. Aminoglycosides usually are not indicated for the treatment of uncomplicated urinary tract infections, although a single intramuscular dose of gentamicin (5 mg/kg) has been effective in uncomplicated infections of the lower urinary tract. However, as strains of E. coli have acquired resistance to β-lactams, trimethoprim-sulfamethoxazole, and fluoroquinolones, use of aminoglycosides may increase. Once the microorganism is isolated and its sensitivities to antibiotics are determined, the aminoglycoside should be discontinued if the infecting microorganism is sensitive to less toxic antibiotics.

Pneumonia. The organisms that cause community-acquired pneumonia are susceptible to broad-spectrum β-lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Aminoglycosides are ineffective for the treatment of pneumonia due to anaerobes or S. pneumoniae, which are common causes of community-acquired pneumonia. They should not be considered as effective single-drug therapy for any aerobic gram-positive cocci (including Staphylococcus aureus or streptococci), the microorganisms commonly responsible for suppurative pneumonia or lung abscess. An amino-glycoside in combination with a β-lactam antibiotic is recommended as standard therapy for hospital-acquired pneumonia in which a multiple-drug-resistant gram-negative aerobe is a likely causative agent. Once it is established that the β-lactam is active against the causative agent, there is generally no benefit from continuing the aminoglycoside.

Meningitis. Availability of third-generation cephalosporins, especially cefotaxime and ceftriaxone, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms resistant to β-lactam antibiotics (e.g., species of Pseudomonas and Acinetobacter). If an aminoglycoside is necessary, in adults, 5 mg of a preservative-free formulation of gentamicin (or equivalent dose of another aminoglycoside) is administered directly intrathecally or intraventricularly once daily.

Peritonitis Associated with Peritoneal Dialysis. Patients who develop
peritonitis as a result of peritoneal dialysis may be treated with aminoglycoside diluted into the dialysis fluid to a concentration of 4-8 mg/L for gentamicin, netilmicin, or tobramycin or 6-12 mg/L for amikacin. Intravenous or intramuscular administration of drug is unnecessary because serum and peritoneal fluid will equilibrate rapidly.

**Bacterial Endocarditis.** “Synergistic” or low-dose gentamicin (3 mg/kg/day in 3 divided doses) in combination with a penicillin or vancomycin has been recommended in certain circumstances for treatment of infections due to gram-positive organisms, primarily bacterial endocarditis. Penicillin and gentamicin in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. In cases of enterococcal endocarditis, concomitant administration of penicillin and gentamicin for 4-6 weeks is recommended. A 2-week regimen of gentamicin or tobramycin in combination with nafcillin is effective for the treatment of selected cases of staphylococcal tricuspid native-valve endocarditis. For patients with native mitral or aortic valve staphylococcal endocarditis, the risks of aminoglycoside administration likely outweigh the benefits.

**Sepsis.** Inclusion of an aminoglycoside in an empirical regimen is commonly recommended for the febrile patient with granulocytopenia and for sepsis when *P. aeruginosa* is a potential pathogen. More recent studies using potent broad-spectrum β-lactams (e.g., carbapenems and anti-pseudomonal cephalosporins) have demonstrated no benefit from adding an aminoglycoside to the regimen unless there is concern that an infection may be caused by a multiple-drug-resistant organism.

**Topical Applications.** Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface, as may be the case in burn patients, plasma
concentrations can reach 4 μg/mL, and 2-5% of the drug may appear in the urine.

**UNTOWARD EFFECTS.** The most important and serious side effects of the use of gentamicin are nephrotoxicity and irreversible ototoxicity. Intrathecal or intraventricular administration is used rarely because it may cause local inflammation.

**TOBRAMYCIN**

The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin are similar to those of gentamicin. Tobramycin may be given either intramuscularly, intravenously, or by inhalation. Tobramycin (TOBREX, others) also is available in ophthalmic ointments and solutions. Indications for the use of tobramycin are the same as those for gentamicin. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections known or suspected to be caused by this organism. Tobramycin usually is used with an anti-pseudomonal β-lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against many strains of enterococci. Most strains of *E. faecium* are highly resistant. Tobramycin is ineffective against mycobacteria. Dosages and serum concentrations are identical to those for gentamicin.

**AMIKACIN**

The spectrum of antimicrobial activity of amikacin is the broadest of the group. Because of its resistance to many of the aminoglycoside-inactivating enzymes, amikacin has a special role for the initial treatment of serious nosocomial gram-negative bacillary infections in hospitals where resistance to gentamicin and tobramycin has become a significant problem. Amikacin is active against most strains of *Serratia, Proteus*, and *P. aeruginosa* as well as most strains of *Klebsiella, Enterobacter*, and *E. coli* that are resistant to gentamicin
and tobramycin. Most resistance to amikacin is found among strains of Acinetobacter, Providencia, and Flavobacterium and strains of Pseudomonas other than P. aeruginosa; these all are unusual pathogens. Amikacin is less active than gentamicin against enterococci and should not be used for this organism. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against Mycobacterium tuberculosis, including streptomycin-resistant strains and atypical mycobacteria.

The recommended dose of amikacin is 15 mg/kg/day as a single daily dose or divided into 2 or 3 equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection, and peak concentrations in plasma approximate 20 μg/mL after injection of 7.5 mg/kg. The concentration 12 h after a 7.5 mg/kg dose is 5-10 μg/mL. A 15 mg/kg once-daily dose produces peak concentrations 50-60 μg/mL and a trough of <1 μg/mL. For treatment of mycobacterial infections, thrice-weekly dosing schedules are used, with doses up to 25 mg/kg. As with the other aminoglycosides, amikacin causes ototoxicity, hearing loss, and nephrotoxicity.

**NETILMICIN**

Netilmicin is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage. Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by most of the aminoglycoside-inactivating enzymes; thus, it may be active against certain bacteria that are resistant to gentamicin (with the exception of resistant enterococci). Netilmicin is useful for the treatment of serious infections owing to susceptible Enterobacteriaceae and other aerobic gram-negative bacilli. The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5-2 mg/kg every 12 h. For other serious systemic infections, a total daily dose of 4-7 mg/kg is administered as
a single dose or 2 to 3 divided doses. Children should receive 3-7 mg/kg/day in 2 to 3 divided doses; neonates receive 3.5-5 mg/kg/day as a single daily dose. The $t_{1/2}$ for elimination is usually 2–2.5 h in adults and increases with renal insufficiency. Netilmicin may produce ototoxicity and nephrotoxicity.

**STREPTOMYCIN**

Streptomycin is used for the treatment of certain unusual infections generally in combination with other antimicrobial agents. It generally is less active than other members of the class against aerobic gram-negative rods.

**THERAPEUTIC USES**

*Bacterial Endocarditis.* The combination of penicillin G (bacteriostatic against enterococci) and streptomycin is effective as bactericidal therapy for enterococcal endocarditis. Gentamicin is generally preferred for its lesser toxicity; also, gentamicin should be used when the strain of enterococcus is resistant to streptomycin (MIC $>2$ mg/mL). Streptomycin should be used instead of gentamicin when the strain is resistant to the latter and has demonstrable susceptibility to streptomycin, which may occur because the enzymes that inactivate these 2 aminoglycosides are different.

Streptomycin may be administered by deep intramuscular injection or intravenously. Intramuscular injection may be painful, with a hot tender mass developing at the site of injection. The dose of streptomycin is 15 mg/kg/day for patients with creatinine clearances $>80$ mL/min. It typically is administered as a 1000-mg single daily dose for tuberculosis or 500 mg twice daily, resulting in peak serum concentrations of $\sim50-60$ and 15-30 μg/mL and trough concentrations of $<1$ and 5-10 μg/mL, respectively. The total daily dose should be reduced in direct proportion to the reduction in creatinine clearance for creatinine clearances $>30$ mL/min (see Table 54–2).

*Tularemia.* Streptomycin (or gentamicin) is the drug of choice for the treatment
of tularemia. Most cases respond to the administration of 1-2 g (15-25 mg/kg) streptomycin per day (in divided doses) for 10-14 days.

**Plague.** Streptomycin is effective agent for the treatment of all forms of plague. The recommended dose is 2 g/day in 2 divided doses for 10 days. Gentamicin is probably as efficacious.

**Tuberculosis.** Streptomycin is a second-line agent for the treatment of active tuberculosis, and streptomycin always should be used in combination with at least 1 or 2 other drugs to which the causative strain is susceptible. The dose for patients with normal renal function is 15 mg/kg/day as a single intramuscular injection for 2-3 months and then 2 or 3 times a week thereafter.

**UNTOWARD EFFECTS.** Streptomycin has been replaced by gentamicin for most indications because the toxicity of gentamicin is primarily renal and reversible, whereas that of streptomycin is vestibular and irreversible. The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot. Among the less common toxic reactions to streptomycin is peripheral neuritis.

**NEOMYCIN**

Neomycin is a broad-spectrum antibiotic. Susceptible microorganisms usually are inhibited by concentrations of ≤10 μg/mL. Gram-negative species that are highly sensitive are *E. coli, Enterobacter aerogenes, Klebsiella pneumoniae*, and *Proteus vulgaris*. Gram-positive microorganisms that are inhibited include *S. aureus* and *E. faecalis*. *M. tuberculosis* also is sensitive to neomycin. Strains of *P. aeruginosa* are resistant to neomycin. Neomycin sulfate is available for topical and oral administration. Neomycin currently is available in many brands of creams, ointments, and other products alone and in combination with polymyxin, bacitracin, other antibiotics, and a variety of corticosteroids. There is no evidence that these topical preparations shorten the time required for wound healing or that those containing a steroid are more effective.
THERAPEUTIC USES. Neomycin is used widely for topical application in a variety of infections of the skin and mucous. The oral administration of neomycin (usually in combination with erythromycin base) has been employed primarily for “preparation” of the bowel for surgery. Neomycin and polymyxin B have been used for irrigation of the bladder to prevent bacteriuria and bacteremia associated with indwelling catheters. For this purpose, 1 mL of a preparation (NEOSPORIN G.U. IRRIGANT) containing 40 mg neomycin and 200,000 units polymyxin B per milliliter is diluted in 1 L of 0.9% sodium chloride solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The bladder is irrigated at the rate of 1 L every 24 h.

ABSORPTION AND EXCRETION. Neomycin is poorly absorbed from the GI tract and is excreted by the kidney. A total daily intake of 10 g for 3 days yields a blood concentration below that associated with systemic toxicity if renal function is normal. About 97% of an oral dose of neomycin is not absorbed and is eliminated unchanged in the feces.

UNTOWARD EFFECTS. Hypersensitivity reactions, primarily skin rashes, occur in 6-8% of patients when neomycin is applied topically. The most important toxic effects of neomycin are ototoxicity and nephrotoxicity; as a consequence, the drug is no longer available for parenteral administration. Neuromuscular blockade with respiratory paralysis also has occurred after irrigation of wounds or serosal cavities. Individuals treated with 4-6 g/day of the drug by mouth sometimes develop a sprue-like syndrome with diarrhea, steatorrhea, and azotorrhea. Overgrowth of yeasts in the intestine also may occur.

KANAMYCIN

Kanamycin is among the most toxic aminoglycosides and there are few indications for its use. It has no therapeutic advantage over streptomycin or amikacin and probably is more toxic; either should be used instead, depending on susceptibility of the isolate.
The antimicrobial agents discussed in this chapter may be grouped as:

- **Bacteriostatic protein-synthesis inhibitors that target the ribosome**, such as tetracyclines and glycylcyclines, chloramphenicol, macrolides and ketolides, lincosamides (clindamycin), streptogramins (quinupristin/dalfopristin), oxazolidinones (linezolid), and aminocyclitols (spectinomycin).

- **Agentsacting on the cell wall or cell membrane** such as polymyxins, glycopeptides (vancomycin and teicoplanin), and lipopeptides (daptomycin).

- **Miscellaneous compounds** acting by diverse mechanisms with limited indications: bacitracin and mupirocin.

**TETRACYCLINES AND GLYCICYLCYCLINES**

The tetracyclines are a series of derivatives of a basic 4-ring structure shown below for doxycycline. Glycylcyclines are tetracycline congeners with substituents that confer broad-spectrum activity and activity against bacteria that are resistant to other antibiotics; the available glycylcycline is tigecycline (TYGACIL).

**MECHANISM OF ACTION.** Tetracyclines and glycylcyclines inhibit bacterial protein synthesis by binding to the 30S bacterial
ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 55–1). These drugs enter gram-negative bacteria by passive diffusion through channels formed by porins in the outer cell membrane and by active transport that pumps tetracyclines across the cytoplasmic membrane.

Figure 55–1 Inhibition of bacterial protein synthesis by tetracyclines. mRNA attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. Tetracyclines bind to the 30S subunit, block tRNA binding to the A site, and thereby inhibit protein synthesis.

ANTIMICROBIAL ACTIVITY. Tetracyclines are bacteriostatic antibiotics with activity against a wide range of aerobic and anaerobic gram-positive and gram-negative bacteria.

Doxycycline, the most important member of the tetracyclines, is a drug of choice for sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections, and is also used for treatment of respiratory tract infections including atypical pneumonia pathogens, and for skin and soft-
tissue infections caused by community strains of methicillin-resistant 
*Staphylococcus aureus* (MRSA), for which minocycline also is effective. 
Glycyclcyclines have activity against bacteria that resistant to the first- and second-generation tetracyclines.

These agents are effective against some microorganisms, such as *Rickettsia*, 
*Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp., 
*Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp., that are resistant to cell-wall-active antimicrobial agents. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenue*. 
Demeclocycline, tetracycline, minocycline, and doxycycline are available in the U.S. for systemic use. Resistance of a bacterial strain to any 1 member of the class may or may not result in cross-resistance to other tetracyclines. Tigecycline is generally active against organisms that are susceptible to tetracyclines as well as those with acquired resistance to tetracyclines.

Tetracyclines intrinsically are more active against gram-positive than gram-negative microorganisms, but acquired resistance is common. Recent data from the U.S. on the activity of tetracycline and other agents are displayed in Table 55–1. *Bacillus anthracis* and *Listeria monocytogenes* are susceptible. 
Doxycycline and minocycline can be active against some tetracycline-resistant isolates. *Haemophilus influenzae* is generally susceptible, but many 
Enterobacteriaceae have acquired resistance. Although all strains of *Pseudomonas aeruginosa* are resistant, 90% of strains of *Burkholderia pseudomallei* (the cause of melioidosis) are sensitive. Most strains of *Brucella* also are susceptible. Tetracyclines remain useful for infections caused by *Haemophilus ducreyi* (chancroid), *Vibrio cholerae*, and *V. vulnificus*, and inhibit the growth of *Legionella pneumophila*, *Campylobacter jejuni*, *Helicobacter pylori*, *Yersinia pestis*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Pasteurella multocida*. The tetracyclines are active against many anaerobic and facultative microorganisms. Tetracycline is a drug of choice for treating actinomycosis.

**Table 55–1**

*Activity of Selected Antimicrobials Against Key Gram-Positive Pathogens*
In general, tigecycline is equally or more active in vitro against bacteria than the tetracyclines, including against tetracycline-resistant organisms, especially gram-negative organisms. There are a few exceptions where other tetracyclines may be more active against certain organisms, such as Stenotrophomonas and Ureaplasma.

**RESISTANCE TO TETRACYCLINES AND GLYCICYCLINES.**
Resistance is primarily plasmid mediated and often inducible. The 3 main resistance mechanisms are:

- Decreased accumulation of tetracycline as a result of either decreased antibiotic influx or acquisition of an energy-dependent efflux pathway
- Production of a ribosomal protection protein that displaces tetracycline from
its target

- Enzymatic inactivation of tetracyclines

Cross-resistance, or lack thereof, among tetracyclines depends on which mechanism is operative. Tetracycline resistance due to a ribosomal protection mechanism (tetM) produces cross-resistance to doxycycline and minocycline because the target site protected is the same for all tetracyclines. The glycylamido moiety characteristic of tigecycline reduces its affinity for most efflux pumps, restoring activity against many organisms displaying tetracycline resistance due to this mechanism. Binding of glycylcyclines to ribosomes is also enhanced, improving activity against organisms that harbor ribosomal protection proteins that confer resistance to other tetracyclines.

ADME

Oral absorption of most tetracyclines is incomplete. The percentage of unabsorbed drug rises as the dose increases. Tigecycline is available only for parenteral administration. Concurrent ingestion of divalent and trivalent cations (e.g., Ca$^{2+}$, Mg$^{2+}$, Al$^{3+}$, Fe$^{2+/3+}$, and Zn$^{2+}$) impairs absorption. Thus, dairy products, antacids, aluminum hydroxide gels; Ca, Mg, and Fe or Zn salts; bismuth subsalicylate (e.g., Pepto-Bismol) and dietary Fe and Zn supplements can interfere with absorption of tetracyclines. After a single oral dose, the peak plasma concentration is attained in 2-4 h. These drugs have half-lives in the range of 6-12 h and frequently are administered 2 to 4 times daily. Demeclocycline also is incompletely absorbed but can be administered in lower daily dosages because its $t_{1/2}$ of 16 h provides effective plasma concentrations for 24-48 h.

Oral doses of doxycycline and minocycline are well absorbed (90-100%) and have half-lives of 16-18 h; they can be administered less frequently and at lower doses than tetracycline or demeclocycline. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally. Food, including dairy products, does not interfere with absorption of doxycycline and minocycline.

Tetracyclines distribute widely throughout the body, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow, and in bone, dentine, and enamel of unerupted teeth. Tigecycline distributes rapidly and extensively into tissues, with an estimated apparent
volume of 7-10 L/kg. Inflammation of the meninges is not required for the passage of tetracyclines into the cerebrospinal fluid. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relatively high concentrations are found in breast milk.

Except for doxycycline, most tetracyclines are eliminated primarily by the kidney, although they also are concentrated in the liver, excreted in bile, and partially reabsorbed via enterohepatic recirculation. Comparable amounts of tetracycline (i.e., 20-60%) are excreted in the urine within 24 h following oral or intravenous administration. Doxycycline is largely excreted unchanged both in the bile and urine, tigecycline is mostly excreted unchanged along with a small amount of glucuronidated metabolites, and minocycline is extensively metabolized by the liver before excretion. Doses of these agents do not require adjustment in patients with renal dysfunction. Specific dosage adjustment recommendations in hepatic disease are available only for tigecycline. There is some evidence for drug interactions between doxycycline and hepatic enzyme-inducing agents such as phenytoin and rifampin, but not for minocycline or tigecycline.

THERAPEUTIC USES AND DOSAGE

The tetracyclines have been used extensively to treat infectious diseases and as an additive to animal feeds to facilitate growth (a use that likely contributes to the development of bacterial resistance). The drugs remain useful as first-line therapy for infections caused by rickettsiae, mycoplasmas, and chlamydiae. The glycylcyclines have restored much of the antibacterial activity lost to the tetracyclines due to resistance and can be used for a number of infections due to gram-positive and gram-negative organisms.

The oral dose of tetracycline ranges from 1-2 g/day in adults. Children >8 years of age should receive 25-50 mg/kg daily in 4 divided doses. The low pH of tetracycline, but not doxycycline or minocycline, invariably causes phlebitis if infused into a peripheral vein. The oral or intravenous dose of doxycycline for adults is 100 mg every 12 h on the first day and then 50 mg every 12 h, 100 mg once a day, or 100 mg twice daily when severe infection is present; for children >8 years of age, the dose is 4-5 mg/kg/day in 2 divided doses the first day, then 2-2.5 mg/kg given once or twice daily. The dose of minocycline for adults is 200 mg orally or intravenously initially, followed by 100 mg every 12 h; for children,
it is 4 mg/kg initially followed by 2 mg/kg every 12 h. Tigecycline is administered intravenously to adults as a 100-mg loading dose, followed by 50 mg every 12 h. For patients with severe hepatic impairment, the loading dose should be followed by a reduced maintenance dose of 25 mg every 12 h. Dosage data are not available for tigecycline in pediatrics.

Tetracyclines should not be administered intramuscularly because of local irritation and poor absorption. GI distress, nausea, and vomiting can be minimized by administration of tetracyclines with food. Generally, oral administration of tetracyclines should occur 2 h before or 2 h after coadministration with any of the agents listed. Cholestyramine and colestipol also bind orally administered tetracyclines and interfere with the absorption of the antibiotic.

**Respiratory Tract Infections.** Doxycycline has good activity against *Streptococcus pneumoniae* and *H. influenzae* and excellent activity against atypical pathogens such as *Mycoplasma* and *Chlamydophilia pneumoniae*. Tigecycline has been demonstrated to be effective for use as a single agent for adults hospitalized with community-acquired bacterial pneumonia.

**Skin and Soft-Tissue Infections.** Tigecycline is approved for the treatment of complicated skin and soft-tissue infections. Low doses of tetracycline have been used to treat acne (250 mg orally twice a day).

**Intra-abdominal Infections.** Resistance among Enterobacteriaceae and gram-negative anaerobes limit the utility of the tetracyclines for intra-abdominal infections. However, tigecycline possesses excellent activity against these pathogens as well as *Enterococcus*.

**GI Infections.** Therapy with the tetracyclines is often ineffective in infections caused by *Shigella, Salmonella*, or other Enterobacteriaceae because of drug-resistant strains. Resistance limits the usefulness of tetracyclines for travelers’ diarrhea. Doxycycline (300 mg as a single dose) is effective in reducing stool volume and eradicating *V. cholerae* from the stool within 48 h. Some strains of *V. cholerae* are resistant to tetracyclines.

**Sexually Transmitted Diseases.** Doxycycline no longer is recommended for gonococcal infections. *Chlamydia trachomatis* often is a coexistent pathogen in
acute pelvic inflammatory disease. Doxycycline, 100 mg intravenously twice daily, is recommended for at least 48 h after substantial clinical improvement, followed by oral therapy at the same dosage to complete a 14-day course. Acute epididymitis is caused by infection with *C. trachomatis* or *Neisseria gonorrhoeae* in men <35 years of age. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline, 100 mg orally twice daily for 10 days. Sexual partners also should be treated. Doxycycline (100 mg twice daily for 21 days) is first-line therapy for treatment of lymphogranuloma venereum. Non-pregnant penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen such as doxycycline, 100 mg orally twice daily for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

**Rickettsial Infections.** Tetracyclines are life-saving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus (Brill disease), murine typhus, scrub typhus, rickettsialpox, and Q fever. Clinical improvement often is evident within 24 h after initiation of therapy. Doxycycline is the drug of choice for treatment of Rocky Mountain spotted fever in adults and in children, including those <9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection.

**Anthrax.** Doxycycline, 100 mg every 12 h (2.2 mg/kg every 12 h for children weighing <45 kg), is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for bioterrorism exposures.

**Local Application.** Except for local use in the eye, topical use of the tetracyclines is not recommended. Minocycline sustained-release microspheres for subgingival administration are used in dentistry.

**Other Infections.** Tetracyclines in combination with rifampin or streptomycin are effective for acute and chronic infections caused by *Brucella melitensis*, *Brucella suis*, and *Brucella abortus*. Although streptomycin is preferable, tetracyclines also are effective in tularemia. Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide
should be used concurrently. Yaws and relapsing fever respond favorably to the tetracyclines. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (*Leptospira* spp.). *Borrelia* spp., including *B. recurrentis* (relapsing fever) and *B. burgdorferi* (Lyme disease), respond to therapy with a tetracycline. The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including *Mycobacterium marinum*.

**UNTOWARD EFFECTS**

**GI.** All tetracyclines can produce GI irritation, most commonly after oral administration. Tolerability can be improved by administering these drugs with food, but tetracyclines should not be taken with dairy products or antacids. Tetracycline has been associated with esophagitis, esophageal ulcers, and pancreatitis. *Pseudomembranous colitis caused by overgrowth of Clostridium difficile* is a potentially life-threatening complication.

**Photosensitivity.** Demeclocycline, doxycycline, and other tetracyclines and glycyclcyclines to a lesser extent may produce photosensitivity reactions in treated individuals exposed to sunlight.

**Hepatic Toxicity.** Hepatic toxicity has developed in patients with renal failure receiving ≥2 g of drug per day parenterally, but this effect also may occur when large quantities are administered orally. Pregnant women are particularly susceptible.

**Renal Toxicity.** Tetracyclines may aggravate azotemia in patients with renal disease because of their catabolic effects. Doxycycline, minocycline, and tigecycline have fewer renal side effects than other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (see Chapter 25). Fanconi syndrome has been observed in patients ingesting outdated tetracycline, presumably due to toxic effects on the proximal renal tubules.

**Effects on Teeth.** Children treated with a tetracycline or glycyclcycline may develop permanent brown discoloration of the teeth. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk is highest when a tetracycline is given to infants before the first dentition but may develop if the drug is given between the ages of 2 months and
5 years when these teeth are being calcified. Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children.

**Other Toxic and Irritative Effects.** Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the period of exposure to the drug is short. Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions. Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura. Tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual therapeutic doses. Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24-48 h after drug cessation. Various skin reactions rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after the oral use. Other hypersensitivity reactions are burning of the eyes, cheilosis, atrophic or hypertrophic glossitis, pruritus ani or vulvae, and vaginitis. Fever of varying degrees and eosinophilia may occur when these agents are administered. Asthma also has been observed. Cross-sensitization among the various tetracyclines is common.

**CHLORAMPHENICOL**

Chloramphenicol can cause serious and fatal blood dyscrasias; consequently, the drug is now reserved for treatment of life-threatening infections in patients who cannot take safer alternatives because of resistance or allergies.

**MECHANISM OF ACTION.** Chloramphenicol inhibits protein synthesis in bacteria, and to a lesser extent, in eukaryotic cells. Chloramphenicol acts primarily by binding reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and clindamycin). The drug prevents the binding of the amino acid—
containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 55–2).

![Diagram of bacterial protein synthesis inhibition by chloramphenicol.](Image)

**Figure 55–2** *Inhibition of bacterial protein synthesis by chloramphenicol.* Chloramphenicol binds to the 50S ribosomal subunit at the peptidyltransferase site, inhibiting transpeptidation. Chloramphenicol binds near the site of action of clindamycin and the macrolide antibiotics. These agents interfere with the binding of chloramphenicol and thus may interfere with each other’s actions if given concurrently. See Figure 55–1 for additional information.

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S); erythropoietic cells are particularly sensitive.

**ANTIMICROBIAL ACTIVITY.** Chloramphenicol is bacteriostatic against most species, although it may be bactericidal against *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*. Many gram-negative bacteria and most anaerobic bacteria are inhibited in vitro. Strains of *S. aureus* tend to be less susceptible. Chloramphenicol is active against *Mycoplasma*, *Chlamydia*, and *Rickettsia*. Enterobacteriaceae are variably sensitive to chloramphenicol. *P. aeruginosa* is resistant to even very high concentrations of chloramphenicol. Strains of *V. cholerae* have remained largely susceptible to chloramphenicol.
Prevalent strains of *Shigella* and *Salmonella* are resistant to multiple drugs, including chloramphenicol.

**RESISTANCE TO CHLORAMPHENICOL.** Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomol mutation.

**ADME.** Chloramphenicol is absorbed rapidly from the GI tract. For parenteral use, chloramphenicol succinate is a prodrug that is hydrolyzed by esterases to chloramphenicol in vivo. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug because as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 h) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF. The drug actually may accumulate in the brain. Chloramphenicol is present in bile, milk, and placental fluid. It also is found in the aqueous humor after subconjunctival injection. Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol are excreted in the urine. Patients with impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted. About 50% of chloramphenicol is bound to plasma proteins; such binding is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. However, if the dose of chloramphenicol has been reduced because of cirrhosis, clearance by hemodialysis may be significant. This effect can be minimized by administering the drug at the end of hemodialysis. Variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

**THERAPEUTIC USES AND DOSAGE.** Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of
the potential toxicities. When other antimicrobial drugs that are equally effective and less toxic are available, they should be used instead of chloramphenicol.

**Typhoid Fever.** Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever. The adult dose of chloramphenicol for typhoid fever is 1 g every 6 h for 4 weeks.

**Bacterial Meningitis.** Chloramphenicol remains an alternative drug for the treatment of meningitis caused by *H. influenzae, N. meningitidis*, and *S. pneumoniae* in patients who have severe allergy to β-lactams and in developing countries. The total daily dose for children should be 50 mg/kg of body weight, divided into 4 equal doses given intravenously every 6 h.

**Rickettsial Diseases.** The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in those with reduced renal function, in pregnant women, and in children <8 years of age who require prolonged or repeated courses of therapy, chloramphenicol may be the drug of choice. Rocky Mountain spotted fever, epidemic, murine, scrub, and recrudescent typhus, and Q fever respond well to chloramphenicol. For adults and children with these diseases, a dosage of 50 mg/kg/day divided into 6-h intervals is recommended. Therapy should be continued until the general condition has improved and is afebrile for 24-48 h.

**UNTOWARD EFFECTS.** Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. Much of the toxicity observed with this drug can be attributed to these effects.

**Hypersensitivity Reactions.** Skin rashes may result from hypersensitivity to chloramphenicol. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after institution of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

**Hematological Toxicity.** Chloramphenicol affects the hematopoietic system in 2 ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia, and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Pancytopenia occurs more
commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than 1 occasion. Although the incidence of the reaction is low, ~1 in ≥30,000 courses of therapy, the fatality rate is high when bone marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for ~70% of cases of blood dyscrasias due to chloramphenicol; hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The proposed mechanism involves conversion of the nitro group to a toxic intermediate by intestinal bacteria.

The risk of aplastic anemia does not contraindicate the use of chloramphenicol in situations in which it may be lifesaving. The drug should never be used, however, in undefined situations or in diseases readily, safely, and effectively treatable with other antimicrobial agents.

Dose-related, reversible erythroid suppression probably reflects an inhibitory action of chloramphenicol on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Bone marrow suppression occurs regularly when plasma concentrations are ≥25 μg/mL and is observed with the use of large doses of chloramphenicol, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop without prior dose-related marrow suppression.

Other Toxic and Irritative Effects. Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow the oral administration of chloramphenicol. Blurring of vision and digital paresthesias may rarely occur. Tissues that have a high rate of oxygen consumption (e.g., heart, brain) may be particularly susceptible to chloramphenicol’s effects on mitochondrial enzymes.

Neonates, especially if premature, may develop a serious illness termed gray baby syndrome if exposed to excessive doses of chloramphenicol. This syndrome usually begins 2-9 days after treatment is started. Within the first 24 h, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose green stools occur. Over the next 24 h, neonates turn an ashen-gray color and become flaccid and hypothermic. A similar “gray syndrome” has been reported in adults who were accidentally overdosed with the drug. Death occurs in ~40% of patients within 2 days of
initial symptoms. Those who recover usually exhibit no sequelae. Two mechanisms apparently are responsible for chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, chloramphenicol concentrations in plasma usually exceed 100 μg/mL, and may be as low as 75 μg/mL. Children ≤2 weeks of age should receive chloramphenicol in a daily dose no larger than 25 mg/kg of body weight; after this age, full-term infants may be given daily quantities up to 50 mg/kg.

**Drug Interactions.** Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of drugs that are metabolized by this system. Severe toxicity and death have occurred because of failure to recognize such effects. Concurrent administration of phenobarbital or rifampin, which potently induce CYPs, shortens the $t_{1/2}$ of the antibiotic and may result in subtherapeutic drug concentrations.

**MACROLIDES AND KETOLIDES**

Macrolides and ketolides are effective for treatment of respiratory tract infections caused by the common pathogens of community-acquired pneumonia. All except azithromycin have important drug interactions because they inhibit hepatic CYPs.

Chapter 55 of the parent text includes a fuller presentation of the structure-activity data of these compounds. *Macrolide antibiotics* contain a multi-membered lactone ring to which are attached 1 or more deoxy sugars. Modest structural modifications (e.g., in clarithromycin and azithromycin) improve acid stability and tissue penetration and broaden the spectrum of activity. *Ketolides* are structurally similar multi-membered ring systems but with different substituents. *Telithromycin* (KETEK) is the only ketolide currently approved in the U.S. Telithromycin differs from erythromycin in that a 3-keto group replaces the α-L-cladinose of the 14-member macrolide ring, and there is a substituted carbamate at C11-C12. These modifications render ketolides less susceptible to methylase-mediated (erm) and efflux-mediated (mef or msr) mechanisms of resistance. Ketolides therefore are active against many macrolide-resistant gram-positive strains.
MECHANISM OF ACTION. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 55–3), at or very near the site that binds chloramphenicol (see Figure 55–2). Erythromycin does not inhibit peptide bond formation per se but rather inhibits the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate ~100 times more erythromycin than do gram-negative bacteria. Ketolides and macrolides have the same ribosomal target site.

Figure 55–3 Inhibition of bacterial protein synthesis by the erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. Erythromycin appears to inhibit the translocation step such that the nascent peptide chain temporarily residing at the A site fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 55–1 for additional information.

ANTIMICROBIAL ACTIVITY. Erythromycin usually is bacteriostatic but
may be bactericidal in high concentrations against susceptible organisms. The antibiotic is most active in vitro against aerobic gram-positive cocci and bacilli (see Table 55–1). Macrolide resistance among S. pneumoniae often co-exists with penicillin resistance. Staphylococci are not reliably sensitive to erythromycin. Macrolide-resistant strains of S. aureus are potentially cross-resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli also are sensitive to erythromycin, including Clostridium perfringens, Corynebacterium diphtheriae, and L. monocytogenes. Erythromycin is inactive against most aerobic enteric gram-negative bacilli. It has modest activity in vitro against H. influenzae and N. meningitidis, and good activity against most strains of N. gonorrhoeae. Useful antibacterial activity also is observed against P. multocida, Borrelia spp., and Bordetella pertussis. Resistance is common for B. fragilis. Macrolides are usually active against C. jejuni. Erythromycin is active against M. pneumoniae and L. pneumophila. Most strains of C. trachomatis are inhibited by erythromycin. Some of the atypical mycobacteria are sensitive to erythromycin in vitro.

Clarithromycin is slightly more potent than erythromycin against sensitive strains of streptococci and staphylococci, and has modest activity against H. influenzae and N. gonorrhoeae. Clarithromycin and azithromycin have good activity against Moraxella catarrhalis, Chlamydia spp., L. pneumophila, B. burgdorferi, M. pneumoniae, and H. pylori. Azithromycin and clarithromycin have enhanced activity against Mycobacterium avium-intracellulare, as well as against some protozoa (e.g., Toxoplasma gondii, Cryptosporidium, and Plasmodium spp.). Clarithromycin has good activity against Mycobacterium leprae. Telithromycin’s spectrum of activity is similar to those of clarithromycin and azithromycin. Telithromycin’s capacity to withstand many macrolide resistance mechanisms increases its activity against macrolide-resistant S. pneumoniae and S. aureus.

RESISTANCE TO MACROLIDES AND KETOLIDES. Resistance to macrolides usually results from 1 of 4 mechanisms:

• Drug efflux by an active pump mechanism
• Ribosomal protection by inducible or constitutive production of methylase enzymes, that modify the ribosomal target and decrease drug binding
• Macrolide hydrolysis by esterases produced by Enterobacteriaceae
• Chromosomal mutations that alter a 50S ribosomal protein (in *Bacillus subtilis, Campylobacter* spp., mycobacteria, and gram-positive cocci)

**ADME**

**Absorption.** Erythromycin base is incompletely but adequately absorbed from the upper small intestine. Because it is inactivated by gastric acid, it is administered as enteric-coated tablets, as capsules containing enteric-coated pellets that dissolve in the duodenum, or as an ester. Food may delay absorption. Esters of erythromycin base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. A single oral 250-mg dose of erythromycin estolate produces peak serum concentrations of ~1.5 μg/mL after 2 h.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but hepatic first-pass metabolism reduces its bioavailability to 50-55%. Peak concentrations occur ~2 h after drug administration. Clarithromycin may be given with or without food, but the extended-release form, typically given once daily as a 1-g dose, should be administered with food to improve bioavailability. Azithromycin administered orally is absorbed rapidly and distributes widely throughout the body, except to the brain and CSF. Azithromycin should not be administered with food. Azithromycin also can be administered intravenously, producing plasma concentrations of 3-4 μg/mL after a 1-h infusion of 500 mg. Telithromycin is formulated as a 400-mg tablet for oral administration. There is no parenteral form. It is well absorbed with ~60% bioavailability. Peak serum concentrations are achieved within 30 min to 4 h.

**Distribution.** Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Concentrations in middle ear exudate may be inadequate for the treatment of otitis media caused by *H. influenzae*. Protein binding is ~70-80% for erythromycin base and even higher for the estolate. Erythromycin traverses the placenta, and drug concentrations in fetal plasma are ~5-20% of those in the maternal circulation. Concentrations in breast milk are 50% of those in serum.

Clarithromycin and its active metabolite, 14-hydroxyclarithromycin, achieve high intracellular concentrations throughout the body, including the middle ear. Azithromycin’s unique pharmacokinetic properties include extensive tissue
distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Telithromycin penetrates well into most tissues, exceeding plasma concentrations by ~2-fold to ≥10-fold. Telithromycin is concentrated into macrophages and white blood cells, where concentrations of 40 μg/mL (500 times the plasma concentration) are maintained 24 h after dosing.

Elimination. Only 2-5% of orally administered erythromycin is excreted in active form in the urine; this value is from 12-15% after intravenous infusion. The antibiotic is concentrated in the liver and excreted in the bile. The serum t1/2 of erythromycin is ~1.6 h. Although the t1/2 may be prolonged in patients with anuria, dosage reduction is not routinely recommended in renal failure patients. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is metabolized in the liver to several metabolites; the active 14-hydroxy metabolite is the most significant. Primary metabolic pathways are oxidative N-demethylation and hydroxylation at the 14 position. The elimination half-lives are 3-7 h for clarithromycin and 5-9 h for 14-hydroxyclarithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics, and longer half-lives with higher dosages. The amount of clarithromycin excreted unchanged in the urine ranges from 20-40%, depending on the dose administered and the formulation (tablet versus oral suspension). An additional 10-15% of a dose is excreted in the urine as 14-hydroxyclarithromycin. Dose adjustment is not necessary unless the creatinine clearance is <30 mL/min.

Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The elimination t1/2, 40-68 h, is prolonged because of extensive tissue sequestration and binding. With a t1/2 of 9.8 h, telithromycin can be given once daily. The drug is cleared primarily by hepatic metabolism, 50% by CYP3A4 and 50% by CYP-independent metabolism. No adjustment of the dose is required for hepatic failure or mild-to-moderate renal failure.

THERAPEUTIC USES AND DOSAGE. The usual oral dose of erythromycin (erythromycin base) for adults ranges from 1-2 g/day, in divided doses, usually
given every 6 h. Daily doses of erythromycin as large as 8 g orally, given for 3 months, have been well tolerated. Food should not be taken concurrently, if possible, with erythromycin base or the stearate formulations, but this is not necessary with erythromycin estolate. The oral dose of erythromycin for children is 30-50 mg/kg/day, divided into 4 portions; this dose may be doubled for severe infections. Intramuscular administration of erythromycin is not recommended because of pain upon injection. Intravenous administration is generally reserved for the therapy of severe infections, such as legionellosis. The usual dose is 0.5-1 g every 6 h; 1 g of erythromycin gluceptate (not available in the U.S.) has been given intravenously every 6 h for as long as 4 weeks with no adverse effects except for local thrombophlebitis. Erythromycin lactobionate is available for intravenous injection. The combination of erythromycin and sulfisoxazole appears to have synergistic antibacterial activity; it is available as a suspension used primarily for treatment of otitis media in children.

Clarithromycin (Biaxin, others) usually is given twice daily at a dose of 250 mg for children >12 years and adults with mild to moderate infection. Larger doses (e.g., 500 mg twice daily) are indicated for more severe infection such as pneumonia or infections caused by more resistant organisms such as H. influenzae. The 500-mg extended-release formulation is given as 2 tablets once daily. Clarithromycin (500 mg) is also packaged with lansoprazole (30 mg) and amoxicillin (1 g) as a combination regimen (Prevpac) that is administered twice daily for 10 or 14 days to eradicate H. pylori.

Azithromycin (Zithromax, other) should be given 1 h before or 2 h after meals when administered orally. For outpatient therapy of community-acquired pneumonia, pharyngitis, or skin and skin-structure infections, a loading dose of 500 mg is given on the first day, and then 250 mg per day is given for days 2 through 5. Treatment or prophylaxis of M. avium-intracellulare infection in AIDS patients requires higher doses: 600 mg daily in combination with 1 or more other agents for treatment, or 1200 mg once weekly for primary prevention. Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated. The treatment of uncomplicated nongonococcal urethritis presumed to be caused by C. trachomatis consists of a single 1-g dose of azithromycin. This dose also is effective for chancroid. Azithromycin (1 g per week for 3 weeks) is an alternative regimen for treatment of granuloma inguinale or lymphogranuloma
venereum. In children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum: 500 mg) and 5 mg/kg (maximum: 250 mg/day) on days 2 through 5. A single 30 mg/kg dose is approved as an alternative for otitis media. The dose for tonsillitis or pharyngitis is 12 mg/kg/day, up to 500 mg total, for 5 days.

**Respiratory Tract Infections.** Macrolides and ketolides are suitable drugs for the treatment of a number of respiratory tract infections. Azithromycin and clarithromycin are suitable choices for treatment of mild to moderate community-acquired pneumonia among ambulatory patients. In hospitalized patients, a macrolide is commonly added to a cephalosporin for coverage of atypical respiratory pathogens. Macrolides, fluoroquinolones, and tetracyclines are drugs of choice for treatment of pneumonia caused by *C. pneumoniae* or *M. pneumoniae*. Erythromycin has been considered as the drug of choice for treatment of pneumonia caused by *L. pneumophila*, *Legionella micdadei*, or other *Legionella* spp. Because of excellent in vitro activity, superior tissue concentration, the ease of administration as a single daily dose, and better tolerability compared to erythromycin, azithromycin (or a fluoroquinolone) has supplanted erythromycin as the first-line agent for treatment of legionellosis. The recommended dose is 500 mg daily, intravenously or orally, for a total of 10-14 days. Macrolides are also appropriate alternative agents for the treatment of acute exacerbations of chronic bronchitis, acute otitis media, acute streptococcal pharyngitis, and acute bacterial sinusitis. Azithromycin or clarithromycin are generally preferred to erythromycin for these indications due to their broader spectrum and superior tolerability.

Telithromycin is effective in the treatment of community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute bacterial sinusitis, and has a potential advantage where macrolide-resistant strains are common. Due to a number of cases of severe hepatotoxicity, the drug’s FDA approval is limited to community-acquired pneumonia; *telithromycin should be used only in circumstances where it provides a substantial advantage over less toxic therapies.*

**Skin and Soft-Tissue Infections.** Macrolides are alternatives for treatment of erysipelas and cellulitis among patients who have a serious allergy to penicillin. Erythromycin has been an alternative agent for the treatment of relatively minor skin and soft-tissue infections caused by either penicillin-sensitive or penicillin-
resistant *S. aureus*. However, many strains of *S. aureus* are resistant to macrolides.

**Chlamydial Infections.** Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. During pregnancy, erythromycin base, 500 mg 4 times daily for 7 days, is recommended as first-line therapy for chlamydial urogenital infections. Azithromycin, 1 g orally as a single dose, is a suitable alternative. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg/day in 4 divided doses for 10-14 days). Azithromycin, 1 g/week for 3 weeks, may be effective for lymphogranuloma venereum.

**Diphtheria.** Erythromycin, 250 mg 4 times daily for 7 days, is very effective for acute infections or for eradicating the carrier state. Other macrolides are not FDA-approved for this indication. Antibiotics do not alter the course of an acute infection with diphtheria or decrease the risk of complications. Antitoxin is indicated in the treatment of acute infection.

**Pertussis.** Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. A 7-day regimen of erythromycin estolate (40 mg/kg/day; maximum: 1 g/day; not available in U.S.) is effective. Clarithromycin and azithromycin also are effective. If administered early in the course of whooping cough, erythromycin may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with erythromycin therapy because resistance has been reported.

**Campylobacter Infections.** Fluoroquinolones have largely has replaced erythromycin for this disease in adults. Erythromycin remains useful for treatment of *Campylobacter* gastroenteritis in children.

**Helicobacter pylori Infection.** Clarithromycin, 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g (*PREVPAC*), each administered twice daily for 10-14 days, is effective for treatment of peptic ulcer disease caused by *H. pylori*. 
**Mycobacterial Infections.** Clarithromycin or azithromycin is recommended as first-line therapy for prophylaxis and treatment of disseminated infection caused by *M. avium-intracellulare* in AIDS patients and for treatment of pulmonary disease in patients not infected with HIV. Azithromycin (1.2 g once weekly) or clarithromycin (500 mg twice daily) is recommended for primary prevention for AIDS patients with <50 CD4 cells/mm³. Single-agent therapy should not be used for treatment of active disease or for secondary prevention in AIDS patients. Clarithromycin (500 mg twice daily) plus ethambutol (15 mg/kg once daily) with or without rifabutin is an effective combination regimen. Clarithromycin also has been used with minocycline for the treatment of *M. leprae* in lepromatous leprosy.

**Prophylactic Uses.** Erythromycin is an effective alternative for the prophylaxis of recurrences of rheumatic fever in individuals who are allergic to penicillin. Clarithromycin or azithromycin (or clindamycin) are recommended alternatives for the prevention of bacterial endocarditis in patients undergoing dental procedures.

**UNTOWARD EFFECTS**

**Hepatotoxicity.** Cholestatic hepatitis is the most striking side effect. It is caused primarily by erythromycin estolate and rarely by the ethylsuccinate or the stearate. The illness starts after 10-20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Findings usually resolve within a few days after cessation of drug therapy. Hepatotoxicity has also been observed with clarithromycin and azithromycin, although at a lower rate than with erythromycin. Telithromycin may induce severe hepatotoxicity and should only be used in circumstances where it represents a clear advantage over alternative agents.

**GI Toxicity.** Oral administration of erythromycin, frequently is accompanied by epigastric distress, which may be quite severe. Intravenous administration of erythromycin may cause similar symptoms. Erythromycin stimulates GI motility by acting on motilin receptors (see Chapter 46). The GI symptoms are dose related and occur more commonly in children and young adults; they may be reduced by prolonging the infusion time to 1 h or by pretreatment with
glycopyrrolate. Intravenous infusion of 1-g doses, even when dissolved in a large volume, often is followed by thrombophlebitis. This can be minimized by slow rates of infusion. Clarithromycin, azithromycin, and telithromycin also may cause GI distress, but to a lesser degree than erythromycin.

**Cardiac Toxicity.** Erythromycin, clarithromycin, and telithromycin have been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. Most patients have had underlying risk factors or were receiving anti-arrhythmics or other agents that prolong QTc.

**Other Toxic and Irritative Effects.** Allergic reactions observed are fever, eosinophilia, and skin eruptions, which disappear shortly after therapy is stopped. Transient auditory impairment with erythromycin has been observed. Visual disturbances due to slowed accommodation have been reported following telithromycin. Telithromycin is contraindicated in patients with myasthenia gravis due to exacerbation of neurological symptoms. Loss of consciousness has been associated with telithromycin.

**Drug Interactions.** Erythromycin, clarithromycin, and telithromycin inhibit CYP3A4 and cause significant drug interactions. Erythromycin and clarithromycin potentiate the effects of carbamazepine, corticosteroids, cyclosporine, digoxin, ergot alkaloids, theophylline, triazolam, valproate, and warfarin, probably by interfering with CYP-mediated metabolism of these drugs (see Chapter 6). Telithromycin is both a substrate and a strong inhibitor of CYP3A4. Coadministration of rifampin, a potent inducer of CYP, decreases the serum concentrations of telithromycin by 80%. CYP3A4 inhibitors (e.g., itraconazole) increase peak serum concentrations of telithromycin. Azithromycin and dirithromycin appear to be free of these drug interactions; however, caution is advised.

**LINCOSAMIDES (CLINDAMYCIN)**

Clindamycin is a congener of lincomycin. Clindamycin principally is used to treat anaerobic infections.

**ANTIMICROBIAL ACTIVITY.** Clindamycin generally is similar to erythromycin in its in vitro activity against susceptible strains of pneumococci, *Streptococcus pyogenes*, and viridans streptococci (see Table 55–1). Methicillin-
susceptible strains of *S. aureus* usually are susceptible to clindamycin, but MRSA and coagulase-negative staphylococci frequently are resistant. Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially *B. fragilis*. From 10-20% of clostridial species other than *C. perfringens* are resistant. Resistance to clindamycin in *Bacteroides* spp. increasingly is encountered. Strains of *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for *Pneumocystis jiroveci* pneumonia and *T. gondii* encephalitis, respectively.

**MECHANISM OF ACTION; RESISTANCE.** Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (see Figures 55–2 and 55–3), and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others. Macrolide resistance due to ribosomal methylation also may produce resistance to clindamycin. Because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. Clindamycin is not a substrate for macrolide efflux pumps; thus strains that are resistant to macrolides by this mechanism are susceptible to clindamycin.

**ADME.** Clindamycin is nearly completely absorbed following oral administration. Peak $C_p$ of 2-3 μg/mL are attained within 1 h after the ingestion of 150 mg. Food in the stomach does not reduce absorption significantly. The $t_{1/2}$ of the antibiotic is ~3 h. Clindamycin palmitate, an oral preparation for pediatric use, is an inactive prodrug that is hydrolyzed rapidly in vivo. The phosphate ester of clindamycin, which is given parenterally, also is rapidly hydrolyzed in vivo to the active parent compound.

Clindamycin is widely distributed in many fluids and tissues, including bone but not to CSF, even when the meninges are inflamed. Concentrations sufficient to treat cerebral toxoplasmosis are achievable. The drug readily crosses the placental barrier. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes, alveolar macrophages, and in abscesses.

Clindamycin is inactivated by metabolism to *N*-demethylclindamycin and
clindamycin sulfoxide, which are excreted in the urine and bile. Dosage adjustments may be required in patients with severe hepatic failure. Only ~10% of the clindamycin administered is excreted unaltered in the urine, and small quantities are found in the feces. However, antimicrobial activity persists in feces for ≥5 days after parenteral therapy with clindamycin is stopped and growth of clindamycin-sensitive microorganisms may be suppressed for up to 2 weeks.

**THERAPEUTIC USES AND DOSAGE.** The oral dose of clindamycin (clindamycin hydrochloride [CLEOCIN]) for adults is 150-300 mg every 6 h; for severe infections, it is 300-600 mg every 6 h. Children should receive 8-12 mg/kg/day of clindamycin palmitate hydrochloride (CLEOCIN PEDIATRIC) in 3 or 4 divided doses or for severe infections, 13-25 mg/kg/day. However, children weighing ≤10 kg should receive ½ teaspoonful of clindamycin palmitate hydrochloride (37.5 mg) every 8 h as a minimal dose. For serious infections, intravenous or intramuscular administration is recommended in dosages of 1200-2400 mg/day, divided into 3 or 4 equal doses for adults. Children should receive 15-40 mg/kg/day in 3 or 4 divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Clindamycin is the drug of choice for treatment of lung abscess and anaerobic lung and pleural space infections. Clindamycin (600 mg intravenously every 8 h, or 300-450 mg orally every 6 h for less severe disease) in combination with primaquine (15 mg of base once daily) is useful for the treatment of mild to moderate cases of *P. jiroveci* pneumonia in AIDS patients. Clindamycin is an alternative agent for the treatment of skin and soft-tissue infections, especially in patients with β-lactam allergies. However, *the high incidence of diarrhea and the occurrence of pseudomembranous colitis should limit its use to infections where it represents a clear therapeutic advantage.*

Clindamycin (600-1200 mg given intravenously every 6 h) in combination with pyrimethamine (a 200-mg loading dose followed by 75 mg orally each day) and *leucovorin* (folinic acid, 10 mg/day) is effective for acute treatment of encephalitis caused by *T. gondii* in patients with AIDS. Clindamycin also is available as a topical solution, gel, or lotion (CLEOCIN T, others) and as a vaginal cream (CLEOCIN, others). It is effective topically (or orally) for acne vulgaris and bacterial vaginosis.
UNTOWARD EFFECTS

GI Effects. The reported incidence of diarrhea associated with the administration of clindamycin ranges from 2-20%. A number of patients have developed pseudomembranous colitis caused by the toxin from the organism C. difficile. This colitis is characterized by watery diarrhea, fever, and elevated peripheral white blood cell counts. *This syndrome may be lethal.* Discontinuation of the drug, combined with administration of metronidazole or oral vancomycin usually is curative, but relapses occur. Agents that inhibit peristalsis (e.g., opioids) may prolong and worsen the condition.

Other Toxic and Irritative Effects. Skin rashes occur in ~10% of patients treated with clindamycin and may be more common in patients with HIV infection. Other uncommon reactions include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. Clindamycin may potentiate the effect of a neuromuscular blocking agent administered concurrently.

STREPTOGRAMINS (QUINUPRISTIN/DALFOPRISTIN)

Quinupristin/dalfopristin (SYNERCID) is a combination of quinupristin (a streptogramin B), with dalfopristin (a streptogramin A), in a 30:70 ratio. These compounds are semisynthetic derivatives of naturally occurring agents produced by *Streptomyces pristinaespiralis*. Quinupristin and dalfopristin are more soluble derivatives of the congeners, pristinamycin IA and IIA, and therefore are suitable for intravenous administration.

ANTIMICROBIAL ACTIVITY. Quinupristin/dalfopristin is active against gram-positive cocci and organisms responsible for atypical pneumonia (e.g., *M. pneumoniae*, *Legionella* spp., and *C. pneumoniae*), but is inactive against gram-negative organisms. The combination is bactericidal against streptococci and many strains of staphylococci but bacteriostatic against *Enterococcus faecium*.

MECHANISM OF ACTION. Quinupristin and dalfopristin are protein synthesis inhibitors that bind the 50S ribosomal subunit. Quinupristin binds at
the same site as macrolides and has a similar effect, with inhibition of polypeptide elongation and early termination of protein synthesis. Dalfopristin binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of quinupristin at its target site. Dalfopristin directly interferes with polypeptide-chain formation. The net result of the cooperative and synergistic binding of these 2 molecules to the ribosome is bactericidal activity.

**RESISTANCE TO STREPTOGRAMINS.** Resistance to quinupristin is mediated by genes encoding a ribosomal methylase that prevents binding of drug to its target, or genes encoding lactonases that inactivate type B streptogramins. Resistance to dalfopristin is mediated by genes that encode acetyltransferases that inactivate type A streptogramins, or staphylococcal genes that encode ATP-binding efflux proteins that pump type A streptogramins out of the cell. These resistance determinants are located on plasmids. Resistance to quinupristin/dalfopristin always is associated with a resistance gene for type A streptogramins. Methylase-encoding genes can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is necessary (e.g., endocarditis).

**ADME.** Quinupristin/dalfopristin is administered by intravenous infusion over at least 1 h. It is incompatible with saline and heparin and should be dissolved in 5% dextrose in water. The $t_{1/2}$ is 0.85 h for quinupristin and 0.7 h for dalfopristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalfopristin. Hepatic metabolism by conjugation is the principal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. Hepatic insufficiency increases the plasma AUC of active component and metabolites by 180% for quinupristin and 50% for dalfopristin.

**THERAPEUTIC USES AND DOSAGE.** Quinupristin/dalfopristin is approved in the U.S. for treatment of infections caused by vancomycin-resistant strains of *E. faecium* (dose of 7.5 mg/kg every 8-12 h) and complicated skin and skin-structure infections caused by methicillin-susceptible strains of *S. aureus* or *S. pyogenes*. In Europe it also is approved for treatment of nosocomial pneumonia.
and infections caused by MRSA. Quinupristin/dalfopristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant *E. faecium*.

**UNTOWARD EFFECTS.** The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias, more likely to be problematic in patients with hepatic insufficiency are managed by reducing the infusion frequency to every 12 h.

**DRUG INTERACTIONS.** Quinupristin/dalfopristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates with quinupristin/dalfopristin may result in significant toxicity. Caution and monitoring are recommended for drugs in which the toxic therapeutic window is narrow or for drugs that prolong the QTc interval.

**OXAZOLIDINONES (LINEZOLID)**

Linezolid (ZYVOX) is a synthetic antimicrobial agent of the oxazolidinone class.

**ANTIMICROBIAL ACTIVITY.** Linezolid is active against gram-positive organisms including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as *Corynebacterium* spp. and *L. monocytogenes* (see Table 55–1). It has poor activity against most gram-negative aerobic or anaerobic bacteria. It is bacteriostatic against enterococci and staphylococci and bactericidal against streptococci. *Mycobacterium tuberculosis* is moderately susceptible.

**MECHANISM OF ACTION AND RESISTANCE TO OXAZOLIDINONES.** Linezolid inhibits protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-fMet-tRNA complex that initiates protein synthesis. Because of its unique mechanism of action, linezolid is active against strains that are resistant to multiple other agents, including penicillin-resistant strains of *S. pneumoniae*; methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci. Resistance in
enterococci and staphylococci is due to point mutations of the 23S rRNA. Since bacteria have multiple copies of 23S rRNA genes, resistance generally requires mutations in 2 or more copies.

**ADME.** Linezolid is well absorbed after oral administration and may be administered without regard to food. Dosing for oral and intravenous preparations is the same. The $t_{1/2}$ is ~4-6 h. Linezolid is 30% protein-bound and distributes widely to well-perfused tissues. Linezolid is nonenzymatically oxidized to aminoethoxyacetic acid and hydroxyethyl glycine derivatives. Approximately 80% of a dose of linezolid appears in the urine, 30% as active compound and 50% as the 2 primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. No dose adjustment in renal insufficiency is recommended. Linezolid and its breakdown products are eliminated by dialysis; therefore the drug should be administered after hemodialysis.

**THERAPEUTIC USES AND DOSAGE.** Linezolid (600 mg twice daily) has had clinical and microbiological cure rates in the range of 85-90% in treatment of a variety of infections caused by vancomycin-resistant E. faecium. Linezolid is FDA-approved for treatment of skin and skin structure infections (complicated and uncomplicated) caused by streptococci and S. aureus (methicillin-susceptible and MRSA). A 400-mg twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections. For nosocomial pneumonia caused by MRSA or methicillin-susceptible S. aureus, cure rates with linezolid (~60%) were similar to those with vancomycin. Linezolid also may be an effective alternative for patients with MRSA infections who have reduced susceptibility to vancomycin. Linezolid also is approved for treatment of community-acquired pneumonia caused by penicillin-susceptible strains of S. pneumoniae.

*Linezolid should be reserved as an alternative agent for treatment of infections caused by multiple-drug-resistant strains. It should not be used when other agents are likely to be effective. Indiscriminant use and overuse will hasten selection of resistant strains and the eventual loss of this valuable newer agent.*

**UNTOWARD EFFECTS.** Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving linezolid. Platelet counts should be monitored in patients with risk of bleeding,
preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function and in patients receiving courses of therapy lasting beyond 2 weeks. The drug is well tolerated, with generally minor side effects (e.g., GI complaints, headache, rash). Patients receiving long-term (e.g., >8 weeks) treatment with linezolid have developed peripheral neuropathy, optic neuritis, and lactic acidosis. Linezolid should generally not be used for long-term therapy if there are alternative agents.

**Drug Interactions.** Linezolid is a weak nonspecific inhibitor of monoamine oxidase. Patients receiving concomitant therapy with an adrenergic or serotonergic agent (including selective serotonin reuptake inhibitors [SSRIs]) or consuming >100 mg of tyramine a day may experience serotonin syndrome (palpitations, headache, or hypertensive crisis). Coadministration of these agents is best avoided if possible. However, in patients receiving SSRIs who acutely require linezolid therapy for short-term (10-14 days) treatment, coadministration with careful monitoring is reasonable. Linezolid is neither a substrate nor an inhibitor of CYPs.

**AMINOCYCLITOLS (SPECTINOMYCIN)**

Spectinomycin is indicated only for the treatment of gonococcal infection when β-lactam or fluoroquinolone cannot be given.

**ANTIMICROBIAL ACTIVITY, MECHANISM OF ACTION, AND RESISTANCE TO SPECTINOMYCIN.** Spectinomycin selectively inhibits protein synthesis in gram-negative bacteria by binding to the 30S ribosomal subunit. Its action is similar to that of the aminoglycosides, but spectinomycin is not bactericidal and does not cause misreading of messenger RNA. Bacterial resistance may be mediated by mutations in the 16S ribosomal RNA or by drug modification by adenylyltransferase.

**ADME.** Spectinomycin is rapidly absorbed after intramuscular injection. The drug is not significantly bound to plasma protein, and all of an administered dose is recovered in the urine within 48 h.

**THERAPEUTIC USES AND DOSAGE.** Spectinomycin is active against a number of gram-negative bacterial species, but it is inferior to other drugs to which such microorganisms are susceptible. Its only therapeutic use is in the
treatment of gonorrhea caused by strains resistant to first-line drugs (ceftriaxone, cefixime) or if there are contraindications to these drugs. Spectinomycin is recommended in patients who are intolerant or allergic to β-lactams. The drug is not available in the U.S. The recommended dose for men and women is a single deep intramuscular injection of 2 g. Spectinomycin has no effect on incubating or established syphilis, and is not active against Chlamydia spp. It also is less effective for pharyngeal infections.

UNTOWARD EFFECTS. Local pain, urticaria, chills, fever, dizziness, nausea, and insomnia have been noted. The injection may be painful.

POLYMYXINS

The polymyxins are a group of closely related antibiotics elaborated by strains of Bacillus polymyxa. Colistin (polymyxin E) is produced by Bacillus colistinus. Polymyxin B is a mixture of polymyxins B₁ and B₂. These drugs, which are cationic detergents, are simple basic peptides with molecular masses of ~1000 Da.

ANTIMICROBIAL ACTIVITY, MECHANISM OF ACTION, AND RESISTANCE TO POLYMYXINS. The antimicrobial activities of polymyxin B and colistin are similar and restricted to gram-negative bacteria. Polymyxins are surface-active amphipathic agents. They interact strongly with phospholipids and disrupt the structure of cell membranes. Sensitivity to polymyxin B apparently is related to the phospholipid content of the cell wall–membrane complex. Polymyxin B binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule. The cell walls of certain resistant bacteria may prevent access of the drug to the cell membrane. Although resistance to polymyxins is rare, emergence of resistance while on treatment has been documented.

ADME. Polymyxin B and colistin are not absorbed when given orally and are poorly absorbed from mucous membranes and the surfaces of large burns. They are cleared renally, and modification of the dose is required in patients with impaired renal function.

THERAPEUTIC USES
Topical Uses. Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Infections of the skin, mucous membranes, eye, and ear due to polymyxin B–sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *P. aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative.

Systemic Uses. Colistin is available as colistin sulfate for oral use and as colistimethate sodium for parenteral administration. Due to the emergence of multidrug-resistant gram-negative organisms (especially *Stenotrophomonas maltophilia*, *Acinetobacter* spp., *P. aeruginosa*, and *Klebsiella* spp.), there has been a resurgence in the systemic use of polymyxins, despite their toxicity when administered via this route. Because dosing of these agents varies by drug (polymyxin B or colistin), by the particular commercial preparation, and by the patient’s degree of renal dysfunction, expert consultation is recommended.

Untoward Effects. Because polymyxins are nephrotoxic when administered via systemically, these drugs are rarely used except topically. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitization is uncommon with topical application. Neurological reactions include muscle weakness, apnea, paresthesias, vertigo, and slurred speech.

GLYCOPEPTIDES (VANCOMYCIN AND TEICOPLANIN)

Vancomycin is a tricyclic glycopeptide antibiotic produced by *Streptococcus orientalis*. Teicoplanin is a mixture of related glycopeptides available as an antibiotic in Europe. It is similar to vancomycin in chemical structure, mechanism of action, spectrum of activity, and route of elimination (i.e., primarily renal).

ANTIMICROBIAL ACTIVITY. Vancomycin possesses activity against a broad spectrum of gram-positive bacteria (see Table 55–1). Essentially all species of gram-negative bacilli and mycobacteria are resistant to vancomycin. Teicoplanin is active against methicillin-susceptible and MRSA. Some strains of
staphylococci, coagulase positive and coagulase negative, as well as enterococci and other organisms that are intrinsically resistant to vancomycin (i.e., *Lactobacillus* spp. and *Leuconostoc* spp.), are resistant to teicoplanin.

**MECHANISM OF ACTION.** Vancomycin and teicoplanin inhibit the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the d-alanyl-d-alanine terminus of cell wall precursor units (Figure 55–4). Because of their large molecular size, they are unable to penetrate the outer membrane of gram-negative bacteria.

![Figure 55–4 Inhibition of bacterial cell wall synthesis: vancomycin and \( \beta \)-lactam agents.](image)

Vancomycin inhibits the polymerization or transglycosylase reaction (A) by binding to the d-alanyl-d-alanine terminus of the cell wall precursor unit attached to its lipid carrier and blocks linkage to the glycopeptide polymer (indicated by the subscript \( n \)). These \( (\text{NAM–NAG})_n \) peptidoglycan polymers are located within the cell wall. Van A-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal d-lactate for d-alanine, reducing affinity for vancomycin by 1000-fold. \( \beta \)-Lactam antibiotics inhibit the cross-linking or transpeptidase reaction (B) that links glycopeptide polymer chains by formation of a cross-bridge with the stem peptide (the 5
glycines in this example) of one chain, displacing the terminal D-alanine of an adjacent chain. See also Figure 53–2.

RESISTANCE TO GLYCOPEPTIDES. Glycopeptide-resistant strains of enterococci, primarily *E. faecium*, have emerged as major nosocomial pathogens in hospitals in the U.S. Determinants of vancomycin resistance are located on a transposon that is readily transferable among enterococci, and, potentially, other gram-positive bacteria. These strains are typically resistant to multiple antibiotics, including streptomycin, gentamicin, and ampicillin. Resistance to streptomycin and gentamicin is of special concern because the combination of an aminoglycoside with a cell-wall-synthesis inhibitor is the only reliably bactericidal regimen for treatment of enterococcal endocarditis.

Enterococcal resistance to glycopeptides is the result of alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl D-serine, which bind glycopeptides poorly. Several enzymes within the *van* gene cluster are required for this target alteration to occur. The *Van A* phenotype confers inducible resistance to teicoplanin and vancomycin in *E. faecium* and *Enterococcus faecalis*. The *Van B* phenotype, which tends to be a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible by vancomycin but not teicoplanin, and consequently, many strains remain susceptible to teicoplanin. The *Van C* phenotype, the least important clinically and least well characterized, confers resistance only to vancomycin.

*S. aureus* and coagulase-negative staphylococci may express reduced or “intermediate” susceptibility to vancomycin (MIC, 4-8 μg/mL) or high-level resistance (MIC ≥16 μg/mL). Intermediate resistance is associated with a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10⁵ to 1 in 10⁶) will grow in the presence of vancomycin concentrations >4 μg/mL. Prior treatment courses and low vancomycin levels may predispose patients to infection and treatment failure with vancomycin-intermediate strains. These strains typically are resistant to methicillin and multiple other antibiotics; their emergence is a major concern because until recently vancomycin has been the only antibiotic to which staphylococci were reliably susceptible. High-level vancomycin-resistant *S. aureus* strains (MIC ≥32 μg/mL) harbor a conjugative plasmid into which the *Van A* transposon is integrated by an interspecies horizontal gene transfer from *E. faecalis* to a MRSA. These isolates have been variably susceptible to teicoplanin and the
investigational lipoglycopeptides.

**ADME.** Vancomycin is poorly absorbed after oral administration. The drug should be administered intravenously, never intramuscularly. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed (7-30%); bile; and pleural, pericardial, synovial, and ascitic fluids. About 90% of an injected dose of vancomycin is excreted by glomerular filtration; elimination $t_{1/2}$ is ~6 h. The drug accumulates if renal function is impaired, and dosage adjustments must be made. The drug can be cleared from plasma with hemodialysis. Teicoplanin can be administered by intramuscular injection as well as intravenous administration. An intravenous dose of 1 g in adults produces plasma concentrations of 15-30 μg/mL 1 h after a 1- to 2-h infusion. Teicoplanin is highly bound by plasma proteins (90-95%) and has an extremely long serum elimination $t_{1/2}$ (up to 100 h).

**THERAPEUTIC USES AND DOSAGE.** Vancomycin and teicoplanin have been used to treat a variety of infections, including osteomyelitis and endocarditis caused by methicillin-resistant and methicillin-susceptible staphylococci, streptococci, and enterococci. Teicoplanin is not licensed for use in the U.S.

Vancomycin hydrochloride (VANCOCIN, others) is marketed for *intravenous* use as a sterile powder for solution. It should be diluted and infused over at least a 60-min period to avoid infusion-related adverse reactions; the recommended dose for adults is 30-45 mg/kg/day in 2-3 divided doses. Current recommendations call for monitoring serum trough concentrations (within 30 min prior to a dose) at steady state, typically before the fourth dose of a given dosage regimen. A trough serum concentration of 10 μg/mL is recommended. For patients with more serious infections (including endocarditis, osteomyelitis, meningitis, and MRSA pneumonia), trough levels of 15-20 μg/mL are recommended. Pediatric doses are: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 h; for infants 8-30 days old, 15 mg/kg followed by 10 mg/kg every 8 h; for older infants (>30 days) and children, 10-15 mg/kg every 6 h. Alteration of dosage is required for patients with impaired renal function. In functionally anephric patients and patients receiving dialysis with non-high-flux membranes, administration of 1 g (~15
mg/kg) every 5-7 days typically achieves adequate serum levels. In patients receiving intermittent high-efficiency or high-flux dialysis, maintenance doses administered after each dialysis session are typically required. Blood levels should be monitored to decide on dose adjustments.

**Skin/Soft-Tissue and Bone/Joint Infections.** Vancomycin is used in the treatment of skin/soft-tissue and bone/joint infections, where gram-positive organisms including MRSA are the leading pathogens.

**Respiratory Tract Infections.** Vancomycin is employed for the treatment of pneumonia when MRSA is suspected. Because vancomycin penetration into lung tissue is relatively low, aggressive dosing is generally recommended.

**CNS Infections.** Vancomycin is a key component in the initial empirical treatment of community-acquired bacterial meningitis in locations where penicillin-resistant *S. pneumoniae* is common. Penetration of vancomycin across inflamed meningitis is poor; thus, aggressive dosing is typically warranted. Vancomycin is also used to treat nosocomial meningitis often caused by staphylococci.

**Endocarditis and Vascular Catheter Infections.** Vancomycin is standard therapy for staphylococcal endocarditis when the isolate is methicillin resistant or patients have a severe penicillin allergy. Vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy or for penicillin-resistant isolates. Vancomycin is used for the treatment of vascular catheter infections due to gram-positive organisms.

**Other Infections.** Vancomycin can be administered orally to patients with pseudomembranous colitis due to *C. difficile*. The dose for adults is 125-250 mg every 6 h; the total daily dose for children is 40 mg/kg, given in 3 to 4 divided doses. The standard dose of teicoplanin in adults is 3-6 mg/kg/day, with higher dosages possible for treatment of serious staphylococcal infections. Once-daily dosing is possible due to the prolonged serum $t_{1/2}$. Teicoplanin doses must be adjusted in patients with renal insufficiency. For functionally anephric patients, administration once weekly is appropriate, but serum drug concentrations should be monitored to determine that the therapeutic range has been maintained.
**UNTOWARD EFFECTS.** Hypersensitivity reactions produced by vancomycin and teicoplanin include macular skin rashes and anaphylaxis. Phlebitis and pain at the site of intravenous injection are relatively uncommon. Chills, rash, and fever may occur. Rapid intravenous infusion of vancomycin may cause erythematous or urticarial reactions, flushing, tachycardia, and hypotension. The extreme flushing that can occur is not an allergic reaction but a direct effect of vancomycin on mast cells, causing them to release histamine. This reaction is generally not observed with teicoplanin. Auditory impairment, sometimes permanent, is associated with excessive concentrations of these drugs in plasma (60-100 μg/mL of vancomycin). Nephrotoxicity has become less common with modern formulations at standard dosages. Careful dosing and monitoring of vancomycin is necessary to balance the risks and benefits. Caution should be exercised when ototoxic or nephrotoxic drugs, such as aminoglycosides, are administered concurrently with vancomycin.

**LIPOPEPTIDES (DAPTOMYCIN)**

Daptomycin (CUBICIN), a cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus*, has been resurrected in response to increasing need for bactericidal antibiotics effective against vancomycin-resistant gram-positive bacteria.

**Antimicrobial Activity.** Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria (see Table 55–1). Daptomycin may be active against vancomycin-resistant strains, although MICs tend to be higher for these organisms than for their vancomycin-susceptible counterparts.

**Mechanisms of Action and Resistance to Daptomycin.** Daptomycin binds to bacterial membranes resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity. Daptomycin resistance has been reported to emerge while on therapy. The mechanisms of resistance to daptomycin have not been fully characterized.

**ADME.** Daptomycin is poorly absorbed orally and should be administered only intravenously. Direct toxicity to muscle precludes intramuscular injection. The serum $t_{1/2}$ is 8-9 h, permitting once-daily dosing. Approximately 80% of the
administered dose is recovered in urine; a small amount is excreted in feces. Although the drug penetrates adequately into the lung, the drug is inactivated by pulmonary surfactant. If the creatinine clearance is <30 mL/min; the dose is administered only every 48 h. For hemodialysis patients the dose should be given immediately after dialysis. Daptomycin does not affect CYPs and has no important drug–drug interactions. Caution is recommended when daptomycin is coadministered with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively.

**Therapeutic Uses and Dosage.** Daptomycin is indicated for treatment of complicated skin and soft tissue infections (at 4 mg/kg/day) and complicated bacteremia and right-sided endocarditis (at 6 mg/kg/day). Its efficacy is comparable to that of vancomycin.

**Untoward Effects.** Elevations of creatine kinase may occur; this does not require discontinuation unless findings suggest an otherwise unexplained myopathy. Rhabdomyolysis has been reported to occur rarely.

**BACITRACIN**

Bacitracin is an antibiotic produced by the Tracy-I strain of *B. subtilis*. The bacitracins are a group of polypeptide antibiotics. The commercial products have multiple components; the major constituent is bacitracin A.

**Antimicrobial Activity.** Bacitracin inhibits the synthesis of the bacterial cell wall; a variety of gram-positive cocci and bacilli, *Neisseria, H. influenzae*, and *T. pallidum*, are sensitive to the drug at ≤0.1 unit/mL. *Actinomyces* and *Fusobacterium* are inhibited by concentrations of 0.5-5 units/mL. Enterobacteriaceae, *Pseudomonas, Candida* spp., and *Nocardia* are resistant to the drug. A unit of the antibiotic is equivalent to 26 μg of the USP standard.

**Therapeutic Uses and Dosage.** Current use is restricted to topical application. Bacitracin is available in ophthalmic and dermatologic ointments; the antibiotic also is available as a powder (BACI-Rx) for the extemporaneous compounding of topical solutions. A number of topical preparations of bacitracin, to which neomycin or polymyxin or both have been added, are available. For open infections, such as infected eczema and infected dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive
bacteria. Bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer, when caused by susceptible bacteria, respond well to the topical use of bacitracin. Bacitracin has been used with limited success for eradication of nasal carriage of staphylococci. Oral bacitracin has been used with some success for the treatment of antibiotic-associated diarrhea caused by C. difficile.

**Untoward Effects.** Nephrotoxicity results from the parenteral use of bacitracin.

**MUPIROCIN**

**Antimicrobial Activity, Mechanism of Action, and Resistance.** Mupirocin (BACTROBAN) is for topical use only. The drug is bactericidal against many gram-positive and selected gram-negative bacteria. It has good activity against *S. pyogenes* and methicillin-susceptible and MRSA. Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl transfer-RNA synthase. There is no cross-resistance with other classes of antibiotics. High-level resistance is mediated by a plasmid, which encodes a “bypass” Ile tRNA synthase that binds mupirocin poorly.

**ADME.** Systemic absorption through intact skin or skin lesions is minimal. Any absorbed drug is rapidly metabolized to inactive monic acid.

**Therapeutic Uses and Dosage.** Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*. The nasal ointment is approved for eradication of *S. aureus* nasal carriage. The consensus is that patients who stand to benefit from mupirocin prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for distant infection or a history of skin or soft-tissue infections.

**Untoward Effects.** Mupirocin may cause irritation and sensitization at the site of application. Contact with the eyes causes irritation that may take several days to resolve. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate to severe renal failure to avoid accumulation of polyethylene glycol.
Mycobacteria cause tuberculosis (TB) and leprosy. Although the burden of leprosy has decreased, TB is still the most important infectious killer of humans. *Mycobacterium avium-intracellulare* (or *Mycobacterium avium* complex [MAC]) infection continues to be difficult to treat, mainly due to 3 natural barriers:

- **Cell wall**—More than 60% of the cell wall is lipid, mainly mycolic acids composed of 2-branched, 73-hydroxy fatty acids with chains made of 76-90 carbon atoms. This shield prevents many pharmacological compounds from getting to the bacterial cell membrane or inside the cytosol.

- **Efflux pumps**—These transport proteins export potentially harmful chemicals from the bacterial cytoplasm into the extracellular space, preventing accumulation of effective drug concentrations in the cell. These exporters are responsible for the native resistance of mycobacteria to many standard antibiotics. As an example, ATP-binding cassette (ABC) permeases comprise a full 2.5% of the genome of *Mycobacterium tuberculosis*.

- **Location in host**—Some of the bacilli hide inside the patient’s cells, adding an extra physicochemical barrier that antimicrobial agents must cross to be effective.

Mycobacteria are defined by their rate of growth on agar as *rapid* and *slow* growers (*Table 56–1*). Slow growers tend to be susceptible to antibiotics developed specifically for Mycobacteria; rapid growers tend to be also susceptible to antibiotics used against many other bacteria.

*Table 56–1*

Pathogenic Mycobacterial Rapid and Slow Growers (Runyon Classification)
The mechanisms of action of the anti-mycobacterial drugs are summarized in Figure 56–1. Figure 56–2 depicts the mechanisms of resistance to these drugs. Tables 56–2 and 56–3 summarize the pharmacokinetic parameters of the antimycobacterial agents.
Figure 56–1 *Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections*. Shown at the top are the sites of action of approved drugs for the chemotherapy of mycobacterial diseases. Rifamycin is a generic term for several drugs, of which rifampin is used most frequently. Also included are 2 experimental drugs now under investigation: TMC-207 and PA-824. Clofazimine, whose mode of action is not understood, is omitted.

![Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections](image)

Figure 56–2 *Mechanisms of drug resistance in Mycobacteria*.

**ANTI-MYCOBACTERIAL DRUGS**

**RIFAMYCINS: RIFAMPIN, RIFAPENTINE, AND RIFABUTIN**

Rifampin or *rifampicin* (RIFADIN; RIMACTANE, others), *rifapentine* (PRIFTIN), and *rifabutin* (MYCOBUTIN) are important in treatment of mycobacterial diseases.

**MECHANISM OF ACTION.** Rifampin’s action against *M. tuberculosis* typifies the mechanism by which rifamycins act. Rifampin enters bacilli in a concentration-dependent manner, achieving steady-state concentrations within 15 min. The drug binds to the β subunit of DNA-dependent RNA polymerase.
(rpoB) to form a stable drug–enzyme complex, suppressing chain formation in RNA synthesis.

**ANTIBACTERIAL ACTIVITY.** Rifampin inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms. Rifampin inhibits the growth of many *M. tuberculosis* clinical isolates in vitro at concentrations of 0.06-0.25 mg/L. Rifampin is also bactericidal against *Mycobacterium leprae*. *Mycobacterium kansasii* is inhibited by 0.25-1 mg/L. Most strains of *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *M. avium* are suppressed by concentrations of 4 mg/L. *Mycobacterium fortuitum* is highly resistant to the drug. Rifabutin inhibits the growth of most MAC isolates at concentrations ranging from 0.25-1 mg/L and of many strains of *M. tuberculosis* at concentrations of ≤0.125 mg/L.

**BACTERIAL RESISTANCE.** The prevalence of rifampin-resistant isolates (1 in every 10⁷ to 10⁸ bacilli) is due to altered rpoB. Mutations in genes involved in DNA repair mechanisms will impair the repair of multiple genes, which may lead to hyper-mutable strains (see Chapter 48). *M. tuberculosis* Beijing genotype clinical isolates have been associated with higher rates of simultaneous rifampin and isoniazid resistance associated with mutations in the repair genes *mut* and *ogt*. Inducible or environment-dependent mutators may be more common than these stable mutator phenotypes. Antibiotics, endogenous oxidative and metabolic stressors lead to DNA damage, which induces dnaE2. The induction is associated with error-prone DNA repair and leads to higher rates of rifampin resistance.

**ADME.** After oral administration, the rifamycins are absorbed to variable extents (Table 56–2). Food decreases the rifampin Cₚmax by one-third; a high-fat meal increases the area under the curve (AUC) of rifapentine by 50%. Food has no effect on rifabutin absorption. Rifapentine should be taken with food, if possible. Rifamycins are metabolized by microsomal B-esterases and cholinesterases. A major pathway for rifabutin elimination is CYP3A. Due to autoinduction, all 3 rifamycins reduce their own AUCs with repeated administration (Table 56–3). They have good penetration into many tissues, but levels in the CNS reach only ~5% of those in plasma, likely due to the activity of P-glycoprotein. The drugs and metabolites are excreted by bile and eliminated via feces, with urine elimination accounting for only one-third and less of
metabolites. Tables 56–2 and 56–3 summarize the pharmacokinetic parameters of the rifamycins.

*Tables 56–2 and 56–3.*
PHARMACOKINETICS-PHARMACODYNAMICS. Rifampin’s bactericidal activity is best optimized by a high AUC/MIC ratio. However, resistance suppression and rifampin’s enduring post-antibiotic effect are best optimized by high C\text{max}/MIC. Therefore, the duration of time that the rifampin concentration persists above the MIC is of less importance. These results predict that the $t_{1/2}$ of a rifamycin is less of an issue in optimizing therapy, and that if patients could tolerate it, higher doses would lead to higher bactericidal activities while suppressing resistance.

THERAPEUTIC USES. Rifampin for oral administration is available alone or as a fixed-dose combination with isoniazid (150 mg of isoniazid, 300 mg of rifampin; Rifamate, others) or with isoniazid and pyrazinamide (50 mg of isoniazid, 120 mg of rifampin, and 300 mg pyrazinamide; Rifater). A parenteral form of rifampin is also available. The dose of rifampin for treatment of TB in adults is 600 mg, given once daily, either 1 h before or 2 h after a meal. Children should receive 10-20 mg/kg given in the same way. Rifabutin is administered at 5 mg/kg/day and rifapentine at 10 mg/kg once a week. Rifampin is also useful for the prophylaxis of meningococcal disease and *Haemophilus influenzae* meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children >1 month of age should receive 10-15 mg/kg, to a maximum of 600 mg. Combined with a β-lactam antibiotic or vancomycin, rifampin may be useful for therapy in selected cases of staphylococcal endocarditis or osteomyelitis.

UNTOWARD EFFECTS. Rifampin is generally well tolerated in patients. Fewer than 4% of patients with TB develop significant adverse reactions; the most common are rash, fever, and nausea and vomiting. Chronic liver disease, alcoholism, and old age appear to increase the incidence of severe hepatic problems. GI disturbances have occasionally required discontinuation of the drug. Various nonspecific symptoms related to the nervous system also have been noted.

Hypersensitivity reactions may be encountered. Adverse events associated with high rifampin dose are more commonly encountered when the time between doses is long; thus, high-dose rifampin should not be administered on a dosing schedule of less than twice weekly; less frequent administration is associated with a flu-like syndrome of fever, chills, and myalgias in 20% of patients;
adverse effects may also include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock. Light chain proteinuria, thrombocytopenia, transient leukopenia, and anemia have occurred during rifampin therapy. Rifampin crosses the placenta and its teratogenic potential; thus, its use is best avoided during pregnancy.

Rifabutin is generally well tolerated; primary reasons for discontinuation of therapy include rash (4%), GI intolerance (3%), and neutropenia (2%; 25% in patients with severe HIV infection). Uveitis and arthralgias have occurred in patients receiving rifabutin doses >450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur. Rifabutin causes an orange-tan discoloration of skin, urine, feces, saliva, tears, and contact lenses, like rifampin. Rarely, thrombocytopenia, a flu-like syndrome, chest pain, and hepatitis develop in patients treated with rifabutin. Unique side effects include polymyalgia, pseudojaundice, and anterior uveitis.

**RIFAMYCIN OVERDOSE.** Rifampin overdose is uncommon. The most prominent symptoms are the orange discoloration of skin, fluids, and mucosal surfaces, leading to the term red-man syndrome. Overdose can be life-threatening; treatment consists of supportive measures; there is no antidote.

**DRUG INTERACTIONS.** Because rifampin potently induces CYPs, its administration results in a decreased $t_{1/2}$ for a number of compounds that are metabolized by these CYPs. Rifabutin is a less potent inducer of CYPs than rifampin; however, rifabutin does induce hepatic microsomal enzymes and decreases the $t_{1/2}$ of zidovudine, prednisone, digitoxin, quinidine, ketoconazole, propranolol, phenytoin, sulfonylureas, and warfarin. It has less effect than rifampin on serum levels of indinavir and nelfinavir. Compared to rifabutin and rifampin, the CYP-inducing effects of rifapentine are intermediate.

**PYRAZINAMIDE**

Pyrazinamide is the synthetic pyrazine analog of nicotinamide.

**MECHANISM OF ACTION.** Pyrazinamide is activated to pyrazinoic acid under acidic conditions that likely prevail at the edges of necrotic TB cavities where inflammatory cells produce lactic acid. Some of the parent drug diffuses into $M$. 
*tuberculosis* where a nicotinamidase (pyrazinaminidase) deaminates pyrazinamide to pyrazinoic acid (POA?), which is exported by an efflux pump. In an acidic extracellular milieu, a fraction of POA? is protonated to POAH and enters the bacillus. As the pH of the extracellular medium declines toward the pKₐ of pyrazinoic acid, 2.9, the Henderson-Hasselbalch equilibrium (see Figure 2–3) progressively favors the formation of POAH, its equilibration across bacillar membrane, and its accumulation within the bacillus; acidic conditions also enhance microbial killing. Although the actual mechanism of microbial kill is still unclear, 4 mechanisms have been proposed:

- Inhibition of fatty acid synthase type I leading to interference with mycolic acid synthesis
- Binding to ribosomal protein S1 (RpsA) and inhibition of trans-translation
- Reduction of intracellular pH disruption of membrane transport by HPOA

**ANTIBACTERIAL ACTIVITY.** Pyrazinamide exhibits antimicrobial activity in vitro only at acidic pH. At pH of 5.8-5.95, 80-90% of clinical isolates have an MIC of ≤100 mg/L.

**MECHANISMS OF RESISTANCE.** Pyrazinamide-resistant *M. tuberculosis* express nicotinamidase with reduced affinity for pyrazinamide. This reduced affinity decreases the conversion of pyrazinamide to POA. Single point mutations in the *pncA* gene are encountered in up to 70% of resistant clinical isolates.

**ADME.** Oral bioavailability of pyrazinamide is >90%. GI absorption segregates patients into 2 groups: fast absorbers (56%) with an absorption rate constant of 3.56/h and slow absorbers (44%) with an absorption rate of 1.25/h. The drug is concentrated 20-fold in lung epithelial lining fluid. Pyrazinamide is metabolized by microsomal deamidase to POA and subsequently hydroxylated to 5-hydroxy-POA, which is excreted by the kidneys. CL (clearance) and V_d (volume of distribution) increase with patient mass (0.5 L/h and 4.3 L for every 10 kg above 50 kg), and V_d is larger in males (by 4.5 L) (see Table 56–2). This has several implications: the t½ of pyrazinamide will vary considerably based on weight and gender, and the AUC₀₋₂₄ will decrease with increase in weight for the same dose (same mg drug/kg body weight). Pyrazinamide clearance is reduced in renal failure; therefore, the dosing frequency must be reduced to 3 times a week.
at low glomerular filtration rates. Hemodialysis removes pyrazinamide; therefore, the drug needs to be re-dosed after each session of hemodialysis.

**MICROBIAL PHARMACOKINETICS-PHARMACODYNAMICS.** Pyrazinamide’s sterilizing effect is closely linked to $AUC_{0-24}/MIC$. However, resistance suppression is linked to the fraction of time that $C_p$ persists above MIC ($T > MIC$). Because patient weight impacts both SCL and volume, both AUC and $t_{1/2}$ will be impacted by high weight. Simulations indicate that optimal $AUC_{0-24}/MIC$ and $T > MIC$ are likely to be achieved only by doses much higher than the currently recommended 15-30 mg/kg/day; the safety of such higher doses in patients is unclear.

**THERAPEUTIC USES.** The coadministration of pyrazinamide with isoniazid or rifampin has led to a one-third reduction in the duration of anti-TB therapy, and a two-thirds reduction in TB relapse. The combination has reduced the length of therapy to 6 months, producing the current “short course” regimen. Pyrazinamide is administered at an oral dose of 15-30 mg/kg/day.

**UNTOWARD EFFECTS.** Injury to the liver is the most serious side effect of pyrazinamide. With an oral dose of 40-50 mg/kg, signs and symptoms of hepatic disease appear in ~15% of patients, with jaundice in 2-3% and death due to hepatic necrosis in rare instances. Current regimens (15-30 mg/kg/day) are much safer. Prior to pyrazinamide administration, all patients should undergo studies of hepatic function, and these studies should be repeated at frequent intervals during the entire period of treatment. If there is evidence of significant hepatic damage, therapy must be stopped. Pyrazinamide should not be given to patients with hepatic dysfunction unless its use is unavoidable.

In nearly all patients, pyrazinamide inhibits excretion of urate, and causes a hyperuricemia that may result in acute episodes of gout. Other untoward effects observed with pyrazinamide include arthralgias, anorexia, nausea and vomiting, dysuria, malaise, and fever. Pyrazinamide is not approved in the U.S. during pregnancy because of inadequate data on teratogenicity.

**ISONIAZID**

Isoniazid (isonicotinic acid hydrazide, INH; NYDRAZID, others) is a
primary agent for TB. All patients infected with isoniazid-sensitive strains should receive the drug if they can tolerate it. The combination of isoniazid + pyrazinamide + rifampin provides a “short-course” therapy with improved remission rates.

**MECHANISM OF ACTION.** Isoniazid enters bacilli by passive diffusion. The drug is not directly toxic to the bacillus but must be activated to its toxic form within the bacillus by KatG, a multifunctional catalase-peroxidase. The activated drug forms adducts with bacillar NAD$^+$ and NADP$^+$ that inhibit essential steps in mycolic acid synthesis (cell wall) and nucleic acid synthesis (Figure 56–3). Other products of KatG activation of INH include superoxide, H$_2$O$_2$, alkyl hydroperoxides, and the NO radical, which may also contribute to the mycobactericidal effects of INH.

![Figure 56–3 Metabolism and activation of isoniazid](image-url)

Figure 56–3 Metabolism and activation of isoniazid. metabolized in humans by NAT2 isoforms to its principal metabolite, N-acetyl isoniazid, which is excreted...
by the kidney. Isoniazid diffuses into mycoplasma where it is “activated” by KatG (oxidase/peroxidase) to the nicotinoyl radical. The nicotinoyl radical reacts spontaneously with NAD⁺ to produce adducts that inhibit essential enzymes in synthesis of the cell-wall component mycolic acid, and with NADP⁺ to produce an inhibitor of nucleic acid synthesis. InhA, enoyl acyl carrier protein; KasA, enoyl acyl carrier protein synthase; DHFR, dihydrofolate reductase.

**MECHANISMS OF RESISTANCE.** Resistance to INH is associated with mutation or deletion of katG, overexpression of the genes for inhA (confers low-level resistance to INH and some cross-resistance to ethionamide) and ahpC, and mutations in the kasA gene. The prevalence of drug-resistant mutants is ~1 in 10⁶ bacilli. Because TB cavities may contain as many as 10⁷-10⁹ microorganisms, preexistent resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants will be selected and amplified by monotherapy. Thus, 2 or more agents are usually used. Because the mutations resulting in drug resistance are independent events, the probability of resistance to 2 antimycobacterial agents is small, ~1 in 10^{12} (1 × 10⁶ × 10⁶), a low probability considering the number of bacilli involved.

**ADME.** The bioavailability of orally administered isoniazid is ~100% for the 300 mg dose. The pharmacokinetics of isoniazid are best described by a one-compartment model, with the pharmacokinetic parameters in Table 56–2. Isoniazid is metabolized by hepatic arylamine N-acetyltransferase type 2 (NAT2), encoded by a variety of NAT2* alleles (see Figure 56–3). Isoniazid clearance in patients has been traditionally classified as 1 of 2 phenotypic groups: “slow” and “fast” acetylators (Figure 56–4), and more recently as 3 groups, including “intermediate” metabolizers; this variability largely reflects expression of various NAT2 alleles. Most (75-95%) of a dose of isoniazid is excreted in the urine within 24 h, predominantly as acetylisoniazid and isonicotinic acid.
Multi-modal distribution of INH clearance due to NAT2 polymorphisms. A group of matched male volunteers received INH (250 mg orally) and the time courses of plasma drug levels ($C_p$) were assessed. One-third of the subjects had INH elimination $t_{1/2}$ values >1.5 h; these are the fast acetylators. Two-thirds had $t_{1/2}$ values ranging from 2.1 to 4.0 h, with a suggestion of multiple groups; these are the slow acetylators. Plots of the mean data ($C_p$ vs. time after administration) demonstrate the pharmacokinetic effects of acetylation rate. Both groups reached $C_{p_{\text{max}}}$ at 1 h. The slow acetylators (red line) achieved a higher $C_p$ (4 μg/mL) with a mean elimination $t_{1/2} = 3.0$ h; the fast acetylators (green line) reached a lower maximal $C_p$ (2 μg/mL) with a mean elimination $t_{1/2} = 1.0$ h. The acetylation rate reflects variable expression of active and defective polymorphic forms of NAT2. Slow acetylators may be a greater risk for adverse effects from INH, sulfonamides, and procainamide; fast acetylators may have diminished responses to standard doses of these agents but greater risk from bioactivation by NAT2 of arylamine/hydrazine carcinogens. Recently, researchers have identified 3 elimination subgroups for INH metabolism: fast, slow, and intermediate (codominant fast and slow alleles).

MICROBIAL PHARMACOKINETICS-PHARMACODYNAMICS. Isoniazid’s microbial kill is best explained by the AUC$_{0-24}$-to-MIC ratio. Resistance emergence is closely related to both AUC/MIC and $C_{\text{max}}$/MIC. Because AUC is proportional to dose/CL, efficacy is most dependent on drug dose and CL, and
thus on the activity of NAT-2 polymorphic forms. This also suggests that dividing the total isoniazid dose into more frequent doses may be detrimental in terms of resistance emergence (see Figure 48–4).

**THERAPEUTIC USES.** Isoniazid is available as a pill, as an elixir, and for parenteral administration. The commonly used total daily dose of isoniazid is 5 mg/kg, with a maximum of 300 mg. Children should receive 10-15 mg/kg/day (300 mg maximum). Pyridoxine, vitamin B₆, (10-50 mg/day) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, HIV-infected individuals, diabetic patients, alcoholic patients, and uremic patients).

**UNTOWARD EFFECTS.** The initial metabolite acetylisoniazid may be further acetylated by NAT-2 to diacetylhydrazine, which is nontoxic. Alternatively, acetylisoniazid can be converted to acetylhydrazine and then to hepatotoxic metabolites by CYP2E1. Thus, rapid acetylators will rapidly remove acetylhydrazine while slower acetylators or induction of CYP2E1 will lead to more toxic metabolites. Rifampin is a potent inducer of CYP2E1, which is the mechanism by which it potentiates isoniazid hepatotoxicity. Elevated serum aspartate and alanine transaminases are encountered commonly in patients on isoniazid. Severe hepatic injury occurs in ~0.1% of all patients taking the drug. Hepatic damage is rare in patients <20 years old but the incidence increases with age. Overall risk is increased by coadministration with rifampin to ~3%. Most cases of hepatitis occur 4-8 weeks after the start of therapy.

If pyridoxine is not given concurrently, peripheral neuritis is encountered in ~2% of patients receiving isoniazid 5 mg/kg of the drug daily. Neuropathy is more frequent in “slow” acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. Other neurological toxicities include convulsions in patients with seizure disorders, optic neuritis and atrophy, muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy. Mental abnormalities may appear during the use of this drug.

Patients may develop hypersensitivity to isoniazid. Hematological reactions also may occur. Arthritic symptoms also have been attributed to this agent. Miscellaneous reactions associated with isoniazid therapy include dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. A
drug-induced syndrome resembling systemic lupus erythematosus has also been reported.

**ISONIAZID OVERDOSE.** Isoniazid overdose has been associated with the clinical triad of:

- Seizures refractory to treatment with phenytoin and barbiturates
- Metabolic acidosis with an anion gap that is resistant to treatment with sodium bicarbonate
- Coma

Treatment involves cessation of isoniazid dosing and administration of intravenous pyridoxine over 5-15 min on a gram-to-gram basis with the ingested isoniazid. If the dose of ingested isoniazid is unknown, then a pyridoxine dose of 70 mg/kg should be used. In patients with seizures, benzodiazepines are used.

**DRUG INTERACTIONS.** Isoniazid is a potent inhibitor of CYP2C19, CYP3A, and a weak inhibitor of CYP2D6. However, isoniazid induces CYP2E1. Drugs that are metabolized by these enzymes will potentially be affected (Table 56–4).

**ETHAMBUTOL**

Ethambutol hydrochloride (MYAMBUTOL) is a water-soluble and
heat-stable compound.

**MECHANISM OF ACTION.** Ethambutol inhibits arabinosyl transferase III (catalyzes the transfer of arabinose in arabinogalactan biosynthesis), thereby disrupting the assembly of mycobacterial cell wall.

**ANTIBACTERIAL ACTIVITY.** Ethambutol has activity against a wide range of mycobacteria. Ethambutol MICs are 0.5-2 mg/L in clinical isolates of *M. tuberculosis*, ~0.8 mg/L for *M. kansasii*, and 2-7.5 mg/L for *M. avium*. The following species are also susceptible: *Mycobacterium gordonae*, *M. marinum*, *M. scrofulaceum*, *M. szulgai*. However, the majority of *M. xenopi*, *M. fortuitum*, and *M. chelonae* are resistant.

**MECHANISMS OF RESISTANCE.** In vitro, mycobacterial resistance to the drug develops via mutations in the *embB* gene, which encodes arabinosyl transferases. Enhanced efflux pump activity induces resistance to both isoniazid and ethambutol in vitro.

**ADME.** The oral bioavailability of ethambutol is ~80%. The decline in ethambutol is biexponential, with a $t_{1/2}$ of 3 h in the first 12 h, and a $t_{1/2}$ of 9 h between 12 and 24 h, due to redistribution of drug. Clearance and $V_d$ are greater in children than in adults on a per kilogram basis. Slow and incomplete absorption is common in children, so that good peak concentrations of drug are often not achieved with standard dosing. See Table 56–2 for PK data on this drug. About 80% of the drug is not metabolized and is renally excreted. Therefore, in renal failure ethambutol should be dosed at 15-25 mg/kg, 3 times a week instead of daily. The remainder of ethambutol (~20%) is excreted as aldehyde and dicarboxylic acid derivatives (produced by alcohol and aldehyde dehydrogenases).

**MICROBIAL PHARMACOKINETICS-PHARMACODYNAMICS.** Ethambutol’s microbial kill of *M. tuberculosis* is optimized by AUC/MIC, while that against disseminated MAC is optimized by $C_{max}$/MIC. Thus, to optimize microbial kill, high intermittent doses such as 25 mg/kg every other day to 50 mg/kg twice a week may be superior to daily doses of 15 mg/kg.

**THERAPEUTIC USES.** Ethambutol is available for oral administration in tablets containing the D-isomer. It is used for the treatment of TB, disseminated
and in M. kansasii infection.

**UNTOWARD EFFECTS.** Ethambutol produces very few serious untoward reactions: ~1% experience diminished visual acuity resulting from a reversible optic neuritis, 0.5% a rash, and 0.3% drug fever. Other side effects that have been observed are pruritus, joint pain, GI upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations. Therapy with ethambutol results in an increased concentration of urate in the blood in ~50% of patients, owing to decreased renal excretion of uric acid.

**AMINOGLYCOSIDES: STREPTOMYCIN, AMIKACIN, AND KANAMYCIN**

Streptomycin, amikacin, and kanamycin are used for the treatment of mycobacterial diseases. These aminoglycosides inhibit protein synthesis by binding to the 30S ribosomal subunit (see Figure 54–2). The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in Chapter 54.

The MICs for *M. tuberculosis* in Middlebrook broth are 0.25-3.0 mg/L for all 3 aminoglycosides. For *M. avium* streptomycin and amikacin, MICs are 1-8 mg/L; those of kanamycin are 3-12 mg/L. *M. kansasii* is frequently susceptible to these agents but other nontuberculous mycobacteria are only occasionally susceptible.

**BACTERIAL RESISTANCE.** Primary resistance to streptomycin is found in 2-3% of *M. tuberculosis* clinical isolates. Resistance results from mutations in 2 components of the 30S ribosomal subunit, *rpsL* and *rrs*; in the rRNA methyltransferase gene *gidB*, and in efflux pumps.

**CLOFAZIMINE**

Clofazimine (Lamprene), a fat-soluble riminophenazine dye, was discontinued in 2005 but remains licensed as an orphan drug.

**MECHANISM OF ACTION.** Clofazimine has both antibacterial activity as well as anti-inflammatory effects via inhibition of
macrophages, T cells, neutrophils, and complement. Clofazimine is recommended as a component of multiple drug therapy for leprosy. The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*. Possible mechanisms of action include:

- Membrane disruption
- Inhibition of mycobacterial phospholipase A₂
- Inhibition of microbial K⁺ transport
- Generation of hydrogen peroxide
- Interference with the bacterial electron transport chain

**ANTIBACTERIAL ACTIVITY.** The MICs for *M. avium* are 1-5 mg/L. The MICs for *M. tuberculosis* are ~1.0 mg/L. It also has activity against many gram-positive bacteria.

**ADME.** Clofazimine is administered orally at doses up to 300 mg/day. Bioavailability is variable (45-60%) and is increased 2-fold by high-fat meals and decreased 30% by antacids. After a single dose of 200 mg of clofazimine, the $t_{\text{max}}$ is 5.3-7.8 h. After prolonged repeated dosing, the $t_{1/2}$ is ~70 days. For PK data, see Table 56–2. Clofazimine is metabolized by the liver.

**UNTOWARD EFFECTS.** GI problems are encountered in 40-50% of patients. In patients who have died following the abdominal pain, crystal deposition in intestinal mucosa, liver, spleen, and abdominal lymph nodes has been demonstrated. Body secretion discoloration, eye discoloration, and skin discoloration occur in most patients.

**DRUG INTERACTIONS.** Anti-inflammatory effects may be inhibited by dapsone.

**FLUOROQUINOLONES**

Fluoroquinolones are DNA gyrase inhibitors (see Chapter 52). Drugs such as ofloxacin and ciprofloxacin have been second-line anti-TB agents for many years, but they are limited by the rapid development
of resistance.

Adding C8 halogen and C8 methoxy groups markedly reduces the propensity for drug resistance. Of the C8 methoxy quinolones, moxifloxacin (FDA-approved for nontubercular infections) is furthest along in clinical testing as an anti-TB agent. Moxifloxacin is being studied to replace either isoniazid or ethambutol.

THERAPEUTIC USES IN TREATMENT OF TB. In TB patients, moxifloxacin (400 mg/day) has bactericidal effects similar to that of standard doses of isoniazid. When replacing ethambutol in the standard multidrug regimen, 400 mg/day of moxifloxacin produces faster sputum conversion at 4 weeks than ethambutol. Moxifloxacin is currently being studied in a phase 3 trial that may eventually lead to 4-month duration of anti-TB therapy compared to the current 6 months.

TMC-207 (R207910)

MECHANISM OF ACTION. TMC-207 is an experimental diarylquinone for treatment of multidrug-resistant TB. The compound targets bacillar energy metabolism, acting on subunit c of the ATP synthase of M. tuberculosis and leading to inhibition of the proton pump activity of the ATP synthase. The TMC-207 MIC for M. tuberculosis is 0.03-0.12 mg/L. It has good activity against MAC, M. leprae, M. bovis, M. marinum, M. kansasii, M. ulcerans, M. fortuitum, M. szulgai, and M. abscessus.

PHARMACOKINETICS, EFFICACY, AND THERAPEUTIC USE. A regimen of TMC207 400 mg daily for 2 weeks followed by 200 mg 3 times day thereafter was added to a background second-line regimen of either kanamycin or amikacin, ofloxacin with or without ethambutol in patients with TB resistant to both isoniazid and rifampin (MDRTB), and led to an 8-week sputum conversion of ~50% with TMC207 compared to 9% without.

UNTOWARD EFFECTS. The adverse events encountered in the limited number of patients exposed to this experimental agent are mild and include nausea in 26% of patients and diarrhea in 13% of patients, with others (e.g., arthralgia, pain in extremities, and hyperuricemia) in a small proportion of patients.
PA-824

PA-824, an experimental agent, is a nitroimidazopyran prodrug that requires activation by the bacteria via a nitro-reduction step, similar to the structurally related agent, metronidazole. Activation requires a specific glucose-6-phosphate dehydrogenase, FGD1.

MECHANISM OF ACTION. PA-824 inhibits *M. tuberculosis* mycolic acid and protein synthesis. Another mechanism involves generation of reactive nitrogen species such as NO by PA-824’s des-nitro metabolite, which then augment the kill of intracellular nonreplicating persistent bacilli by the innate immune system.

ANTIBACTERIAL ACTIVITY. In vitro, the drug kills both nonreplicating *M. tuberculosis* that are under anaerobic conditions as well as replicating bacteria in ambient air. The MICs of PA-824 against *M. tuberculosis* range from 0.015–0.25 mg/L, but the drug lacks activity against other mycobacteria.

BACTERIAL RESISTANCE. The proportion of mutants resistant to 5 mg/L of PA-824 is 10⁻⁶. Resistance can arise due to changes in structure of FGD, resulting from point mutations in *fgd* gene. However, resistant isolates have also been identified that lack *fgd* mutations, so that resistance may also be due to other mechanisms.

ETHIONAMIDE

Ethionamide (TRECATOR) is a congener of thioisonicotinamide.

MECHANISM OF ACTION. Ethionamide is a prodrug that is activated to a sulfoxide by a mycobacterial NADPH-specific monooxygenase (EthaA), and then to 2-ethyl-4-aminopyridine. Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Like isoniazid, ethionamide inhibits mycobacterial growth by inhibiting the activity of the *inhA* gene product, the enoyl-ACP reductase of fatty acid synthase II. Both drugs inhibit mycolic acid biosynthesis with consequent impairment of cell-wall synthesis.
ANTIBACTERIAL ACTIVITY. The multiplication of *M. tuberculosis* is suppressed by concentrations of ethionamide ranging from 0.6-2.5 mg/L. A concentration of ≤10 mg/L will inhibit ~75% of photochromogenic mycobacteria; the scotochromogens are more resistant.

BACTERIAL RESISTANCE. Resistance occurs mainly via changes in the enzyme that activates ethionamide. Mutations in *inhA* gene lead to resistance to both ethionamide and isoniazid.

ADME. The oral bioavailability of ethionamide approaches 100%. The pharmacokinetics are adequately explained by a one-compartment model with first-order absorption and elimination; see PK values in Table 56–2. The $t_{1/2}$ is ~2 h. Ethionamide is cleared by hepatic metabolism. Metabolites are eliminated in the urine. Ethionamide is administered only orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/day every 5 days until a dose of 15-20 mg/kg/day is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10-20 mg/kg/day in 2 divided doses, not to exceed 1 g/day.

UNTOWARD EFFECTS. Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms. Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Convulsions and peripheral neuropathy are rare. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine (vitamin B₆) relieves the neurologic symptoms, and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia have also been observed. A metallic taste also may be noted. Hepatitis has been associated with the use of the ethionamide in ~5% of cases. Hepatic function should be assessed at regular intervals in patients receiving the drug.

PARA-AMINOSALICYLIC ACID

Para-aminosalicylic acid (PAS) was the first effective treatment for
MECHANISM OF ACTION. PAS is a congener of para-aminobenzoic acid, the substrate of dihydropteroate synthase (fol P1/P2); this structural similarity accounted for PAS’s postulated action as a competitive inhibitor of the enzyme (Figure 56–5). PAS is a poor inhibitor of dihydropteroate synthase in vitro; moreover, only 37% of the PAS-resistant clinical isolates or spontaneous mutants encode a mutation in any genes for enzymes in the folate pathway or biosynthesis of thymine nucleotides. Furthermore, mutations in thyA (the gene for thymidylate synthase) lead to drug resistance in only a minority of drug-resistant isolates. Unidentified actions of PAS likely play important roles in its anti-TB effects.

ANTIBACTERIAL ACTIVITY. PAS is bacteriostatic. In vitro, most strains of M. tuberculosis are sensitive to a concentration of 1 mg/L. It has no activity
against other bacteria.

**ADME.** PAS is administered orally in a daily dose of 12 g, with the daily dose divided into 3 equal portions. Children should receive 150-300 mg/kg/day in 3-4 divided doses. PAS oral bioavailability is >90%. PK data are shown in Table 56–2. The $C_{\text{Pmax}}$ increases 1.5-fold and AUC 1.7-fold with food; indeed, PAS should be administered with food, which also reduces gastric irritation. PAS is $N$-acetylated in the liver to $N$-acetyl PAS, a potential hepatotoxin. Over 80% of the drug is excreted in the urine; >50% is in the form of the acetylated compound. Excretion of PAS is reduced by renal dysfunction, requiring a reduction in dosage.

**UNTOWARD EFFECTS.** The incidence of untoward effects associated with the use of PAS is ~10-30%. GI problems predominate and often limit patient adherence. Hypersensitivity reactions to PAS are seen in 5-10% of patients and manifest as skin eruptions, fever, eosinophilia, and other hematological abnormalities.

**CYCLOSERINE**

Cycloserine (SEROMYCIN) is a broad-spectrum antibiotic produced by *Streptococcus orchidaceous* that is used in the multi-agent treatment of TB when primary agents have failed.

**MECHANISM OF ACTION.** Cycloserine is a congener of d-alanine. d-alanyl-d-alanine is an essential component of the peptidoglycan of the bacterial cell wall (see Figure 55–4). Cycloserine inhibits 2 enzymes that are necessary for incorporation of alanine into the cell wall: a racemase that converts L-alanine to D-alanine, and a ligase that joins 2 D-alanines to make D-alanyl-D-alanine.

**ANTIBACTERIAL ACTIVITY; RESISTANCE.** Cycloserine inhibits *M. tuberculosis* at concentrations of 5-20 mg/L. It has good activity against MAC, enterococci, *Escherichia coli*, *Staphylococcus aureus*, *Nocardia* species, and *Chlamydia*. Resistance of *M. tuberculosis* occurs in 10-82% of clinical isolates. Mutations involved in cycloserine resistance of pathogenic *Mycobacteria* are currently unknown.

**ADME.** The usual dose for adults is 250-500 mg orally, twice daily. Oral
cycloserine is almost completely absorbed. $C_{\text{max}}$ in plasma is reached in 45 min in fasting subjects, but is delayed for up to 3.5 h with a high-fat meal. See Table 56–2 for PK values. Cycloserine is well distributed throughout body. About 50% of cycloserine is excreted unchanged in the urine in the first 12 h; a total of 70% is recoverable in the active form over a period of 24 h. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of it is removed by hemodialysis.

**UNTOWARD EFFECTS.** Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/day, so much so that the drug has earned the nickname “psych-serine.” Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideas. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

**CAPREOMYCIN**

Capreomycin (CAPASTAT) is an antimycobacterial cyclic peptide. Antimycobacterial activity is similar to that of aminoglycosides as are adverse effects, and capreomycin should not be administered with other drugs that damage cranial nerve VIII. Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and neomycin. The adverse reactions associated with the use of capreomycin are hearing loss, tinnitus, transient proteinuria, cylindruria, and nitrogen retention. Eosinophilia is common. Leukocytosis, leukopenia, rashes, and fever have also been observed. Capreomycin is a second-line antituberculosis agent. The recommended daily dose is 1 g (no more than 20 mg/kg) per day for 60-120 days, followed by 1 g 2 to 3 times a week.

**MACROLIDES**

The pharmacology, bacterial activity, resistance mechanisms of macrolides are discussed in Chapter 55. Azithromycin and
clarithromycin are used for the treatment of MAC.

**DAPSONE**

Dapsone is a broad-spectrum agent with antibacterial, anti-protozoal, and antifungal effects.

![Dapsone](image)

**MECHANISM OF ACTION.** Dapsone (DDS, diamino-diphenylsulfone) is a structural analog of para-aminobenzoic acid (PABA) and a competitive inhibitor of dihydropteroate synthase (fol P1/P2) in the folate pathway, shown in Figure 56–5 (see also Figures 52–1 and 52–1). The anti-inflammatory effects of dapsone occur via inhibition of tissue damage by neutrophils. Dapsone is extensively used for acne, but this therapy is not recommended.

**ANTIMICROBIAL EFFECTS**

*Antibacterial.* Dapsone is bacteriostatic against *M. leprae* at concentrations of 1-10 mg/L. More than 90% of clinical isolates of MAC and *M. kansasii* have an MIC of <8 mg/L, but the MICs for *M. tuberculosis* isolates are high. It has little activity against other bacteria.

*Anti-parasitic.* Dapsone is highly effective against *Plasmodium falciparum* with IC\(_{50}\) of 0.006-0.013 mg/mL (0.6-1.3 mg/L) even in sulfadoxine-pyrimethamine–resistant strains. Dapsone has an IC\(_{50}\) of 0.55 mg/L against *Toxoplasma gondii* tachyzoites.

*Antifungal.* Dapsone is effective at concentrations of 0.1/mg/L against the fungus *Pneumocystic jiroveci*.

**DRUG RESISTANCE.** Resistance to dapsone results primarily from mutations in genes encoding dihydropteroate synthase (see Figure 56–5).

**ADME.** After oral administration, absorption is complete; the elimination \(t_{1/2}\) is
20-30 h. The population pharmacokinetics of dapsone are shown in Table 56–2. Dapsone undergoes N-acetylation by NAT2 and N-oxidation to dapsone hydroxylamine via CYP2E1 and CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones (e.g., dapsone) tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Approximately 70-80% of a dose of dapsone is excreted in the urine as an acid-labile mono-N-glucuronide and mono-N-sulfamate.

**THERAPEUTIC USES.** Dapsone is administered as an oral agent. Therapeutic uses of dapsone in the treatment of leprosy are described later. Dapsone is combined with chlorproguanil for the treatment of malaria. The anti-inflammatory effects are the basis for therapy for pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider.

**DAPSONE AND G6PD DEFICIENCY.** Glucose-6-phosphate dehydrogenase (G6PD) protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide. Dapsone, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of dapsone wherever possible.

**OTHER UNTOWARD EFFECTS.** Doses of ≤100 mg in healthy persons and ≤50 mg in healthy individuals with a G6PD deficiency do not cause hemolysis. Hemolysis develops in almost every individual treated with 200-300 mg of dapsone per day; methemoglobinemia also is common. A genetic deficiency in the NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy, drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes have been reported. An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally.

**PRINCIPLES OF ANTITUBERCULOSIS CHEMOTHERAPY**
Tuberculosis is not caused by a single species, but by a mixture of species with 99.9% similarity at the nucleotide level. The complex includes *M. tuberculosis* (*typus humanus*), *M. canettii*, *M. africanum*, *M. bovis*, and *M. microti*. They all cause TB, with *M. microti* responsible for only a handful of human cases.

**ANTITUBERCULOSIS THERAPY.** With anti-TB drug monotherapy, emergence of resistance renders the drugs ineffective. The mutation rates to first-line anti-TB drugs are between $10^{-7}$ and $10^{-10}$, so that the likelihood of resistance is high to any single anti-TB drugs in patients with cavitary TB who have $\sim 10^9$ CFU of bacilli in a 3-cm pulmonary lesion. However, the likelihood that bacilli would develop mutations to 2 or more different drugs is the product of 2 mutation rates (between $1$ in $10^{14}$ and 1 in $10^{20}$), a probability of resistance emergence that is acceptably small. *Thus, only combination therapy anti-TB therapy is currently recommended for treatment of TB.* Multidrug therapy has led to a reduction in length of therapy.

Isoniazid, pyrazinamide, rifampin, ethambutol, and streptomycin are currently considered first-line anti-TB agents. Moxifloxacin is being studied as a first-line agent. First-line agents are more efficacious and better tolerated, relative to second-line agents. Second-line drugs include ethionamide, PAS, cycloserine, amikacin, kanamycin, and capreomycin.

**TYPES OF ANTITUBERCULOSIS THERAPY**

**PROPHYLAXIS.** After infection with *M. tuberculosis*, $\sim 10\%$ of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction $\geq 5$ mm who also fall into 1 of the following categories: recently exposed to TB, have HIV co-infection, or are immunosuppressed. If the tuberculin skin test is $\geq 10$ mm, high risk of TB is encountered in recent ($\leq 5$ years) immigrants from areas of high TB prevalence, children $< 4$ years of age, intravenous drug users, as well as residents and employees of high-risk congregate settings. Any person with a skin test $> 15$ mm is also at high risk. In these patients at high risk of active TB, prophylaxis is recommended to prevent active disease. Prophylaxis consists of oral isoniazid, 300 mg daily or twice weekly, for 6 months in adults. Those who cannot take isoniazid should be given rifampin, 10 mg/kg daily, for 4 months. In children,
isoniazid 10-15 mg/kg daily (maximum 300 mg) is administered, or 20-30 mg/kg 2 times a week directly observed, for 9 months. In children who cannot tolerate isoniazid, rifampin 10-20 mg/kg daily for 6 months is recommended.

**DEFINITIVE THERAPY.** The current standard regimen for drug-susceptible TB consists of isoniazid (5 mg/kg, maximum 300 mg/day), rifampin (10 mg/kg, maximum 600 mg/day), and pyrazinamide (15-30 mg/kg, maximum of 2 g/day) for 2 months, followed by intermittent 10 mg/kg rifampin and 15 mg/kg isoniazid 2 or 3 times a week for 4 months. Children should receive 10-20 mg/kg isoniazid per day (300 mg maximum). Rifabutin 5 mg/kg/day can be used for the entire 6 months of therapy in adult HIV-infected patients because rifampin can adversely interact with some antiretroviral agents to reduce their effectiveness. In case there is resistance to isoniazid, initial therapy also may include ethambutol (15-20 mg/kg/day) or streptomycin (1 g/day) until isoniazid susceptibility is documented. Ethambutol doses in children are 15-20 mg/kg/day (maximum 1 g) or 50 mg/kg twice weekly (2.5 g). Because monitoring of visual acuity is difficult in children <5 years old, caution should be exercised in using ethambutol in these children.

The first 2 months of the 4-drug regimen is termed the initial phase of therapy, and the last 4 months the continuation phase of therapy. Rifapentine (10 mg/kg once a week) may be substituted for rifampin in the continuation phase in patients with no evidence of HIV infection or cavitary TB. Pyridoxine, vitamin B<sub>6</sub>, (10-50 mg/day) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy. The duration of therapy for drug-susceptible pulmonary TB is 6 months. A 9-month duration should be used for patients with cavitary disease who are still sputum culture positive at 2 months. Most cases of extrapulmonary TB are treated for 6 months. TB meningitis is an exception that requires a 9- to 12-month duration. In addition, corticosteroids are recommended for TB pericarditis, and results of a meta-analysis suggest they should also be used in TB meningitis.

**DRUG-RESISTANT TB.** In documented drug resistance, therapy should be based on evidence of susceptibility and should include:

- At least 3 drugs to which the pathogen is susceptible, with at least 1 injectable anti-TB agent
• In the case of multidrug resistant-TB, use of 4 to 6 medications for better outcomes
• At least 18 months of therapy

The addition to the regimen of a fluoroquinolone and surgical resection of the main lesions have been associated with improved outcome. There are currently no data to support intermittent therapy.

PRINCIPLES OF THERAPY AGAINST MYCOBACTERIUM AVIUM COMPLEX (MAC)

The MAC is made up of at least 2 species: *M. intracellulare* and *M. avium*. *M. intracellulare* causes pulmonary disease often in immunocompetent individuals. *M. avium* is further divided into a number of subspecies: *M. avium* subsp. *hominissuis* causes disseminated disease in immunocompromised patients, *M. avium* subsp. *paratuberculosis* has been implicated in the etiology of Crohn disease, and *M. avium* subsp. *avium* causes TB of birds. These bacteria are ubiquitous in the environment and can be encountered in water, food, and soil.

THERAPY OF MAC PULMONARY INFECTION

*M. intracellulare* often infects immunocompetent patients. In newly diagnosed patients with MAC pneumonia, triple drug therapy is recommended: a rifamycin, ethambutol, and a macrolide. For the macrolides, either oral clarithromycin or azithromycin may be used. Rifampin is often the rifamycin of choice. Clarithromycin, 1000 mg, or azithromycin, 500 mg, are combined with ethambutol, 25 mg/kg, and rifampin, 600 mg, and administered 3 times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are administered for patients with cavitary disease, but the dosing regimens are azithromycin 250 mg, ethambutol 15 mg/kg, and rifampin 600 mg. Parenteral streptomycin or amikacin at 15 mg/kg is recommended as a fourth drug. Duration of therapy is as for nodular disease. In advanced pulmonary disease or during re-treatment, rifabutin 300 mg daily may replace rifampin. Because clarithromycin susceptibility correlates
with outcome, risk of failure is high when high clarithromycin MICs are documented. Patients at risk for failure also include those with cavitary disease, presumably due to higher bacillary load. Even with these therapies, long-term success is still fairly limited (~50%).

**THERAPY FOR DISSEMINATED M. AVIUM COMPLEX**

Disseminated MAC disease is caused by *M. avium* in 95% of patients. This is a disease of the immunocompromised patient. Patients at risk for infection are those who have had other opportunistic infections, are colonized with MAC, or have an HIV RNA burden >5 log₁₀ copies/mm³.

The symptoms of disseminated disease are nonspecific and include fever, night sweats, weight loss, elevated serum alkaline phosphates, and anemia at the time of diagnosis. However, when disease occurs in patients already on anti-retroviral therapy, it may manifest as a focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection.

**PROPHYLACTIC THERAPY.** Monotherapy with either oral azithromycin 1200 mg once a week or clarithromycin 500 mg twice a day is started when patients present with a CD4 count <50/mm³. For patients intolerant of macrolides, rifabutin 300 mg/day is administered. Once the CD4 count is >100 per mm³ for ≥3 months, MAC prophylaxis should be discontinued.

**DEFINITIVE AND SUPPRESSIVE THERAPY.** In patients with disease due to MAC, the goals of therapy include suppression of symptoms and conversion to negative blood cultures. The infection itself is not completely eradicated until immune reconstitution. Recommended therapy consists of a combination of clarithromycin 500 mg twice a day with ethambutol 15 mg/kg daily, administered orally. Azithromycin 500-600 mg daily is an acceptable alternative to clarithromycin. The addition of rifabutin 300 mg/day may improve outcomes. Mortality in disseminated MAC is high in patients with either a CD4 cell count <50/mm³ or a MAC burden of >2 log₁₀ CFU/mm³ of blood, or in the absence of effective antiretroviral therapy. In these patients, a fourth drug may be added, based on susceptibility testing. Potential fourth agents include amikacin, 10-15 mg/kg intravenously daily; streptomycin, 1 g intravenously or intramuscularly
daily; ciprofloxacin, 500-750 mg orally twice daily; levofloxacin, 500 mg orally daily; or moxifloxacin, 400 g orally daily. Patients should be continued on suppressive therapy until all of these criteria are met:

- Therapy duration of at least 12 months
- CD4 count >100/mm³ for at least 6 months
- Asymptomatic for MAC infection

**PRINCIPLES OF ANTI-LEPROSY THERAPY**

The global prevalence of leprosy has declined by 90% since 1985, largely due to the global initiative of the WHO to eliminate leprosy (Hansen disease) as a public health problem by providing multidrug therapy (rifampin, clofazimine, and dapsone) free of charge.

**TYPES OF ANTI-LEPROSY THERAPY**

Therapy for leprosy is based on multidrug regimens using rifampin, clofazimine, and dapsone. The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. The most bactericidal drug in current regimens is rifampin. Because of high kill rates and massive release of bacterial antigens, rifampin is not often given during a “reversal” reaction (see below) or in patients with erythema nodosum leprosum. Clofazimine is only bacteriostatic against *M. leprae*. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema nodosum leprosum. The third major agent in the regimen is dapsone. The objective of administering these drugs is total cure.

**PAUCI-BACILLARY LEPROSY.** The WHO regimen consists of a single dose of oral rifampin, 600 mg, combined with dapsone, 100 mg, administered under direct supervision once every month for 6 months, and dapsone, 100 mg a day, in between for 6 months. In the U.S., the regimen consists of dapsone, 100 mg, and rifampin, 600 mg, daily for 6 months, followed by dapsone monotherapy for 3-5 years.

**MULTIBACILLARY THERAPY.** The WHO recommends the same regimen as
for paucibacillary leprosy, with 2 major changes. First, clofazimine, 300 mg a
day, is added for the entirety of therapy. Second, the regimen lasts 1 year instead
of 6 months. In the U.S., the regimen is also the same as for paucibacillary, but
dual therapy continues for 3 years, followed by dapsone monotherapy for 10
years. Clofazimine is added when there is dapsone resistance or chronically
reactional patients. Viable bacilli are killed within 3 months of therapy,
suggesting that the length of current therapy for multibacillary leprosy may be
unnecessarily long. Recently, the WHO proposed that all forms of leprosy be
treated with the same dose as for paucibacillary leprosy. This new shorter
regimen promises to reduce duration of therapy radically.

TREATMENT OF REACTIONS IN LEPROSY. Patients with tuberculoid
leprosy may develop “reversal reactions,” manifestations of delayed
hypersensitivity to antigens of *M. leprae*. Early therapy with corticosteroids or
clofazimine is effective. Reactions in the lepromatous form of the disease
(erythema nodosum leprosum) are characterized by the appearance of raised,
tender, intracutaneous nodules, severe constitutional symptoms, and high fever.
Treatment with clofazimine or thalidomide is effective.

THERAPY FOR OTHER NONTUBERCULOUS MYCOBACTERIA

Mycobacteria other than those already discussed can be recovered
from a variety of lesions in humans. Therapy for infections from these
organisms is summarized in Table 56–5.

*In HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and non-nucleoside reverse transcriptase inhibitors.*

*Based on animal models.

*For Mycobacterium ulcerans, surgery is the primary therapy.
There are 200,000 known species of fungi, and estimates of the total size of Kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, smuts, the pathogens *Aspergillus fumigatus* and *Candida albicans*, and the source of penicillin, *Penicillium chrysogenum*. Fortunately, only ~400 fungi cause disease in animals, and even fewer cause significant human disease. However, fungal infections are becoming more common in patients with compromised immune systems. Fungi are eukaryotes with unique cell walls containing glucans and chitin, and their eradication requires different strategies than those for treatment of bacterial infections. Available agents have effects on the synthesis of membrane and cell-wall components, on membrane permeability, on the synthesis of nucleic acids, and on microtubule/mitotic spindle function (Figure 57–1). Antifungal agents described in this chapter are discussed under two major headings, systemic and topical, although this distinction is somewhat arbitrary. The imidazole, triazole, and polyene antifungal agents may be used either systemically or topically, and many superficial mycoses can be treated either systemically or topically. Table 57–1 summarizes common mycoses and their pharmacotherapy.

*Figure 57–1 Sites of action of antifungal drugs.* Amphotericin B and other polyenes (e.g., nystatin) bind to ergosterol in fungal cell membranes and increase
membrane permeability. The imidazoles and triazoles (itraconazole, et al.) inhibit 14-α-sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of 14-α-methylsterols. The allylamines (e.g., naftifine and terbinafine) inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins, such as caspofungin, inhibit the formation of glucans in the fungal cell wall.

</table>
AMPHOTERICIN B. Amphotericin B is an amphoteric polyene macrolide with broad spectrum antifungal activity.

MECHANISM OF ACTION. Amphotericin B has useful clinical activity against a broad range of pathogenic fungi and limited activity against the protozoa Leishmania spp. and Naegleria fowleri. The antifungal activity of amphotericin B depends principally on its binding to a sterol moiety, primarily ergosterol in the membrane of sensitive fungi. By virtue of their interaction with these sterols, polyenes appear to form pores or channels that increase the permeability of the membrane, allowing leakage of a variety of small molecules (see Figure 57–1).

FORMULATIONS. Table 57–2 summarizes the pharmacokinetic properties of the 4 available preparations.

C-AMB (conventional amphotericin B, FUNGIZONE). Amphotericin B is insoluble in water but is formulated for intravenous infusion by complexing it with the bile salt deoxycholate. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely <0.4 μm in diameter. Filters in intravenous infusion lines that trap particles >0.22 μm in diameter will remove significant amounts of drug. Addition of electrolytes to infusion solutions causes the colloid to aggregate.

ABCD. Amphotericin B colloidal dispersion (AMPHOTEC, AMPHOCIL) contains roughly equimolar amounts of amphotericin B and cholesteryl sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when dispersed in aqueous solution.

L-AMB. Liposomal amphotericin B is a small, unilamellar vesicle formulation of amphotericin B (AMBISOME). The drug is supplied as a lyophilized powder, which is reconstituted with sterile water for injection.

ABLC (ABELCET). Amphotericin B lipid complex is a complex of amphotericin B with lipids (dymristoylphosphatidylcholine and dymristoylphosphatidylglycerol).
The 3 lipid formulations collectively appear to reduce the risk of the patient’s serum creatinine doubling during therapy by 58%. However, the cost of the lipid formulations greatly exceeds that of C-AMB, making them unavailable in many countries.

**ADME.** GI absorption of all amphotericin B formulations is negligible and IV delivery is indicated for systemic use. Amphotericin B in plasma is more than 90% bound to proteins. Pharmacokinetic parameters vary with the formulation. Azotemia, liver failure, or hemodialysis does not have a measurable impact on plasma concentrations. Concentrations of amphotericin B (via C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are approximately two-thirds of trough concentrations in plasma. Little amphotericin B from any formulation penetrates into cerebrospinal fluid (CSF), vitreous humor, or normal amniotic fluid.

**ANTIFUNGAL ACTIVITY; FUNGAL RESISTANCE.** Amphotericin B has useful clinical activity against *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides* spp., *Paracoccidioides brasiliensis*, *Aspergillus* spp., *Penicillium marneffei*, and the agents of mucormycosis. Amphotericin B has limited activity against the protozoa *Leishmania* spp. and *N. fowleri*. The drug has no antibacterial activity. Some isolates of *Candida lusitaniae* have been relatively resistant to amphotericin B. *Aspergillus terreus* and perhaps *Aspergillus nidulans* may be more resistant to amphotericin B than other *Aspergillus* species.

**THERAPEUTIC USES.** The recommended doses for each formulation are summarized in Table 57–2. Candida esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB is useful in patients with meningitis caused by *Coccidioides*. Too little is known about intrathecal administration of lipid formulations to recommend them. C-AMB can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10-15 mg of hydrocortisone. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used successfully for fungal endophthalmitis. Intravenous administration of amphotericin B is the treatment of choice for mucormycosis and is used for initial treatment of cryptococcal meningitis, severe or rapidly progressing
histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis marneffei, as well as in patients not responding to azole therapy of invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, and trichosporonosis. Amphotericin B (C-AMB or L-AMB) is often given to selected patients with profound neutropenia who have fever that does not respond to broad-spectrum antibacterial agents over 5-7 days.

</table>

UNTOWARD EFFECTS. The major acute reactions to intravenous amphotericin B formulations are fever and chills. Infusion-related reactions are worst with ABCD and least with L-AMB. Tachypnea and respiratory stridor or modest hypotension also may occur, but true bronchospasm or anaphylaxis is rare. Patients with pre-existing cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30-45 min; meperidine may shorten it. Pretreatment with oral acetaminophen or use of intravenous glucocorticoids at the start of the infusion decreases reactions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses. Lipid formulations are less nephrotoxic, being much less with ABLC, even less with L-AMB, and minimal with ABCD. Toxicity is dose-dependent and usually transient and increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or cyclosporine. Permanent functional impairment is uncommon in adults with normal renal function prior to treatment unless the cumulative dose exceeds 3-4 g. Renal tubular acidosis and renal wasting of K<sup>+</sup> and Mg<sup>2+</sup> also may be seen during and for several weeks after therapy, often
requiring repletion. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommended for adults who are able to tolerate the Na⁺ load.

Hypochromic, normocytic anemia commonly occurs during treatment with C-AMB. Anemia is less with lipid formulations and usually not seen over the first 2 weeks. The anemia is most likely due to decreased production of erythropoietin and often responds to administration of recombinant erythropoietin. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common. Arachnoiditis has been observed as a complication of injecting C-AMB into the CSF.

**FLUCYTOSINE**

Flucytosine (5-fluorocytosine) has a spectrum of antifungal activity that is considerably more restricted than that of amphotericin B.

**MECHANISM OF ACTION.** All susceptible fungi are capable of deaminating flucytosine to 5-fluorouracil (5-FU) ([Figure 57–2](#)), a potent antimetabolite that is used in cancer chemotherapy (see Chapter 61). Fluorouracil is metabolized first to 5-fluorouracil-ribose monophosphate (5-FUMP) by the enzyme uracil phosphoribosyl transferase (UPRTase). 5-FUMP then is either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5-fluoro-2′-deoxyuridine-5′-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthetase and thus of DNA synthesis. The selective action of flucytosine is due to the lack of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.
Flucytosine (5-fluorocytosine) is transported by cytosine permease into the fungal cell, where it is deaminated to 5-fluorouracil (5-FU). The 5-FU is converted to 5-fluorouracil-ribose monophosphate (5-FUMP) and then is either converted to 5-fluorouridine triphosphate (5-FUTP) and incorporated into RNA or converted to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthase. 5-FUDP, 5-fluorouridine-5'-diphosphate; dUMP, deoxyuridine-5'-monophosphate; dTMP, deoxythymidine-5'-monophosphate; PRT, phosphoribosyltransferase.

**ANTIFUNGAL ACTIVITY.** Flucytosine has clinically useful activity against *C. neoformans*, *Candida* spp., and the agents of chromoblastomycosis.

**FUNGAL RESISTANCE.** Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (see Figure 57–2).

**ADME.** Flucytosine is absorbed rapidly and well from the GI tract and widely distributed in the body. Approximately 80% of a given dose is excreted unchanged in the urine. The $t_{1/2}$ of the drug is 3-6 h but may reach 200 h in renal
failure. The clearance of flucytosine is approximately equivalent to that of creatinine. Reduction of dosage is necessary in patients with decreased renal function, and concentrations of drug in plasma should be measured periodically (desirable range of peak concentrations, 50 and 100 μg/mL). Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis; the drug also is removed by peritoneal dialysis.

**THERAPEUTIC USES.** Flucytosine (ANCOBON) is given orally at 50-150 mg/kg/day, in 4 divided doses at 6-h intervals. Flucytosine is used predominantly in combination with amphotericin B. An all-oral regimen of flucytosine plus fluconazole also has been advocated for therapy of AIDS patients with cryptococcosis, but the combination has substantial GI toxicity with no evidence that flucytosine adds benefit. The addition of flucytosine to ≥6 weeks of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B–induced azotemia occurs. The guidelines for the treatment of cryptococcal meningoencephalitis recommend addition of flucytosine (100 mg/kg orally in 4 divided doses) for the first 2 weeks of treatment with amphotericin B in AIDS patients.

**Untoward Effects.** Flucytosine may depress the bone marrow and lead to leukopenia. Other untoward effects include rash, nausea, vomiting, diarrhea, and severe enterocolitis. In ~5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia and when plasma drug concentrations exceed 100 μ/mL.

**IMIDAZOLES AND TRIAZOLES**

The azole antifungals include two broad classes, imidazoles and triazoles. Of the drugs now on the market in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, and sulconazole are imidazoles; terconazole,itraconazole, fluconazole, voriconazole, and posaconazole are triazoles. The topical use of azole antifungals is described in the second section of this chapter.
MECHANISM OF ACTION. The major effect of imidazoles and triazoles on fungi is inhibition of 14-α-sterol demethylase, a microsomal CYP (see Figure 57–1). Imidazoles and triazoles thus impair the biosynthesis of ergosterol for the cytoplasmic membrane and lead to the accumulation of 14-α-methylsterols. These methylsterols may disrupt the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems, thus inhibiting growth of the fungi.

ANTIFUNGAL ACTIVITY. Azoles as a group have clinically useful activity against *C. albicans*, *Candida tropicalis*, *Candida parapsilosis*, *Candida glabrata*, *C. neoformans*, *B. dermatitidis*, *H. capsulatum*, *Coccidioides* spp., *Paracoccidioides brasiliensis*, and ringworm fungi (dermatophytes). *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *S. schenckii* are intermediate in susceptibility. *Candida krusei* and the agents of mucormycosis are more resistant. These drugs have antiprotozoal effects against *Leishmania major*. Posaconazole has slightly improved activity in vitro against the agents of mucormycosis.

RESISTANCE. Azole resistance emerges gradually during prolongedazole therapy, causing clinical failure in patients with far-advanced HIV infection and oropharyngeal or esophageal candidiasis. The primary mechanism of resistance in *C. albicans* is accumulation of mutations in *ERG11*, the gene coding for the 14-α-sterol demethylase; cross-resistance is conferred to all azoles.

INTERACTION OF AZOLE ANTI-FUNGALS WITH OTHER DRUGS. The azoles interact with hepatic CYPs as substrates and inhibitors (Table 57–3), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some coadministered drugs (Table 57–4). Other coadministered drugs can decrease plasma concentrations of azole antifungal agents (Table 57–5). As a consequence of myriad interactions, combinations of certain drugs with azole antifungal medications may be contraindicated (Table 57–6).

**Table 57–3**

Interaction of Azole Antifungal Agents with Hepatic CYPs

**Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles. For details, see Chapter 6 and reference to Table 57–5.**

Table 57–6

Some Additional Contraindicated Azole Drug Combinations
KETOCONAZOLE

Ketoconazole, administered orally, has been replaced by itraconazole for the treatment of all mycoses except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Ketoconazole sometimes is used to inhibit excessive production of glucocorticoids in patients with Cushing syndrome (see Chapter 42) and is available for topical use.

ITRACONAZOLE

Itraconazole lacks ketoconazole’s corticosteroid suppression while
retaining most of ketoconazole’s pharmacological properties and expanding the antifungal spectrum. This synthetic triazole is an equimolar racemic mixture of 4 diastereoisomers.

**ADME.** Itraconazole (Sporanox, others) is available as a capsule and a solution in hydroxypropyl-β-cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations >150% of those obtained with the capsule. Itraconazole is metabolized in the liver; it is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxyitraconazole. The native drug and metabolite are >99% bound to plasma proteins. Neither appears in urine or CSF. The $t_{1/2}$ of itraconazole at steady state is ~30-40 h. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect.

**DRUG INTERACTIONS.** Tables 57–4, 57–5, and 57–6 list select interactions of azoles with other drugs.

**THERAPEUTIC USES.** Itraconazole is the drug of choice for patients with indolent, nonmeningeal infections due to *B. dermatitidis, H. capsulatum, P. brasiliensis,* and *Coccidioides immitis.* The drug also is useful in the therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with amphotericin B. Although not an approved use, itraconazole is a reasonable choice for the treatment of pseudallescheriasis, an infection not responding to amphotericin B therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or *P. marneffei* infections have a decreased incidence of relapse if given prolonged itraconazole “maintenance” therapy (see Chapter 59). Itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term therapy has been used in non-HIV–infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm. Itraconazole solution is effective and approved for use in oropharyngeal and esophageal
candidiasis. Because the solution has more GI side effects than fluconazole tablets, itraconazole solution usually is reserved for patients not responding to fluconazole.

**Dosage.** In treating deep mycoses, a loading dose of 200 mg of itraconazole is administered 3 times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. Divided doses may increase the AUC. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or for infections isolated to fingernails, 2 monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy. Once-daily terbinafine (250 mg) is superior to pulse therapy with itraconazole. For oropharyngeal candidiasis, itraconazole oral solution should be taken fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect. Patients with esophageal thrush unresponsive or refractory to treatment with fluconazole tablets are given 100 mg of the solution twice a day for 2-4 weeks.

**UNTOWARD EFFECTS; PRECAUTIONS.** Adverse effects of itraconazole therapy can occur as a result of interactions with many other drugs (see Tables 57–3 and 57–4). Serious hepatotoxicity has rarely led to hepatic failure and death. Intravenous itraconazole causes a dose-dependent inotropic effect that can lead to congestive heart failure in patients with impaired ventricular function. In the absence of interacting drugs, itraconazole capsules and suspension are well tolerated at 200 mg daily. Diarrhea, abdominal cramps, anorexia, and nausea are more common with the suspension than with the capsules. In patients receiving 50-400 mg of the capsules per day, nausea and vomiting, hypertriglyceridemia, hypokalemia, increased serum aminotransferase, and rash occurred in 2-10% of patients. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving ≥600 mg daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least 1 case, rhabdomyolysis. Doses >400 mg/day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome. Itraconazole is pregnancy
Category C and is contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy.

**FLUCONAZOLE**

**ADME.** Fluconazole is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously; its bioavailability is unaltered by food or gastric acidity. Renal excretion accounts for >90% of elimination; the elimination $t_1/2 \sim 25-30$ h. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50-90% of the values in plasma. The dosage interval should be increased in renal insufficiency. A dose of 100-200 mg should be given after each hemodialysis.

**DRUG INTERACTIONS.** Fluconazole is an inhibitor of CYP3A4 and CYP2C9 (see Tables 57–3 and 57–4). Patients who receive >400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen.

**THERAPEUTIC USES**

**Candidiasis.** Fluconazole, 200 mg on day 1 and then 100 mg daily for at least 2 weeks, is effective in oropharyngeal candidiasis. Doses of 100-200 mg daily have been used to decrease candiduria in high-risk patients. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A dose of 400 mg daily decreases the incidence of deep candidiasis in allogeneic bone marrow transplant recipients and is useful in treating candidemia of non-immunosuppressed patients. The drug has been used successfully as empirical treatment of febrile neutropenia in patients not responding to antibacterial agents and who are not at high risk of mold infections. *C. glabrata* becomes resistant upon prolonged exposure to fluconazole. Empirical use of fluconazole for suspected candidemia may not be advisable in patients who have been receiving long-term fluconazole prophylaxis and may be
colonized with azole-resistant *C. glabrata, Candida krusei* would not be expected to respond to fluconazole or other azoles.

**Cryptococcosis.** Fluconazole, 400 mg daily, is used for the initial 8 weeks in the treatment of cryptococcal meningitis in patients with AIDS after the patient’s clinical condition has been stabilized with at least 2 weeks of intravenous amphotericin B. After 8 weeks in patients no longer symptomatic, the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment for cryptococcosis, responds to HAART, has a CD4 count maintained >200/mm³ for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. Fluconazole, 400 mg daily, has been recommended as continuation therapy in non-AIDS patients with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis.

**Other Mycoses.** Fluconazole is the drug of choice for treatment of coccidioidal meningitis because of good penetration into the CSF and much less morbidity than intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has no useful activity against histoplasmosis, blastomycosis, or sporotrichosis and is not effective in the prevention or treatment of aspergillosis. Fluconazole has no activity in mucormycosis.

**UNTOWARD EFFECTS.** Side effects in patients receiving >7 days of drug, regardless of dose, include nausea, headache, skin rash, vomiting, abdominal pain, and diarrhea (all in the range of 2-4%). Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole has been associated with skeletal and cardiac deformities in several infants born to women taking high doses during pregnancy. Fluconazole is a Category C agent that should be avoided during pregnancy.

**DOSAGE.** Fluconazole (DIFLUCAN, others) is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. Generally recommended dosages are 50-400 mg
once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 3-12 mg/kg once daily (maximum: 600 mg/day).

**VORICONAZOLE**

Voriconazole (VFEND) is a triazole with a structure similar to fluconazole but with an expanded spectrum and poor aqueous solubility.

**ADME.** Oral bioavailability is 96%. Volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYPs 2C19 and 2C9; CYP3A4 plays a limited role. Plasma elimination $t_{1/2}$ is 6 h. Voriconazole exhibits nonlinear metabolism so that higher doses cause greater-than-linear increases in systemic drug exposure. Genetic polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure: ~20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Less than 2% of parent drug is recovered from urine; 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Patients with mild-to-moderate cirrhosis should receive the same loading dose of voriconazole but half the maintenance dose. The intravenous formulation of voriconazole contains sulfobutyl ether β-cyclodextrin (SBECD), which is excreted by the kidney. Significant accumulation of SBECD occurs with a creatinine clearance <50 mL/min; in that setting, oral voriconazole is preferred.

**DRUG INTERACTIONS.** Voriconazole is metabolized by, and inhibits, CYPs 2C19, 2C9, and CYP3A4 (in that order of decreasing potency). The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease voriconazole plasma concentrations, respectively. Voriconazole and its major metabolite can increase the plasma concentrations of other drugs metabolized by these enzymes (see Tables 57–3, 57–4, and 57–5). Because the sirolimus AUC increases 11-fold when voriconazole is given, coadministration is contraindicated. *When starting voriconazole in a patient receiving ≥40 mg/day of omeprazole, reduce the dose of omeprazole by half.*
**THERAPEUTIC USES.** Voriconazole provided superior efficiency to C-AMB in the primary therapy of invasive aspergillosis. Although not approved, voriconazole has been used in the empirical therapy of neutropenic patients whose fever did not respond to >96 h of antibacterial therapy. Voriconazole is approved for use in esophageal candidiasis. Voriconazole is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with *P. boydii* (*S. apiospermum*) and *Fusarium* infections. Positive response of patients with cerebral fungal suggest that the drug penetrates infected brain.

**UNTOWARD EFFECTS.** Voriconazole is teratogenic in animals and is contraindicated in pregnancy (Category D). Although voriconazole is generally well-tolerated, occasional cases of hepatotoxicity have been reported; liver function should be monitored. Voriconazole can prolong the QTc interval, which can become significant in patients with other risk factors for torsade de pointes. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration; symptoms diminish with time. Patients receiving their first intravenous infusion have had anaphylactoid reactions requiring drug discontinuation. Rash occurs in 6% of patients.

**DOSAGE.** Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 h for two doses, followed by 3-4 mg/kg every 12 h, administered no faster than 3 mg/kg/h. As the patient improves, oral administration is continued as 200 mg every 12 h. Patients failing to respond may be given 300 mg every 12 h. Because high-fat meals reduce voriconazole bioavailability, oral drug should be given either 1 h before or 1 h after meals.

**POSACONAZOLE**

Posaconazole (NOXAFIL) is a synthetic structural analog of itraconazole with the same broad antifungal spectrum but with up to 4-fold greater activity in vitro against yeasts and filamentous fungi, including the agents of mucormycosis. As for other imidazoles, the mechanism of action is inhibition of sterol 14-α demethylase.

**ADME.** Bioavailability is variable and significantly enhanced by the presence of
food. The drug has a long $t_{1/2}$ (25-31 h), a large volume of distribution (331-1341 L), and extensive binding (>98%) to protein. Systemic exposure is 4 times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7-10 days when dosed 4 times daily. Hepatic impairment causes a modest increase in plasma concentrations. Almost 80% of the drug and its metabolites are excreted in the stool, with 66% as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation. Hemodialysis does not remove drug from the circulation. Gastric acid improves absorption. Drugs that reduce gastric acid (e.g., cimetidine and esomeprazole) decrease posaconazole exposure by 32-50%. Diarrhea reduces the average plasma concentration by 37%.

**THERAPEUTIC USE.** Posaconazole is used for treatment of oropharyngeal candidiasis, although fluconazole is preferred because of safety and cost. Posaconazole is approved for prophylaxis against candidiasis and aspergillosis in patients >13 years of age who have prolonged neutropenia or severe graft-versus-host disease (GVHD). It is approved in the E.U. as salvage therapy for aspergillosis and several other infections, as are itraconazole and voriconazole. Posaconazole is available as a flavored suspension containing 40 mg/mL. Dosage for adults and children >8 years of age is 200 mg (5 mL suspension) 3 times daily for prophylaxis. Treatment of active infection is begun at 200 mg 4 times daily and changed to 400 mg twice daily once infection has improved. All doses should be taken with a full meal.

**DRUG INTERACTIONS.** Posaconazole inhibits CYP3A4. Coadministration with rifabutin or phenytoin increases the plasma concentration of these drugs and decreases posaconazole exposure by 2-fold. Posaconazole is not known to prolong cardiac repolarization but should not be coadministered with drugs that are CYP3A4 substrates and prolong the QTc interval (see Tables 57–4 and 57–6).

**UNTOWARD EFFECTS.** Common adverse effects include nausea, vomiting, diarrhea, abdominal pain, and headache. Although adverse effects occur in at least a third of patients, discontinuation due to adverse effects in long-term studies has been only 8%. Posaconazole is pregnancy Category C.

**DOSAGE.** Dosage for adults and children >8 years of age is 200 mg (5 mL suspension) 3 times daily for prophylaxis. Treatment of active infection is begun
at 200 mg 4 times daily and changed to 400 mg twice daily once infection has improved. All doses should be taken with a full meal.

**ISAVUCONAZOLE**

Isavuconazole (BAL8557) is an investigational water-soluble prodrug of the synthetic triazole, BAL4815. The prodrug is readily cleaved by esterases in the human body to release the active triazole. In vitro activity is comparable to voriconazole. Following oral administration, the drug has a long half-life, ~100 h, and is well tolerated. Phase III trials are enrolling patients with deeply invasive candidiasis and aspergillosis.

**ECHINOCANDINS**

*Echinocandins* inhibit formation of 1,3-β-D-glucans in the fungal cell wall, reducing its structural integrity ([Figure 57–3](#)), resulting in osmotic instability and cell death. Three echinocandins are approved for clinical use: caspofungin, micafungin, and anidulafungin. All are cyclic lipopeptides with a hexapeptide nucleus. Susceptible fungi include *Candida* and *Aspergillus* species.

![Diagram of fungal cell wall with echinocandins](image)

**Figure 57–3 The action of echinocandins.** The strength of the fungal cell wall is maintained by fibrillar polysaccharides, largely β-1,3-glucan and chitin, which
bind covalently to each other and to proteins. A glucan synthase complex in the plasma membrane catalyzes the synthesis of β-1,3-glucan; the glucan is extruded into the periplasm and incorporated into the cell wall. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. A subunit of glucan synthase designated Fks1p is thought to be the target of the echinocandin. Mutations in Fks1p, coded by FSK1, cause resistance to echinocandins.

**GENERAL PHARMACOLOGICAL CHARACTERISTICS.** Echinocandins differ somewhat pharmacokinetically (Table 57–7) but all share lack of oral bioavailability, extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight to modest effect of hepatic insufficiency on plasma drug concentration. Adverse effects are minimal. All 3 agents are pregnancy Category C.

**CASPOFUNGIN**

Caspofungin acetate (CANCIDAS) is a water-soluble, semisynthetic lipopeptide.

**CLINICAL PHARMACOLOGY.** Catabolism is largely by hydrolysis and N-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increase the AUC by 55% and 76%, respectively. Caspofungin increases tacrolimus levels by 16%, which should be managed by standard monitoring. Cyclosporine slightly increases caspofungin levels. Rifampin and other drugs activating CYP3A4 can cause reduction in caspofungin levels. Caspofungin is approved for initial therapy of deeply invasive candidiasis and as salvage therapy for patients with invasive aspergillosis who are failing approved drugs, such as amphotericin B.
formulations or voriconazole. Caspofungin is also approved for esophageal candidiasis and for the treatment of persistently febrile neutropenic patients with suspected fungal infections. Caspofungin is well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. Other symptoms have been equivalent to those observed in patients receiving fluconazole.

Caspofungin is administered intravenously once daily over 1 h. In candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving rifampin as well as in those failing to respond to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

MICAFUNGIN
Micafungin (MYCAMINE) is a water-soluble semisynthetic echinocandin. Micafungin has linear pharmacokinetics over a large range of doses (1-3 mg/kg) and ages. Small amounts of drug are metabolized in the liver by arylsulfatase and catechol O-methyltransferase. About 71% of both native drug and metabolites are excreted in the feces. Reduction of dose in moderate hepatic failure is not required. Clearance is more rapid in premature infants compared to older children and adults. Micafungin is a mild inhibitor of CYP3A4, increasing AUC of nifedipine by 18% and sirolimus by 21%. Micafungin has no effect on tacrolimus clearance.

The drug is approved for the treatment of deeply invasive candidiasis and esophageal candidiasis and for prophylaxis of deeply invasive candidiasis in hematopoietic stem cell transplant recipients. Micafungin is given intravenously as 100 mg daily over 1 h for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis.

ANIDULAFUNGIN
Anidulafungin (ERAXIS) is a water-insoluble semisynthetic compound extracted from the fungus A. nidulans. The drug is cleared from the body by slow chemical degradation. No metabolism by the liver or
renal excretion occurs. There are no known drug interactions. Anidulafungin appears noninferior to fluconazole in candidemia of non-neutropenic patients and is approved for the treatment of esophageal candidiasis. Drug dissolved in the supplied diluent is infused once daily in saline or 5% dextrose in water at a rate not exceeding 1.1 mg/min. For deeply invasive candidiasis, anidulafungin is given daily as a loading dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading dose of 100 mg is followed by 50 mg daily.

**GRISEOFULVIN**

**MECHANISM OF ACTION.** Griseofulvin is a practically insoluble fungistatic that inhibits microtubule function and thereby disrupts assembly of the mitotic spindle. Although the effects of the drug are similar to those of *colchicine* and the vinca alkaloids, griseofulvin’s binding sites on the tubulin are distinct; griseofulvin also interacts with microtubule-associated protein.

**ADME.** Blood levels after oral administration are quite variable. Absorption is improved when the drug is taken with a fatty meal. Because the rates of dissolution and disaggregation limit the bioavailability of griseofulvin, micro-sized and ultra-micro-sized powders are now used in preparations (Grifulvin V and Gris-PEG, respectively). Griseofulvin has a plasma t½ of 1 day, and 150% of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites; the primary metabolite is 6-methylgriseofulvin. Barbiturates decrease griseofulvin absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug remains tightly bound to keratin, providing prolonged resistance to fungal invasion. For this reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum of the skin within 4-8 h of oral administration. Only a very small fraction of a dose of the drug is present in body fluids and tissues.
ANTIFUNGAL ACTIVITY. Griseofulvin is fungistatic in vitro for various species of the dermatophytes *Microsporum*, *Epidermophyton*, and *Trichophyton*. The drug has no effect on bacteria or on other fungi.

THERAPEUTIC USES. Mycotic disease of the skin, hair, and nails responds to griseofulvin therapy. For tinea capitis in children, griseofulvin remains the drug of choice; efficacy is best for tinea capitis caused by *Microsporum canis*, *Microsporum audouinii*, *Trichophyton schoenleinii*, and *Trichophyton verrucosum*. Griseofulvin is also effective for ringworm of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis*, *Trichophyton rubrum*, *T. verrucosum*, and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *Trichophyton mentagrophytes*) and beard (*Trichophyton species*). *T. rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses of griseofulvin.

DOSAGE. The recommended daily dose of griseofulvin is 2.3 mg/kg (up to 500 mg) for children and 500 mg to 1 g for adults. Doses of 1.5-2 g daily may be used for short periods in severe or extensive infections. Best results are obtained when the daily dose is divided and given at 6-h intervals. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6-9 months for fingernails, and at least a year for toenails. Itraconazole or terbinafine is much more effective for onychomycosis.

UNTOWARD EFFECTS. The incidence of serious reactions due to griseofulvin is very low. Headache occurs in 15% of patients. Other side effects include GI and nervous system manifestations, and augmentation of the effects of alcohol. Hepatotoxicity also has been observed. Hematological effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity, lichen planus, erythema, erythema multiforme–like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes and severe angioedema develop rarely. Estrogen-like effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.
Griseofulvin induces hepatic CYPs, thereby increasing the rate of metabolism of warfarin; adjustment of the dosage of the latter agent may be necessary in some patients. The drug may reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

**TERBINAFINE**

Terbinafine is a synthetic allylamine, structurally similar to the topical agent naftifine (see below). It acts by inhibiting fungal squalene epoxidase, thereby reducing ergosterol biosynthesis (see Figure 57–1).

Terbinafine is well absorbed, but bioavailability is ~40% due to first-pass metabolism in the liver. The drug accumulates in skin, nails, and fat. The initial $t_{1/2}$ is ~12 h but extends to 200-400 h at steady state. Terbinafine is not recommended in patients with marked azotemia or hepatic failure. Rifampin decreases and cimetidine increases plasma terbinafine concentrations. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. The drug is pregnancy Category B and it is recommended that systemic terbinafine therapy for onychomycosis be postponed until after pregnancy is complete. Terbinafine (LAMISIL, others), given as one 250-mg tablet daily for adults, is somewhat more effective for nail onychomycosis than itraconazole. Duration of treatment varies with the site being treated but typically is 6-12 weeks. Efficacy in onychomycosis can be improved by the simultaneous use of amorolfine 5% nail lacquer. Terbinafine also is effective in tinea capitis and is used off-label for ringworm elsewhere on the body.

**TOPICAL ANTIFUNGAL AGENTS**

Topical treatment is useful in many superficial fungal infections, i.e., those confined to the stratum corneum, squamous mucosa, or cornea. Such diseases include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis.

The preferred formulation for cutaneous application usually is a cream or
solution. Ointments are messy and are too occlusive. The use of powders is largely confined to the feet and moist lesions of the groin and other intertriginous areas. Topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and has no place in the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy.

**IMIDAZOLES AND TRIAZOLES FOR TOPICAL USE**

These closely related classes of drugs are synthetic antifungal agents that are used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is very rare among the fungi that cause ringworm.

**CUTANEOUS APPLICATION.** The preparations for cutaneous use described below are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3-6 weeks. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

**VAGINAL APPLICATION.** Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1-7 days, preferably at bedtime. None is useful in trichomoniasis. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher doses. These preparations are administered for 3-7 days. Approximately 3-10% of the vaginal dose is absorbed. No adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles.

**ORAL USE.** Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis.

**CLOTRIMAZOLE.** Absorption of clotrimazole is <0.5% after application to the
intact skin; from the vagina, it is 3-10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. The small amount absorbed is metabolized in the liver and excreted in bile. Clotrimazole on the skin may cause stinging, erythema, edema, vesication, desquamation, pruritus, and urticaria. When it is applied to the vagina, ~1.6% of recipients complain of a mild burning sensation, and rarely of lower abdominal cramps, a slight increase in urinary frequency, or skin rash. The sexual partner may experience penile or urethral irritation. By the oral route, clotrimazole can cause GI irritation. In patients using troches, the incidence of this side effect is ~5%.

**THERAPEUTIC USES.** Clotrimazole is available as a 1% cream, lotion, powder, aerosol solution, and solution (LOTRIMIN AF, MYCELEX, others), 1% or 2% vaginal cream, or vaginal tablets of 100, 200, or 500 mg (GYNE-LOTRIMIN, others), and 10-mg troches (MYCELEX, others). For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth 5 times a day for 14 days.

Topical clotrimazole cures dermatophyte infections in 60-100% of cases. The cure rates in cutaneous candidiasis are 80-100%. In vulvovaginal candidiasis, the cure rate is usually >80% with the 7-day regimen. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

**ECONAZOLE**

Econazole is the deschloro derivative of miconazole. Econazole readily penetrates the stratum corneum and is found in effective concentrations down to the mid-dermis. Less than 1% of an applied dose appears to be absorbed into the blood. Approximately 3% of recipients have local erythema, burning, stinging, or itching. Econazole nitrate (SPECTAZOLE, ECOSTATIN, others) is available as a water-miscible cream (1%) to be applied twice a day.

**MICONAZOLE**
Miconazole readily penetrates the stratum corneum of the skin and persists there for >4 days after application. Less than 1% is absorbed into the blood. Absorption is no more than 1.3% from the vagina. Adverse effects from topical application to the vagina include burning, itching, or irritation in ~7% of recipients, and infrequently, pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy, although some recommend avoiding its use during the first trimester.

**THERAPEUTIC USES.** Miconazole nitrate is available as a cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution (Micatin, Zeasorb-AF, others). To avoid maceration, only the lotion should be applied to intertriginous areas. Miconazole is available as a 2% and 4% vaginal cream, and as 100-mg, 200-mg, or 1200-mg vaginal suppositories (Monistat 7, Monistat 3, Monistat 1, others), to be applied high in the vagina at bedtime for 7, 3, or 1 day(s), respectively. In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate may be >90%. In the treatment of vulvovaginal candidiasis, the mycologic cure rate at the end of 1 month is ~80-95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *C. glabrata* also respond.

**TERCONAZOLE AND BUTOCONAZOLE**

Terconazole (TERAZOL, others) is a ketal triazole with a mechanism of action similar to that of the imidazoles. The 80-mg vaginal suppository is inserted at bedtime for 3 days; the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for clotrimazole in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically comparable to clotrimazole. Butoconazole nitrate ( Femstat 3, others) is available as a 2% vaginal cream. Because of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimester).
Tioconazole (VAGISTAT 1, others) is an imidazole marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg) is given at bedtime.

**OXICONAZOLE, SULCONAZOLE, AND SERTACONAZOLE**
These imidazole derivatives are used for the topical treatment of infections caused by the common pathogenic dermatophytes. Oxiconazole nitrate (OXISTAT) is available as a 1% cream and lotion; sulconazole nitrate (EXELDERM, SULCOSYN) is supplied as a 1% solution and/or cream. Sertaconazole (ERTACZO) is a 2% cream marketed for tinea pedis.

**KETOCONAZOLE**
This imidazole is available as a 0.5% cream, foam, gel, and shampoo (NIZORAL, others) for common skin dermatophytes infections, for tinea versicolor, and seborrheic dermatitis.

**STRUCTURALLY DIVERSE ANTIFUNGAL AGENTS**

**CICLOPIROX OLAMINE**
Ciclopirox olamine (LOPROX, others) has broad-spectrum antifungal activity. It is fungicidal to *C. albicans*, *E. floccosum*, *M. canis*, *T. mentagrophytes*, and *T. rubrum*. It also inhibits the growth of *Malassezia furfur*. After application to the skin, it penetrates through the epidermis into the dermis, but even under occlusion, <1.5% is absorbed into the systemic circulation. Because the $t_{1/2}$ is 1.7 h, no systemic accumulation occurs. The drug penetrates into hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% topical solution (PENLAC NAIL LACQUER, others) is available for onychomycosis. Ciclopirox gel and 1% shampoo are also used for the treatment of seborrheic dermatitis of the scalp. Cure rates in the dermatomycoses and candidal infections are 81-94%. No topical toxicity has been noted.
**HALOPROGIN**

*Haloprogin* is a halogenated phenolic ether. It is fungicidal to *Epidermophyton, Pityrosporum, Microsporum, Trichophyton,* and *Candida*. Irritation, pruritus, burning sensations, vesiculation, increased maceration, and “sensitization” (or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive footgear is worn. Haloprogin is poorly absorbed through the skin; it is converted to trichlorophenol in the body; the systemic toxicity from topical application appears to be low. Haloprogin (HALOTEX) cream or solution is applied twice a day for 2-4 weeks. Its principal use is against tinea pedis. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the U.S.

**TOLNAFTATE**

Tolnaftate is a thiocarbamate. It is effective in the treatment of most cutaneous mycoses caused by *T. rubrum, T. mentagrophytes, Trichophyton tonsurans, E. floccosum, M. canis, M. audouinii, Microsporum gypseum,* and *M. furfur,* but it is ineffective against *Candida*. In tinea pedis, the cure rate is ~80%, compared with ~95% for miconazole. Tolnaftate (AFTATE, TINACTIN, others) is available in a 1% concentration as a cream, gel, powder, aerosol powder, and topical solution, or as a topical aerosol liquid. Pruritus is usually relieved in 24-72 h. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7-21 days. Toxic or allergic reactions to tolnaftate have not been reported.

**NAFTIFINE**

Naftifine, a synthetic allylamine, inhibits squalene-2,3-epoxidase and thus inhibit fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity in vitro. Naftifine hydrochloride (NAFTIN) is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Although not
approved for these uses, naftifine may be efficacious for cutaneous candidiasis and tinea versicolor.

**TERBINAFINE**
Terbinafine 1% cream or spray is applied twice daily and is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against *Candida* species and *M. furfur*, but the cream also can be used in cutaneous candidiasis and tinea versicolor.

**BUTENAFINE**
Butenafine hydrochloride (MENTAX, LOTRIMIN ULTRA) is a benzylamine derivative with a mechanism of action and spectrum of activity similar to those of terbinafine, naftifine, and other allylamines.

**POLYENE ANTIFUNGAL AGENTS**

**NYSTATIN**
Nystatin, a tetraene macrolide produced by *Streptomyces noursei*, is structurally similar to amphotericin B and has the same mechanism of action. The drug is not absorbed from the GI tract, skin, or vagina. Nystatin (MYCOSTATIN, NILSTAT, others) is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions and are applied 2 to 3 times daily. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available. Imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis. Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

**MISCELLANEOUS ANTIFUNGAL AGENTS**

**UNDECYLENIC ACID**
Undecylenic acid is primarily fungistatic and against a variety of fungi, including those that cause ringworm. Undecylenic acid (DESENEX, others) is available in a cream, powder, spray powder, soap, and liquid. Zinc undecylenate is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compound undecylenic acid ointment contains both undecylenic acid (~5%) and zinc undecylenate (~20%). Calcium undecylenate (CALDESENE, CRUEX) is available as a powder. Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compound ointment, may be applied to the skin. The preparations usually are not irritating to tissue, and sensitization to them is uncommon. In tinea pedis, the infection frequently persists despite intensive treatment and the clinical “cure” rate is ~50%, which is much lower than that obtained with the imidazoles, haloprogin, or tolnaftate. Undecylenic acid preparations also are approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

**Benzoic Acid and Salicylic Acid.** An ointment containing benzoic and salicylic acids is known as Whitfield’s ointment. It combines the fungistatic action of benzoate with the keratolytic action of salicylate (in a ratio of 2:1, usually 6-3%) and is used mainly in the treatment of tinea pedis. Because benzoic acid is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed. Continuous medication is required for several weeks to months. The salicylic acid accelerates the desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.
Viruses are simple microorganisms that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a capsid. Some viruses also possess a lipid envelope derived from the infected host cell, which, like the capsid, may contain antigenic glycoproteins. Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit virus-directed rather than host cell–directed nucleic acid or protein synthesis (Table 58–1). Host cell molecules that are essential to viral replication also offer targets for intervention. Figure 58–1 gives a schematic diagram of the replicative cycle of typical DNA and RNA viruses.

*Depends on specific replication strategy of virus, but virus-specified enzyme required for part of process.*
Figure 58–1 Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. cDNA, complementary DNA; cRNA, complementary RNA; DNAP, DNA polymerase; mRNA, messenger RNA; RNAP, RNA polymerase; vRNA, viral RNA. The symbol ——— indicates a block to virus growth. A. Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as thymidine
kinases, DNA polymerases, etc. After DNA replication, the bulk of the herpesvirus genes (called late genes) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions. B. Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP (ribonuclear protein) segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAp complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus.

DNA viruses include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes), adenoviruses (conjunctivitis, sore throat), hepadnaviruses (hepatitis B virus [HBV]), and papillomaviruses (warts). Most DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into mRNA by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. Poxviruses are an exception; they carry their own RNA polymerase and replicate in the host cell cytoplasm.

For RNA viruses, the replication strategy relies either on enzymes in the virion to synthesize mRNA or has the viral RNA serving as its own mRNA. The mRNA is transcribed into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA. Most RNA viruses complete their replication in the host cell cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses include rubella virus (German measles), rhabdoviruses (rabies), picornaviruses (poliomyelitis, meningitis, colds, hepatitis A), arenaviruses (meningitis, Lassa fever), flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C), orthomyxoviruses (influenza), paramyxoviruses (measles, mumps), and coronaviruses (colds, severe acute respiratory syndrome [SARS]). Retroviruses are RNA viruses that include human immunodeficiency virus (HIV); chemotherapy for retro-viruses is described in Chapter 59.

Table 58–2 summarizes currently approved drugs for nonretroviral infections. Their pharmacological properties are presented below, class by class, as listed in the table.

*Not currently approved for use in U.S. IV, intravenous; O, oral; T, topical; ophth, opthalmic.

**ANTI-HERPESVIRUS AGENTS**

Herpes simplex virus type 1 (HSV-1) typically causes diseases of the mouth, face, skin, esophagus, or brain. Herpes simplex virus type 2 (HSV-2) usually causes infections of the genitals, rectum, skin, hands, or meninges. Both cause serious infections in neonates. Acyclovir is the prototype of a group of antiviral agents that are nucleoside congeners that are phosphorylated intracellularly by a viral kinase and
subsequently by host cell enzymes to become inhibitors of viral DNA synthesis. Related agents include penciclovir and ganciclovir.

**ACYCLOVIR AND VALACYCLOVIR.** Acyclovir is an acyclic guanine nucleoside analog that lacks the 2′ and 3′positions normally supplied by ribose. Valacyclovir is the L-valyl ester prodrug of acyclovir.

![Acyclovir Structure](image)

Acyclovir’s clinical use is limited to herpesviruses. Acyclovir is most active against HSV-1 (0.02-0.9 μg/mL), approximately half as active against HSV-2 (0.03-2.2 μg/mL), a tenth as potent against varicella zoster virus (VZV; 0.8-4.0 μg/mL) and Epstein-Barr virus (EBV), and least active against cytomegalovirus (CMV) (generally >20 μg/mL) and human herpesvirus 6 (HHV-6). Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (>50 μg/mL).

**THERAPEUTIC USES.** In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones. These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Because VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating VZV infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster. Acyclovir is ineffective therapeutically in established cytomegalovirus (CMV) infections but ganciclovir is effective for CMV prophylaxis in immunocompromised patients. EBV-related oral hairy leukoplakia may improve with acyclovir. Oral acyclovir in conjunction with systemic corticosteroids appears beneficial in treating Bell palsy; valacyclovir is
ineffective in acute vestibular neuritis. See the 12th edition of the parent text for details of dosage regimens for specific indications in treating HSV, VZV, and CMV.

**MECHANISMS OF ACTION AND RESISTANCE.** Acyclovir inhibits viral DNA synthesis via a mechanism outlined in Figure 58–2. Its selectivity of action depends on interaction with HSV thymidine kinase and DNA polymerase. Cellular uptake and initial phosphorylation are facilitated by HSV thymidine kinase. The affinity of acyclovir for HSV thymidine kinase is ~200 times greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which competes for endogenous dGTP. The immunosuppressive agent mycophenolate mofetil (see Chapter 35) potentiates the anti-herpes activity of acyclovir and related agents by depleting intracellular dGTP pools. Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much lesser extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 3’-hydroxyl group. By a mechanism termed suicide inactivation, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.
Figure 58–2 *Mechanism of action of acyclovir in cells infected by herpes simplex virus.* A herpes simplex virion is shown attaching to a susceptible host cell, fusing its envelope with the cell membrane, and releasing naked capsids that deliver viral DNA into the nucleus, where it initiates synthesis of viral DNA. Acyclovir molecules entering the cell are converted to acyclovir monophosphate by virus-induced thymidine kinase. Host-cell enzymes add 2 more phosphates to form acyclovir triphosphate, which is transported into the nucleus. After the herpes DNA polymerase cleaves pyrophosphate from acyclovir triphosphate (*indicated by the red arrow in the inset*), viral DNA polymerase inserts acyclovir monophosphate rather than 2′-deoxyguanosine monophosphate into the viral DNA (*indicated by black arrows in the inset*). Further elongation of the chain is impossible because acyclovir monophosphate lacks the 3′ hydroxyl group necessary for the insertion of an additional nucleotide, and the exonuclease associated with the viral DNA polymerase cannot remove the acyclovir moiety. In contrast, ganciclovir and penciclovir have a 3′ hydroxyl group; therefore, further synthesis of viral DNA is possible in the presence of these drugs. Foscarnet acts at the pyrophosphate-binding site of viral DNA polymerase and

Acyclovir resistance in HSV can result from impaired production of viral thymidine kinase, altered thymidine kinase substrate specificity (e.g., phosphorylation of thymidine but not acyclovir), or altered viral DNA polymerase. Alterations in viral enzymes are caused by point mutations and base insertions or deletions in the corresponding genes. Resistant variants are present in native virus populations and in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral thymidine kinase activity; viral DNA polymerase mutants are rare. Phenotypic resistance typically is defined by in vitro inhibitory concentrations of >2-3 μg/mL, which predict failure of therapy in immunocompromised patients. Acyclovir resistance in VZV isolates is caused by mutations in VZV thymidine kinase and less often by mutations in viral DNA polymerase.

ADME. The oral bioavailability of acyclovir is ~10-30% and decreases with increasing dose. Valacyclovir is converted rapidly and virtually completely to acyclovir after oral administration. This conversion is thought to result from first-pass intestinal and hepatic metabolism through enzymatic hydrolysis. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptide transporters. The oral bioavailability of acyclovir increases ~70% following valacyclovir administration. Peak plasma concentrations of valacyclovir are only 4% of acyclovir levels. Less than 1% of an administered dose of valacyclovir is recovered in the urine; most is eliminated as acyclovir. Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and cerebrospinal fluid (CSF). Compared with plasma, salivary concentrations are low, and vaginal secretion concentrations vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of acyclovir after topical administration is low. The elimination $t_{1/2}$ of acyclovir is ~2.5 h (range: 1.5-6 h) in adults with normal renal function. The elimination $t_{1/2}$ of acyclovir is ~4 h in neonates and increases to 20 h in anuric patients. Renal excretion is the principal route of elimination.
UNTOWARD EFFECTS. Acyclovir generally is well tolerated. Topical acyclovir in a polyethylene glycol base may cause mucosal irritation and transient burning when applied to genital lesions. Oral acyclovir has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. Valacyclovir also may be associated with headache, nausea, diarrhea, nephrotoxicity, and CNS symptoms (confusion, hallucinations). Uncommon side effects include severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients. Acyclovir has been associated with neutropenia in neonates. The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Nephrotoxicity usually resolves with drug cessation and volume expansion. Hemodialysis may be useful in severe cases. Severe somnolence and lethargy may occur with combinations of zidovudine (see Chapter 59) and acyclovir. Concomitant cyclosporine and probably other nephrotoxic agents enhance the risk of nephrotoxicity. Probenecid decreases the acyclovir renal clearance and prolongs the elimination $t_{1/2}$. Acyclovir may decrease the renal clearance of other drugs eliminated by active renal secretion, such as methotrexate.

CIDOFOVIR. Cidofovir is a cytidine nucleotide analog with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses.

Because cidofovir is a phosphonate that is phosphorylated by cellular but not viral enzymes, it inhibits acyclovir-resistant thymidine kinase (TK)–deficient or TK-altered HSV or VZV strains, ganciclovir-resistant CMV strains with UL97 mutations (but not those with DNA polymerase mutations), and some foscarnet-resistant CMV strains. Cidofovir synergistically inhibits CMV replication in combination with ganciclovir or foscarnet.

THERAPEUTIC USES. Intravenous cidofovir is approved for the treatment of CMV retinitis in HIV-infected patients. Intravenous cidofovir has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients, and extensive molluscum contagiosum in HIV patients. Reduced doses without probenecid may be beneficial in BK virus nephropathy in renal transplant patients. Topical cidofovir gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum
contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intraloesional cidofovir induces remissions in adults and children with respiratory papillomatosis. See the 12th edition of the parent text for details of dosage regimens for specific indications.

MECHANISMS OF ACTION AND RESISTANCE. Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to ~30% of retinitis patients by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

ADME. Cidofovir has very low oral bioavailability. Penetration into the CSF is low. Topical cidofovir gel may result in low plasma concentrations (<0.5 μg/mL) in patients with large mucocutaneous lesions. Plasma levels after intravenous dosing decline in a biphasic pattern with a terminal $t_{1/2}$ that averages 2.6 h. The active form, cidofovir diphosphate, has a prolonged intracellular $t_{1/2}$ and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases. A phosphocholine metabolite also has a long intracellular $t_{1/2}$ (~87 h) and may serve as an intracellular reservoir of drug. The prolonged intracellular $t_{1/2}$ of cidofovir diphosphate allows infrequent dosing regimens. Cidofovir is cleared by the kidney via glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine. Probenecid blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. Elimination relates linearly to creatinine clearance; the $t_{1/2}$ increases to 32.5 h in patients on chronic ambulatory peritoneal dialysis (CAPD). Hemodialysis removes >50% of the administered dose.
UNTOWARD EFFECTS. Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Concomitant oral probenecid and saline prehydration reduce the risk of renal toxicity; however, probenecid alters renal clearance of many agents, albeit not of cidofovir. For example, probenecid alters zidovudine pharmacokinetics such that zidovudine doses should be reduced when probenecid is present, as should the doses of other drugs whose renal secretion probenecid inhibits (e.g., β-lactam antibiotics, nonsteroidal anti-inflammatory drugs [NSAIDs], acyclovir, lorazepam, furosemide, methotrexate, theophylline, and rifampin). On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10-15% show an elevated serum creatinine concentration, and 15-20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly and low intraocular pressure occurs infrequently with intravenous cidofovir. Administration with food and pretreatment with antiemetics, antihistamines, and/or acetaminophen may improve tolerance. Concurrent nephrotoxic agents are contraindicated, and at least 7 days should elapse before initiation of cidofovir treatment is recommended after prior exposure to aminoglycosides, intravenous pentamidine, amphotericin B, foscarnet, NSAID, or contrast dye. Cidofovir and oral ganciclovir are poorly tolerated in combination at full doses.

Topical application of cidofovir is associated with dose-related application-site reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. Cidofovir is considered a potential human carcinogen. It may cause infertility and is classified as pregnancy Category C.

FAMCICLOVIR AND PENCICLOVIR. Famciclovir is the diacetyl ester prodrug of 6-deoxy penciclovir and lacks intrinsic antiviral activity. Penciclovir is an acyclic guanine nucleoside analog. Penciclovir is similar to acyclovir in its spectrum of activity and potency against HSV and VZV. It also is inhibitory for HBV.

THERAPEUTIC USES. Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for managing HSV and VZV infections. See the 12th edition of the parent text for details of dosage regimens for specific indications.

MECHANISMS OF ACTION AND RESISTANCE. Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral TK. Penciclovir triphosphate is a competitive
inhibitor of viral DNA polymerase (see Figure 58–2). Although penciclovir triphosphate is approximately one one-hundredth as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in infected cells at much higher concentrations and for more prolonged periods. The prolonged intracellular $t_{1/2}$ of penciclovir triphosphate, 7-20 h, is associated with prolonged antiviral effects. Because penciclovir has a 3'-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation. Resistance during clinical use is low. TK–deficient, acyclovir-resistant herpes viruses are cross-resistant to penciclovir.

**ADME.** Oral penciclovir has low (<5%) bioavailability. In contrast, famciclovir is well absorbed orally (bioavailability ~75%) and is converted rapidly to penciclovir by deacetylation of the side chain and oxidation of the purine ring during and following absorption. Food slows absorption but does not reduce overall bioavailability. The plasma elimination $t_{1/2}$ of penciclovir averages ~2 h, and >90% is excreted unchanged in the urine. Following oral famciclovir administration, nonrenal clearance accounts for ~10% of each dose, primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor (<10% of dose) are eliminated primarily in the urine. The plasma $t_{1/2}$ averages 9.9 h in renal insufficiency ($Cl_{cr}$ 30 mL/min); hemodialysis efficiently removes penciclovir.

**UNTOWARD EFFECTS.** Oral famciclovir is associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical penciclovir (~1%) rarely is associated with local reactions. The short-term tolerance of famciclovir is comparable with that of acyclovir. Penciclovir is mutagenic at high concentrations. Long-term administration (1 year) does not affect spermatogenesis in men. Safety during pregnancy has not been established.

**FOMIVIRSEN.** Fomivirsen, a 21-base phosphorothioate oligonucleotide, provides antisense therapy.

The drug is complementary to the messenger RNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to
ganciclovir, foscarnet, and cidofovir. Fomivirsen is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous ($t_{1/2}$ 55 h) through distribution to the retina and probable exonuclease digestion. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen injections (330 μg weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression. Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15-20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions. The drug is no longer available in the U.S.

**FOSCARNET.** Foscarnet (trisodium phosphonoformate) is an inorganic pyrophosphate analog that is inhibitory for all herpesviruses and HIV.

**THERAPEUTIC USES.** Intravenous foscarnet is effective for treatment of CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections. Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration. See the 12th edition of the parent text for details of dosage regimens for specific indications.

**MECHANISMS OF ACTION AND RESISTANCE.** Foscarnet inhibits viral nucleic acid synthesis by interacting directly with herpesvirus DNA polymerase or HIV reverse transcriptase (see Figures 58–1A and 58–2). Foscarnet has ~100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase-α. Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase.

**ADME.** Oral bioavailability of foscarnet is low. Vitreous levels approximate those in plasma; CSF levels average 66% of those in plasma at steady state. Over 80% of foscarnet is excreted unchanged in the urine. Dose adjustments are indicated for small decreases in renal function. Plasma elimination has initial bimodal half-lives totaling 4-8 h and a prolonged terminal elimination $t_{1/2}$ averaging 3-4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10-20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).
UNTOWARD EFFECTS. Major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are generally reversible after cessation. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Saline loading may reduce the risk of nephrotoxicity. Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in Ca²⁺ and phosphate, hypomagnesemia, and hypokalemia. Concomitant intravenous pentamidine administration increases the risk of symptomatic hypocalcemia. CNS side effects include headache (25%), tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation and ulceration, and oral foscarnet may cause GI disturbance. Preclinical studies indicate that high foscarnet concentrations are mutagenic. Safety in pregnancy or childhood is uncertain.

GANCICLOVIR AND VALGANCICLOVIR. Ganciclovir is an acyclic guanine nucleoside analog that is similar in structure to acyclovir. Valganciclovir is the L-valyl ester prodrug of ganciclovir. Ganciclovir has inhibitory activity against all herpesviruses and is especially active against CMV.

THERAPEUTIC USES. Ganciclovir is effective for treatment and chronic suppression of CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant patients. A ganciclovir ophthalmic gel formulation (ZIRGAN) is effective in treating HSV keratitis. See the 12th edition of the parent text for details of dosage regimens for specific indications.

MECHANISMS OF ACTION AND RESISTANCE. Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral TK during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by cellular enzymes. At least 10-fold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of deoxyguanosine triphosphate incorporation into DNA and preferentially inhibits viral rather than host cellular
DNA polymerases. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (see Figures 58–1A and 58–2).

CMV can become resistant to ganciclovir by either of 2 mechanisms: reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase and mutations in viral DNA polymerase. Highly resistant variants with both mutations are cross-resistant to cidofovir and variably to foscarin. Ganciclovir also is much less active against acyclovir-resistant TK–deficient HSV strains.

**ADME.** The oral bioavailability of ganciclovir is 6-9% following ingestion with food. Oral valganciclovir is well absorbed and hydrolyzed rapidly to ganciclovir; the bioavailability of ganciclovir averages 61% following administration of valganciclovir. Food increases the bioavailability of valganciclovir by ~25%. Following intravenous administration of ganciclovir, vitreous fluid levels are similar to or higher than those in plasma and decline with a t1/2 of 23-26 h. Intraocular sustained-release ganciclovir implants provide vitreous levels of ~4.1 µg/mL. The plasma elimination t1/2 is ~2-4 h. Intracellular ganciclovir triphosphate concentrations are 10-fold higher than those of acyclovir triphosphate and decline much more slowly, with an intracellular elimination t1/2 >24 h. Over 90% of ganciclovir is eliminated unchanged by renal excretion. Plasma t1/2 increases in patients with severe renal insufficiency.

**UNTOWARD EFFECTS.** Myelosuppression is the principal dose-limiting toxicity of ganciclovir. Neutropenia occurs in ~15-40% of patients and is observed most commonly during the second week of treatment and usually is reversible within 1 week of drug cessation. Persistent fatal neutropenia has occurred. Recombinant granulocyte colony-stimulating factor (G-CSF; filgrastim, lenograstim) may be useful in treating ganciclovir-induced neutropenia (see Chapter 37). Thrombocytopenia occurs in 5-20% of patients. Zidovudine and probably other cytotoxic agents increase the risk of myelosuppression, as do nephrotoxic agents that impair ganciclovir excretion. Probenecid and possibly acyclovir reduce renal clearance of ganciclovir. Oral ganciclovir increases the absorption and peak plasma concentrations of didanosine by approximately 2-fold and that of zidovudine by ~20%. CNS side effects (5-15%) range in severity from headache to behavioral changes to convulsions and coma. About one-third of patients must interrupt or prematurely
stop intravenous ganciclovir therapy because of bone marrow or CNS toxicity. Infusion-related phlebitis, azotemia, anemia, rash, fever, liver function test abnormalities, nausea or vomiting, and eosinophilia also have been described. Ganciclovir is classified as pregnancy Category C.

**DOCOSANOL**

Docosanol is a long-chain saturated alcohol that is approved as an over-the-counter 10% cream for the treatment of recurrent orolabial herpes. Docosanol inhibits the in vitro replication of many lipid-enveloped viruses, including HSV. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibits viral entry into the cell. Topical treatment beginning within 12 h of prodromal symptoms or lesion onset reduces healing time by ~1 day and is well tolerated. Treatment initiation at papular or later stages provides no benefit.

**IDOXURIDINE**

Idoxuridine is an iodinated thymidine analog that inhibits the in vitro replication of various DNA viruses, including herpesviruses and poxviruses. Idoxuridine lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. In the U.S., idoxuridine is approved only for topical (ophthalmic) treatment of HSV keratitis. Idoxuridine formulated in dimethylsulfoxide is available outside the U.S. for topical treatment of herpes labialis, genitalis, and zoster. Adverse reactions include pain, pruritus, inflammation, and edema of the eye or lids; allergic reactions are rare.

**TRIFLURIDINE**

Trifluridine is a fluorinated pyrimidine nucleoside that has in vitro inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adenoviruses. Trifluridine inhibits replication of herpesviruses, including acyclovir-resistant strains, and also inhibits cellular DNA synthesis at relatively low concentrations. Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate is a competitive inhibitor of thymidine triphosphate incorporation into DNA; trifluridine is incorporated into viral and cellular DNA. Trifluridine-resistant HSV has been described.
Trifluridine currently is used for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions and irritation are uncommon. Topical trifluridine also appears to be effective in some patients with acyclovir-resistant HSV cutaneous infections.

ANTI-INFLUENZA AGENTS

Recently, there has been concern about the possibility of new influenza pandemics, stemming from small but severe outbreaks of H5N1 avian influenza and the novel 2009 influenza A H1N1, thought to be of swine origin. Four drugs are currently approved for the treatment and prevention of influenza virus infection: the adamantine antivirals, amantadine and rimantadine; oseltamivir; and zanamivir; peramivir, an investigational neuraminidase inhibitor, is available for intravenous use via emergency use authorization (EUA). Development of resistance to these drugs, and the spread of resistant viruses, are major challenges in the chemotherapy and chemoprophylaxis of influenza and are likely to drive future recommendations for use of these drugs in global populations.

AMANTADINE AND RIMANTADINE. Amantadine and its derivative rimantadine are uniquely configured tricyclic amines.

THERAPEUTIC USES. Although both drugs are useful for the prevention and treatment of infections caused by influenza A virus, vaccination against influenza is a more cost-effective means of reducing disease burden. Amantadine
and rimantadine are active only against susceptible influenza A viruses (not influenza B); rimantadine is 4- to 10-fold more active than amantadine. Virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs.

Seasonal prophylaxis with either amantadine or rimantadine (a total of 200 mg/day in 1 or 2 divided doses in young adults) is ~70-90% protective against influenza A illness. These agents are efficacious in preventing nosocomial influenza and in curtailing nosocomial outbreaks during pandemic influenza. Doses of 100 mg/day are better tolerated and still appear to be protective against influenzal illness. Seasonal prophylaxis is an alternative in high-risk patients if the influenza vaccine cannot be administered or may be ineffective (i.e., in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4-8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

The amantadines are effective against influenza A H1N1 if treatment is initiated within 2 days of the onset of symptoms. In uncomplicated influenza A illness of adults, early amantadine or rimantadine treatment (200 mg/day for 5 days) reduces the duration of fever and systemic complaints by 1-2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding. The usual regimen in children (≥1 year of age) is 5 mg/kg/day, up to 150 mg, administered once or twice daily. Resistant variants have been recovered from ~30% of treated children or outpatient adults by the fifth day of therapy.

**MECHANISMS OF ACTION AND RESISTANCE.** Amantadine and rimantadine inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH–induced conformational changes in hemagglutinin during its intracellular transport later in replication. Resistance to these drugs results from a mutation in the RNA sequence encoding for the M2 protein transmembrane domain; resistant isolates typically appear in
the treated patient within 2-3 days of starting therapy.

**ADME.** Table 58–3 summarizes important pharmacokinetics properties of these anti-viral agents. The 2 adamantanes differ in several respects. Amantadine is excreted largely unmetabolized in the urine ($t_{1/2}$ of elimination is ~12-18 h in young adults, increasing up to 2-fold in the elderly and even more in those with renal impairment). By contrast, elimination of rimantadine depends on hepatic function; the drug is subject to phase 1 and phase 2 reactions prior to renal excretion of metabolites (elimination $t_{1/2}$ ~24-36 h; 60-90% is excreted in the urine as metabolites). The elderly require only one-half the weight-adjusted dose of amantadine needed for young adults. Amantadine is excreted in breast milk. Rimantadine concentrations in nasal mucus average 50% higher than those in plasma.

*Clᵣ creatinine clearance
A fifth agent, peramivir, is investigational in the U.S. and approved in Japan at a dose of 600 mg intravenously once daily in adults. Its elimination is primarily renal, with dosage adjustment required for renal insufficiency.
⁺Investigational at present.
⁻Systemic absorption 4-17% after inhalation.
⁻⁻For antivirally active oseltamivir carboxylate.
⁻⁻⁻Inhaled formulation only.

**UNTOWARD EFFECTS.** The most common side effects related to amantadine and rimantadine are minor dose-related CNS and GI effects: nervousness, light-headedness, difficulty concentrating, insomnia, and loss of appetite, and nausea.
CNS side effects (5-33%) occur in patients treated with amantadine at doses of 200 mg/day but are significantly less frequent with rimantadine. The neurotoxic effects of amantadine appear to be increased by concomitant ingestion of antihistamines and psychotropic or anticholinergic drugs, especially in the elderly. At comparable doses of 100 mg/day, rimantadine is significantly better tolerated in nursing home residents than amantadine. High amantadine plasma concentrations (1.0-5.0 μg/mL) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures, and coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Both drugs are considered pregnancy Category C.

**OSELTAMIVIR**

Oseltamivir carboxylate is a transition-state analog of sialic acid that is a potent selective inhibitor of the neuraminidases of influenza A and B virus. Oseltamivir phosphate is an ethyl ester prodrug that lacks antiviral activity. Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of zanamivir: it inhibits amantadine and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

**THERAPEUTIC USES.** Oral oseltamivir is effective in the treatment and prevention of influenza A and B virus infections. Treatment of previously healthy adults (75 mg twice daily for 5 days) or children 1-12 years of age (weight-adjusted dosing) with acute influenza reduces illness duration by ~1-2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40-50%. Treatment is associated with approximate halving of the risk of subsequent hospitalization in adults. When used for prophylaxis during the typical influenza season, oseltamivir (75 mg once daily) is effective (~70-90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing home residents; short-term use protects against influenza in household contacts.

**MECHANISMS OF ACTION AND RESISTANCE.** Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions,
and in respiratory secretions. This enzymatic action is essential for release of virus from infected cells. Interaction of oseltamivir carboxylate with the neuraminidase causes a conformational change within the enzyme’s active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract. Influenza variants selected in vitro for resistance to oseltamivir carboxylate contain hemagglutinin and/or neuraminidase mutations. Seasonal influenza A (H1N1) has become virtually 100% resistant to oseltamivir worldwide. Importantly, novel H1N1 (nH1N1 or swine influenza) remains susceptible to oseltamivir.

ADME. Table 58–3 summarizes important pharmacokinetics properties of oseltamivir carboxylate. Oral oseltamivir phosphate is absorbed rapidly and cleaved by esterases in the GI tract and liver to the active carboxylate. Food does not decrease bioavailability but reduces the risk of GI intolerance. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. Probenecid doubles the plasma $t_{1/2}$ of the carboxylate, which indicates tubular secretion by the anionic pathway. Children <2 years of age exhibit age-related changes in oseltamivir carboxylate clearance and total drug exposure.

UNTOWARD EFFECTS. Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis. GI complaints typically resolve in 1-2 days despite continued dosing, and are preventable by administration with food. An increased frequency of headache was reported in one prophylaxis study in elderly adults. Neither the phosphate nor the carboxylate form interacts with CYPs in vitro. Oseltamivir does not appear to impair fertility, but safety in pregnancy is uncertain (pregnancy Category C).

ZANAMIVIR. Zanamivir is a sialic acid analog that potently and specifically inhibits the neuraminidases of influenza A and B viruses. Zanamivir inhibits in vitro replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants.

THERAPEUTIC USES. Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections. Early zanamivir treatment (10 mg [2 inhalations] twice daily for 5 days) of febrile influenza in ambulatory adults and children >5 years of age shortens the time to illness resolution by 1-3
days and in adults reduces by 40% the risk of lower respiratory tract complications leading to antibiotic use. Once-daily inhaled zanamivir is highly protective against community-acquired influenza illness, and when given for 10 days, it protects against household transmission. Intravenous zanamivir ($t_{1/2} \sim 1.7$ h) is available in the U.S. as an emergency investigational new drug (EIND) and in the E.U. on a compassionate use basis for life-threatening resistant influenza.

**MECHANISMS OF ACTION AND RESISTANCE.** Zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract. In vitro selection of viruses resistant to zanamivir is associated with mutations in the viral hemagglutinin and/or neuraminidase. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir-resistant variants usually have decreased infectivity in animals.

**ADME.** Table 58–3 summarizes important pharmacokinetics properties of zanamivir. Oral bioavailability of zanamivir is <5%, and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath-actuated and requires a cooperative patient. Following inhalation of the dry powder, ~15% is deposited in the lower respiratory tract and ~80% in the oropharynx. Overall bioavailability is 4-17%.

**UNTOWARD EFFECTS.** Orally inhaled zanamivir generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. Zanamivir is not generally recommended for treatment of patients with underlying airway disease because of the risk of serious adverse events. Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy Category C). No clinically significant drug interactions have been recognized to date. Zanamivir does not diminish the immune response to injected influenza vaccine.

**ANTI-HEPATITIS VIRUS AGENTS**
A number of agents are available for treatment of HBV and HCV infections. Several agents (e.g., interferons, ribavirin, and the nucleoside/nucleotide analogs lamivudine, telbivudine, and tenofovir) have other uses as well (see Chapter 59). Therapeutic strategies for hepatitis B and C are very different and are described separately.

**DRUGS USED MAINLY FOR HEPATITIS C VIRUS INFECTION**

HCV infection is associated with significant morbidity and mortality. Untreated, this virus can cause progressive hepatocellular injury with fibrosis and eventual cirrhosis. Chronic HCV is also a major risk factor for hepatocellular carcinoma. Although the virus is quite prolific, producing several billion new particles every few days in an infected individual, this RNA virus does not integrate into chromosomal DNA, and it does not establish latency per se. Therefore, the infection is, in theory, curable in all affected individuals. The current standard of care for treatment is a combination of peginterferon alfa and ribavirin, which produces a high cure rate in selected virus genotypes only.

**Interferons.** Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative activities (see Chapter 35). Three major classes of human interferons with significant antiviral activity are: α, β, and γ. Clinically used recombinant α-IFNs (see Table 58–2) are non-glycosylated proteins of e19,500 Da, the pegylated forms predominating in the U.S. market.

IFN-α and IFN-β may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin 1, interleukin 2, and tumor necrosis factor). IFN-γ production is restricted to T lymphocytes and natural killer cells responding to antigenic stimuli, mitogens, and specific cytokines. IFN-α and IFN-β exhibit antiviral and antiproliferative actions; stimulate the cytotoxic activity of lymphocytes, natural killer cells, and macrophages; and upregulate
class I major histocompatibility (MHC) antigens and other surface markers. IFN-γ has less antiviral activity but more potent immunoregulatory effects, particularly macrophage activation, expression of class II MHC antigens, and mediation of local inflammatory responses. Most animal viruses are inhibited by IFNs, although many DNA viruses are relatively insensitive. The biological activity of IFN usually is measured in terms of antiviral effects in cell culture and generally is expressed as international units (IU) relative to reference standards.

MECHANISMS OF ACTION. Following binding to specific cellular receptors, IFNs activate the JAK-STAT signal-transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes containing an IFN-specific response element. This, in turn, leads to synthesis of over 2 dozen proteins that contribute to viral resistance mediated at different stages of viral penetration (Figure 58–3).
Interferon-mediated antiviral activity occurs via multiple mechanisms. The binding of IFN to specific cell surface receptor molecules signals the cell to produce a series of antiviral proteins. The stages of viral replication that are inhibited by various IFN-induced antiviral proteins are shown. Most of these act to inhibit the translation of viral proteins (mechanism 2), but other steps in viral replication also are affected (mechanisms 1, 3, and 4). The roles of these mechanisms in the other actions of IFNs are under study.

2′5′A, 2′-5′-oligoadenylates; eIF-2α, protein synthesis initiation factor; IFN, interferon; mRNA, messenger RNA; Mx, IFN-induced cellular protein with antiviral activity; RNase L, latent cellular endoribonuclease; tRNA, transfer RNA.

(Modified from Baron S, Coppenhaver DH, Dianzani F, et al. Introduction to the...

A given virus may be inhibited at several steps, and the principal inhibitory effect differs among virus families. Certain viruses are able to counter IFN effects by blocking production or activity of selected IFN-inducible proteins. For example, IFN resistance in HCV is attributable to inhibition of the IFN-induced protein kinase, among other mechanisms. Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects and/or by modifying the immune response to infection. For example, IFN-induced expression of MHC antigens may contribute to the antiviral actions of IFN by enhancing the lytic effects of cytotoxic T-lymphocytes. Conversely, IFNs may mediate some of the systemic symptoms associated with viral infections and contribute to immunologically mediated tissue damage in certain viral diseases.

ADME. After intramuscular or subcutaneous injection of IFN-α, absorption is >80%. Plasma levels are dose related, peaking at 4-8 h and returning to baseline by 18-36 h. Increased levels of 2′-5′-oligoadenylate synthase [2-5(A) synthase] in peripheral blood mononuclear cells are apparent at 6 h and last for 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 h and decreases slowly to baseline by 6 days after injection. After systemic administration, low levels of IFN are detected in respiratory secretions, CSF, eye, and brain. Because IFNs induce long-lasting cellular effects, their activities are not easily predictable from usual pharmacokinetic measures. After intravenous dosing, clearance of IFN from plasma occurs in a complex manner. With subcutaneous or intramuscular dosing, the plasma $t_{1/2}$ of IFN-α ranges from 3-8 h, due to distribution to the tissues, cellular uptake, and catabolism primarily in the kidney and liver. Negligible amounts are excreted in the urine. Clearance of IFN-a2B is reduced by ~80% in dialysis patients.

Attachment of IFN proteins to large inert polyethylene glycol (PEG) molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing. Two pegylated IFNs are available commercially: peginterferon alfa-2a (PEGASYS) and peginterferon alfa-2B (PEG-INTRON). PegIFN alfa-2B has a 12 kDa PEG that
increases the plasma $t_{1/2}$ to $\sim 30-54$ h. PegIFN alfa-2A contains a branched-chain 40 kDa PEG bonded to IFN-α2A and has a plasma $t_{1/2}$ averaging $\sim 80-90$ h. Increasing PEG size is associated with longer $t_{1/2}$ and less renal clearance. About 30% of pegIFN alfa-2B is cleared by the kidneys; pegIFN alfa-2A also is cleared primarily by the liver. Dose reductions in both pegylated IFNs are indicated in end-stage renal disease.

UNTOWARD EFFECTS. Injection of recombinant IFN doses of $\geq 1-2$ million units (MU) usually is associated with an acute influenza-like syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Fever usually resolves within 12 h. Tolerance develops gradually in most patients. Febrile responses can be moderated by pretreatment with antipyretics. Up to one-half of patients receiving intralesional therapy for genital warts experience the influenzal illness initially, as well as discomfort at the injection site, and leukopenia.

Dose-limiting toxicities of systemic IFN are myelosuppression; neurotoxicity (e.g., somnolence, confusion, and depression); autoimmune disorders including thyroiditis and hypothyroidism; and uncommonly, cardiovascular effects with hypotension. Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children. The development of serum neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility; safety during pregnancy is not established. IFNs can increase the hematological toxicity of drugs such as zidovudine and ribavirin and may increase the neurotoxicity and cardiotoxic effects of other drugs. Thyroid function and hepatic enzymes should be monitored during IFN therapy. Pegylated IFNs are better tolerated than standard IFNs, with discontinuation rates ranging from 2-11%, although the frequencies of fever, nausea, injection-site inflammation, and neutropenia may be somewhat higher. Severe neutropenia and the need for dose modifications are higher in HIV-coinfected persons.

THERAPEUTIC USES. Recombinant, natural, and pegylated IFNs currently are approved in the U.S. for treatment of condyloma acuminatum, chronic HCV
infection, chronic HBV infection, Kaposi sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis. In addition, interferons have been granted orphan drug status for a variety of rare disease states including idiopathic pulmonary fibrosis, laryngeal papillomatosis, juvenile rheumatoid arthritis, and infections associated with chronic granulomatous disease.

**Hepatitis B Virus.** In patients with chronic HBV infection, parenteral administration of various IFNs is associated with serological, biochemical, and histological improvement in ~25-50% of the patients. Lasting responses require moderately high IFN doses and prolonged administration (typically 5-10 MU/day in adults and 6 MU/m² in children 3 times per week of IFNα-2B for 4 to 6 months). Low pretherapy serum HBV DNA levels and high aminotransferase levels are predictors of response. PegIFN alfa-2A (180 μg once weekly for 24-48 weeks) appears superior to conventional IFN alfa-2A in HbeAg-positive patients. High-dose IFN can cause myelosuppression and clinical deterioration in those with decompensated liver disease.

Antiviral effects and improvements occur in about one-half of chronic hepatitis D virus (HDV) infections, but relapse is common unless HbsAg disappears. IFN does not appear to be beneficial in acute HBV or HDV infections.

**Hepatitis C Virus.** In chronic HCV infection, IFN alfa-2B monotherapy (3 MU 3 times weekly) is associated with ~50-70% rate of aminotransferase normalization and loss of plasma viral RNA, but sustained virologic remission is observed in only 10-25% of patients. Sustained viral responses are associated with long-term histological improvement and probably reduced risk of hepatocellular carcinoma and hepatic failure. Viral genotype and pretreatment RNA level influence response to treatment, but early viral clearance is the best predictor of sustained response. Nonresponders generally do not benefit from IFN monotherapy retreatment, but they and patients relapsing after monotherapy often respond to combined pegylated IFN and ribavirin treatment. IFN treatment may benefit HCV-associated cryoglobulinemia and glomerulonephritis. IFN administration during acute HCV infection appears to reduce the risk of chronicity.

Pegylated IFNs are superior to conventional thrice-weekly IFN monotherapy in inducing sustained remissions in treatment-naive patients. Monotherapy with pegIFN alfa-2A (180 μg subcutaneously weekly for 48 weeks) or pegIFN alfa-
2B (1.5 μg/kg/week for 1 year) is associated with sustained response in 30-39%, including stable cirrhotic patients, and it is a treatment option in patients unable to take ribavirin. The efficacy of conventional and pegylated IFNs is enhanced by the addition of ribavirin to the treatment regimens, particularly for genotype 1 infections. Combined therapy with pegIFN alfa-2A (180 μg once weekly for 48 weeks) and ribavirin (1000-1200 mg/day in divided doses) gives higher sustained viral response rates than IFN-ribavirin combinations. The dose and duration of therapy depend on genotype of HCV infections. Approximately 15-20% of those failing to respond to combined IFN-ribavirin will have sustained responses to combined pegIFN-ribavirin.

**Papillomavirus.** In refractory condylomata acuminata (genital warts), intralesional injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36-62% of patients, but other treatments are preferred. Relapse occurs in 20-30% of patients. Verruca vulgaris may respond to intralesional IFN-α. Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients.

**Other Viruses.** IFNs have been shown to have virological and clinical effects in various herpesvirus infections including genital HSV infections, localized herpes-zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections.

In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of zidovudine and IFN is associated with only transient benefit and excessive hematological toxicity. IFN-α (3 MU 3 times weekly) is effective for treatment of HIV-related thrombocytopenia resistant to zidovudine therapy.

Except for adenovirus, IFN has broad-spectrum antiviral activity against respiratory viruses. However, prophylactic intranasal IFN-α is protective only against rhinovirus colds, and chronic use is limited by the occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus
colds.

**RIBAVIRIN.** Ribavirin, a purine nucleoside analog with a modified base and D-ribose sugar, inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxvo-, arena-, bunya-, and flavivirus- in vitro. Therapeutic concentrations may reversibly inhibit macromolecular synthesis and proliferation of uninfected cells, suppress lymphocyte responses, and alter cytokine profiles in vitro.

![Chemical structure of Ribavirin](image)

**THERAPEUTIC USES.** Oral ribavirin in combination with injected pegIFN alfa-2A or alfa-2B is standard treatment for chronic HCV infection. Ribavirin aerosol is approved in the U.S. for treatment of RSV bronchiolitis and pneumonia in hospitalized children. Aerosolized ribavirin (usual dose of 20 mg/mL as the starting solution in the drug reservoir of the small particle aerosol generator unit for an 18 h exposure/day for 3-7 days) may reduce some illness measures, but its use generally is not recommended. Aerosol ribavirin combined with intravenous immunoglobulin appears to reduce mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients.

Intravenous and/or aerosol ribavirin has been used occasionally in treating severe influenza virus infection and in the treatment of immunosuppressed patients with adenovirus, vaccinia, parainfluenza, or measles virus infections. Aerosolized ribavirin is associated with reduced duration of fever but no other clinical or antiviral effects in influenza infections in hospitalized children. Intravenous ribavirin decreases mortality in Lassa fever and has been used in treating other arenavirus-related hemorrhagic fevers. Intravenous ribavirin is beneficial in hemorrhagic fever with renal syndrome owing to hantavirus infection but appears ineffective in hantavirus-associated cardiopulmonary
syndrome or SARS. Intravenous ribavirin is investigational in the U.S.

MECHANISMS OF ACTION AND RESISTANCE. Ribavirin alters cellular nucleotide pools and inhibits viral mRNA synthesis. Host cell enzymes phosphorylate ribavirin to mono-, di-, and tri-phosphate derivatives. In both uninfected and RSV-infected cells, the predominant derivative (>80%) is the triphosphate, which has an intracellular \( t_{1/2} < 2 \) h. Ribavirin monophosphate competitively inhibits cellular IMP dehydrogenase and interferes with the synthesis of GTP and thus nucleic acid synthesis in general. Ribavirin triphosphate also competitively inhibits the GTP-dependent 5′ capping of viral messenger RNA and specifically influenza virus transcriptase activity. Ribavirin has multiple sites of action, and some of these (e.g., inhibition of GTP synthesis) may potentiate others (e.g., inhibition of GTP-dependent enzymes). Ribavirin also may enhance viral mutagenesis to an extent that some viruses may be inhibited from effective replication, so-called lethal mutagenesis. Emergence of viral resistance to ribavirin has been reported in Sindbis and HCV.

ADME. Ribavirin is actively taken up by nucleoside transporters in the proximal small bowel; oral bioavailability averages ~50%. Food increases plasma levels substantially. With aerosol administration, levels in respiratory secretions are very high but variable. The elimination of ribavirin is complex. The plasma \( t_{1/2} \) increases to ~200-300 h at steady state. Erythrocytes concentrate ribavirin triphosphate; the drug exits red cells gradually, with a \( t_{1/2} \) of ~40 days. Hepatic metabolism and renal excretion of ribavirin and its metabolites are the principal routes of elimination. Hepatic metabolism involves deribosylation and hydrolysis to yield a triazole carboxamide. Ribavirin should be used cautiously in patients with creatinine clearances of <50 mL/min.

UNTOWARD EFFECTS. Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of ventilator valves and tubing with ribavirin. Techniques to reduce environmental exposure of healthcare workers are recommended. Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy Category X).
Systemic ribavirin causes dose-related reversible anemia owing to extravascular hemolysis and suppression of bone marrow. Associated increases occur in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. Bolus intravenous infusion may cause rigors. About 20% of chronic HCV infection patients receiving combination IFN-ribavirin therapy discontinue treatment early because of side effects. In addition to IFN toxicities, oral ribavirin increases the risk of fatigue, cough, rash, pruritus, nausea, insomnia, dyspnea, depression, and particularly, anemia. Preclinical studies indicate that ribavirin is teratogenic, embroytotoxic, oncogenic, and possibly gonadotoxic. To prevent possible teratogenic effects, up to 6 months is required for washout following cessation of long-term treatment. Ribavirin inhibits the phosphorylation and antiviral activity of pyrimidine nucleoside HIV reverse-transcriptase inhibitors such as zidovudine and stavudine but increases the activity of purine nucleoside reverse-transcriptase inhibitors (e.g., didanosine) in vitro. It appears to increase the risk of mitochondrial toxicity from didanosine (see Chapter 59).

**BOCEPREVIR.** Boceprevir (VICTRELIS) inhibits hepatitis C virus non-structural protein 3 (NS3) serine protease.

Boceprevir is indicated for the treatment of chronic hepatitis genotype 1 infection in adults >18 years old with compensated liver disease, including cirrhosis, who are previously untreated or who have failed previous interferon and ribavirin therapy. Boceprevir is administered in combination with peginterferon alfa and ribavirin. The recommended dose is 800 mg (four 200-mg capsules) three times daily (every 7-9 hours) with food. The \( t_{1/2} \) is \(~3.4 \) h. The drug is metabolized mostly by aldoketoreductase and partly by CYP3A4/5, which the drug strongly inhibits. Side effects of combination treatment include fatigue, anemia, nausea, headache, and dysgeusia. Boceprevir is contraindicated in pregnancy.

**DRUGS FOR HEPATITIS B VIRUS INFECTION**

Unlike HCV, HBV is transcribed into DNA that can be integrated into host chromosomal DNA and is capable of establishing lifelong chronic infection in \(~10\)% of patients. Those with chronic HBV may develop active hepatitis that can lead to fibrosis and cirrhosis, and all
such individuals have a greatly increased incidence of hepatocellular carcinoma.

Interferon, or a combination of interferon and ribavirin, can cure patients with chronic infection but is associated with a high rate of side effects, often leading to premature treatment discontinuation. Several antiretroviral nucleoside or nucleotide analog polymerase inhibitors, including lamivudine, telbivudine, and tenofovird, have potent anti-HBV activity and have provided a popular alternative therapy: chronic suppressive oral single agent or combination treatment. These regimens are much better tolerated than IFN-containing regimens but are not usually curative.

**ADEFOVIR.** Adefovir dipivoxil is a prodrug of adefovir, an acyclic phosphonate nucleotide analog of adenosine monophosphate.

**THERAPEUTIC USES.** Adefovir dipivoxil is approved for treatment of chronic HBV infections. In patients with HBV e-antigen (HbeAg)–positive chronic hepatitis B, adefovir dipivoxil (10 mg/day) reduces serum HBV DNA levels by 99% and, in about one-half of patients, improves hepatic histology and normalization of aminotransferase levels by 48 weeks. In patients with HbeAg-negative chronic HBV, adefovir is associated with similar biochemical and histological benefits. Regression of cirrhosis may occur in some patients. In patients with lamivudine-resistant HBV infections, adefovir dipivoxil monotherapy results in sustained reductions in serum HBV DNA levels. In patients with dual HIV and lamivudine-resistant HBV infections, adefovir dipivoxil (10 mg/day) causes significant HBV DNA level reductions.

**MECHANISMS OF ACTION AND RESISTANCE.** Adefovir dipivoxil enters cells and is de-esterified to adefovir, which cellular enzymes convert to the diphosphate, a competitive inhibitor of dATP at viral DNA polymerases and reverse transcriptases and also serves as a chain terminator of viral DNA synthesis. Its selectivity relates to a higher affinity for HBV DNA polymerase compared with cellular polymerases. Adefovir resistance has been detected in ~4% of chronically infected HBV patients during 3 years of treatment. Such variants have unique point mutations in the HBV polymerase but retain
susceptibility to lamivudine.

**ADME.** The dipivoxil prodrug is absorbed rapidly and hydrolyzed in the intestine and blood to adefovir with liberation of pivalic acid, providing a bioavailability ~30-60%. Food does not affect bioavailability. Adefovir is eliminated unchanged by renal excretion. After oral administration of adefovir dipivoxil, ~30-45% of the dose is recovered within 24 h; the $t_{1/2}$ of elimination is 5-7.5 h. Dose reductions are recommended for $Cl_{Cr}$ values >50 mL/min. Adefovir is removed by hemodialysis.

**UNTOWARD EFFECTS.** Adefovir dipivoxil causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria that usually are reversible months after discontinuation. The dose (10 mg/day) used in chronic HBV infection patients has been associated with fewer adverse events (e.g., headache, abdominal discomfort, diarrhea, and asthenia) and negligible renal toxicity than higher doses. Acute, sometimes severe exacerbations of hepatitis can occur in patients stopping adefovir or other anti-HBV therapies.

Adefovir is genotoxic, and high doses cause hepatotoxicity, lymphoid toxicity, and renal tubular nephropathy in animals. Adefovir dipivoxil is not associated with reproductive toxicity, although high intravenous doses of adefovir cause maternal and embryotoxicity with fetal malformations in rats (pregnancy Category C). Drugs that reduce renal function could decrease adefovir clearance. Ibuprofen increases adefovir exposure modestly. An increased risk of lactic acidosis and steatosis may exist when adefovir is used in conjunction with nucleoside analogs or other antiretroviral agents. Adefovir is transported efficiently into tubular epithelium by a probenecid-sensitive organic anion transporter (hOAT1).

**ENTECAVIR.** Entecavir is a guanosine nucleoside analog with selective activity against HBV polymerase.

**THERAPEUTIC USES.** Entecavir is indicated for the treatment of chronic HBV infection in adults with active viral replication and either evidence of persistent elevations in serum aminotransferases or histologically active disease. The recommended dose for nucleoside-treatment-naive adults is 0.5 mg once daily.
For patients with lamivudine or telbivudine resistance, the dose is 1 mg once daily. Entecavir is superior to lamivudine in the degree of suppression and associated with a more frequent fall of HBV DNA to undetectable levels. Entecavir had negligible resistance (<1%) for up to 4 years and is active against adefovir-resistant HBV.

MECHANISMS OF ACTION AND RESISTANCE. Entecavir requires intracellular phosphorylation. Entecavir triphosphate competes with endogenous deoxyguanosine triphosphate and inhibits all 3 activities of the HBV polymerase (reverse transcriptase): base priming, reverse transcription of the negative strand from the pregenomic messenger RNA, and synthesis of the positive strand of HBV DNA. Entecavir triphosphate is a weak inhibitor of cellular DNA polymerases α, β, and δ and mitochondrial DNA polymerase γ. HIV reverse transcriptase variants containing the M184V substitution show loss of susceptibility to entecavir. Lamivudine and telbivudine resistance confers decreased susceptibility to entecavir.

ADME. Steady-state is reached after 6-10 days of once daily dosing. Administration with food decreases $C_{\text{max}}$ by 44-46% and AUC by 18-20%; thus entecavir should be administered on an empty stomach. It is primarily eliminated unchanged in the kidney. Renal clearance is independent of dose, suggesting that entecavir undergoes both glomerular filtration and net tubular secretion. Entecavir exhibits biphasic elimination, with a terminal $t_{1/2}$ of 128-149 h; the active triphosphate has an elimination $t_{1/2}$ of 15 h. Dose reductions are needed for patients with $\text{Cl}_{\text{Cr}}>50$ mL/min, typically by extension of the dosing interval.

UNTOWARD EFFECTS. Severe acute exacerbations of hepatitis B have been reported in patients who have discontinued anti-HBV therapy, including entecavir. Hepatic function should be monitored closely with both clinical and laboratory follow-up for several months in patients who discontinue anti-HBV therapy. There is a potential for development of resistance to nucleoside reverse transcriptase inhibitors in HBV/HIV coinfection, especially if HIV is not being treated. Other common adverse reactions include headache, fatigue, dizziness, and nausea.

LAMIVUDINE. Lamivudine is a nucleoside analog that inhibits HIV reverse transcriptase and HBV DNA polymerase. It inhibits HBV replication with
negligible cellular cytotoxicity. Its use as an antiretroviral agent is discussed in Chapter 59.

**THERAPEUTIC USES.** Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children. In adults, doses of 100 mg/day for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels and reductions in hepatic inflammation in 40-50% of patients. Seroconversion with antibody to HbeAg occurs in <20% of recipients at 1 year. Prolonged therapy is associated with sustained suppression of HBV DNA and continued histological improvement. Prolonged therapy halves the risk of clinical progression and development of hepatocellular carcinoma in those with advanced fibrosis or cirrhosis. The frequency of lamivudine-resistant variants increases progressively with continued drug administration, reaching 67% after 4 years of treatment. The risk of resistance development is higher after transplantation and in HIV/HBV coinfected patients.

Combined use of IFN or pegIFN alfa-2A with lamivudine has not improved responses in HBeAg-positive patients consistently. In HIV and HBV coinfections, higher lamivudine doses are associated with antiviral effects and uncommonly anti-HBe seroconversion. Administration of lamivudine before and after liver transplantation may suppress recurrent HBV infection.

**MECHANISMS OF ACTION AND RESISTANCE.** Cellular enzymes convert lamivudine to the triphosphate. Lamivudine triphosphate is a potent competitive inhibitor of the DNA polymerase/reverse transcriptase of HBV and causes chain termination. Lamivudine shows enhanced antiviral activity in combination with adefovir or penciclovir against hepadnaviruses. Point mutations in the YMDD motif of HBV DNA polymerase markedly reduce susceptibility. Lamivudine resistance confers cross-resistance to related agents such as emtricitabine, and is often associated with an additional non-YMDD mutation that confers cross-resistance to famciclovir. Lamivudine-resistant HBV retains susceptibility to adefovir, tenofovir, and partially to entecavir. Viruses bearing YMDD mutations are less replication competent than wild-type HBV. However, lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HbeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients.

**ADME.** The pharmacokinetic properties of lamivudine are described in Chapter
The intracellular $t_{1/2}$ of the triphosphate averages 17-19 h in HBV-infected cells, so once-daily dosing is possible. Dose reductions are indicated for moderate renal insufficiency. Trimethoprim decreases the renal clearance of lamivudine.

**UNTOWARD EFFECTS.** At the doses used for chronic HBV infection, lamivudine generally has been well tolerated. Post-treatment aminotransferase elevations occur in ~15% of patients after cessation.

**TELBIVUDINE.** Telbivudine is a synthetic thymidine nucleoside analog with activity against HBV DNA polymerase.

**THERAPEUTIC USES.** Telbivudine is indicated for the treatment of chronic HBV in adult patients with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease. The recommended dose is 600 mg orally once daily without regard to food. An oral solution is also available. Telbivudine resistance is 25% after 2 years of treatment and higher than observed with other oral anti-HBV agents. Cross-resistance and treatment-emergent resistance limit the use of telbivudine for patients with chronic HBV, compared to alternative agents.

**MECHANISMS OF ACTION AND RESISTANCE.** Telbivudine is phosphorylated by cellular kinases to the active triphosphate form, which has a $t_{1/2}$ of 14 h. Telbivudine 5′-triphosphate inhibits HBV DNA polymerase/reverse transcriptase by competing with the natural substrate, TTP. Incorporation of telbivudine 5′-triphosphate into viral DNA causes chain termination.

Lamivudine-resistant HBV strains expressing either the M204I substitution or the L180M/M204V double substitution have ≥1000-fold reduced susceptibility. HBV encoding the adefovir mutation A181V showed 3- to 5-fold reduced susceptibility. The A181T substitution is associated with decreased clinical response in patients with HBV treated with adefovir and entecavir.

**ADME.** At 600 mg once daily, steady state is achieved after ~5-7 days with ~1.5-fold accumulation. Telbivudine concentrations decline biexponentially with an elimination $t_{1/2}$ of 40-49 h. The drug is eliminated unchanged in the urine. Patients with moderate-to-severe renal dysfunction require dose adjustments.
UNTOWARD EFFECTS. Telbivudine is generally well tolerated and safe. The most common adverse events resulting in telbivudine discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy.

TENOFOVIR. Tenofovir is a nucleotide analog with activity against both HIV-1 and HBV. It is administered orally as the disoproxil prodrug. For more detail, see Chapter 59.

THERAPEUTIC USES. Tenofovir is approved for treatment of HBV infection in adults at a dose of 300 mg once daily without regard to food. In HBeAg-negative patients, tenofovir suppresses HBV DNA to >400 copies/mL in 93% of subjects at 48 weeks, compared to 63% for adefovir. Tenofovir resistance is not evident over 48 weeks of treatment. Due to its safety, efficacy, and resistance profile, tenofovir will likely supersede adefovir for the treatment of chronic HBV infection. Overall, tenofovir has a favorable resistance profile and has been effective in treating lamivudine-resistant HBV. The tenofovir dose should be adjusted for impaired renal function and during hemodialysis.

CLEVUDINE
Clevudine is a nucleoside analog with potent activity against HBV. The oral drug is approved for use in South Korea and the Philippines. However, the drug caused myopathy in large phase 3 clinical trials, casting doubt on its future approval in the U.S.

OTHER AGENTS

IMIQUIMOD. Imiquimod is a novel immunomodulatory agent that is effective for topical treatment of condylomata acuminata, molluscum contagiosum, and certain other dermatologic conditions associated with DNA virus infections. It lacks direct antiviral or antiproliferative effects in vitro; rather, imiquimod induces cytokines and chemokines with antiviral and immunomodulating effects.

When applied topically as a 5% cream to genital warts in humans, imiquimod induces local IFN-α, IFN-β, and IFN-γ and TNFα responses and causes reductions in viral load and wart size. When applied topically (3 times weekly for up to 16 weeks), imiquimod cream results in complete clearance of treated
genital and perianal warts in ~50% of patients in 8-10 weeks, with response rates higher in women than in men. Application is associated with local erythema, excoriations/flaking, itching, burning, and less often, erosions or ulcerations.
The pharmacotherapy of HIV infection is a rapidly moving field. Three-drug combinations are the minimum standard of care for this infection, so current agents constitute several thousand possible regimens. Knowing the essential features of the pathophysiology of this disease and how chemotherapeutic agents affect the virus and the host is critical in developing a rational approach to therapy. Unique features of this drug class include the need for lifelong administration to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly.

PATHOGENESIS OF HIV-RELATED DISEASE

Human immunodeficiency viruses (HIVs) are lentiviruses, a family of retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Replication is constant following infection, and although some infected cells may harbor nonreplicating virus for years, in the absence of treatment there generally is no true period of viral latency following infection. Humans and nonhuman primates are the only natural hosts for these viruses.

There are 2 major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is more closely related to simian immunodeficiency virus (SIV) and is concentrated in western Africa. HIV-1 is genetically diverse, with at least 5 distinct subfamilies or clades. HIV-1 and HIV-2 have similar sensitivity to most antiretroviral drugs, although the non-nucleoside reverse transcriptase inhibitors (NNRTIs) are HIV-1-specific and have no activity against HIV-2.

VIRUS STRUCTURE. HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core
surrounded by a lipid bilayer, or envelope, that is derived from the host cell plasma membrane (Figure 59–1). The viral genome encodes 3 major open reading frames: gag encodes a polyprotein that is processed to release the major structural proteins of the virus; pol overlaps gag and encodes 3 important enzyme activities—an RNA-dependent DNA polymerase or reverse transcriptase with RNAase activity, protease, and the viral integrase; and env encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include tat, rev, nef, and vpr.

Figure 59–1  Replicative cycle of HIV-1 and sites of action of available antiretroviral agents. Available antiretroviral agents are shown in blue. cDNA, complementary DNA; gp120 + gp41, extracellular and intracellular domains, respectively, of envelope glycoprotein; mRNA, messenger RNA; RNase H, ribonuclease H; RT, reverse transcriptase. (Adapted from Hirsch MS, D'Aquila RT. Therapy for human immunodeficiency virus infection. N Engl J Med, 1993; 328:1686–1695.)

VIRUS LIFE CYCLE (see Figure 59–1). HIV tropism is controlled by the envelope protein gp160 (env). The major target for env binding is the CD4 receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the
chemokine receptor CCR5 or CXCR4. CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominantly the CCR5-tropic virus; HIV with this tropism is responsible for nearly all naturally acquired infections. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the increased affinity of HIV-1 for CXCR4 allows infection of T-lymphocyte lines. A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of CD4+ helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still unknown, but it is possible to develop clinical AIDS without this switch.

The gp41 domain of env controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNADNA duplex; the original RNA is degraded by RNase H to allow creation of a full-length double-stranded DNA copy of the virus. Because the HIV reverse transcriptase is error prone and lacks a proofreading function, mutation is quite frequent and occurs at ~3 bases out of every full-length (9300-base-pair) replication. Virus DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location.

Following integration, the virus may remain quiescent, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the virus is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid. The envelope and structural proteins assemble at the cell surface, concentrating in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating new enveloped HIV particles containing 2 complete single-stranded RNA genomes. Reverse transcriptase is incorporated into virus particles so replication can begin immediately after the virus enters a new cell.

**HOW THE VIRUS CAUSES DISEASE.** Sexual acquisition of HIV infection is likely mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2-4 weeks, with ≥10^9 cells becoming infected.
This peak is associated with a transient dip in the number of peripheral CD4+ (helper) T lymphocytes. As a result of new host immune responses and target cell depletion, the number of infectious virions as reflected by the plasma HIV RNA concentration (also known as viral load) declines to a quasi-steady state. This set point reflects the interplay between host immunity and the pathogenicity of the infecting virus. In the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host CD4+ T lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm³, there is an increasing risk of opportunistic diseases and ultimately death. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical AIDS of 8-10 years. Some patients, termed long-term nonprogressors, can harbor HIV for more than 2 decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses.

An important question relevant to treatment is whether HIV disease is a consequence of CD4+ lymphocyte depletion alone. Most natural history data suggest that this is true. Regardless, successful therapy is based on inhibition of HIV replication; interventions designed specifically to boost the host immune response without exerting a direct antiviral effect have had no reliable clinical benefit.

PRINCIPLES OF HIV CHEMOTHERAPY

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly CD4+ T lymphocytes. The goal of therapy is to suppress virus replication as much as possible for as long as possible. The current standard of care is to use at least 3 drugs simultaneously for the entire duration of treatment.

Current guidelines in the U.S. recommend starting therapy in all those with a CD4 count of ≤350 cells/mm³. Treatment is also recommended for HIV-infected
pregnant women, those with HIV nephropathy, and those with concurrent hepatitis B virus infection requiring treatment regardless of CD4 count. Increasing evidence supports the value of antiretroviral therapy in preventing transmission of the virus from person to person. In the foreseeable future, treatment may be recommended for all infected adults and children.

Drug resistance is a key problem. There is a high likelihood that all untreated infected individuals harbor viruses with single-amino-acid mutations conferring some degree of resistance to every known antiretroviral drug because of the high mutation rate of HIV and the tremendous number of infectious virions. Thus, a combination of active agents is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis (see Chapter 56). Intentional drug holidays, also known as structured treatment interruptions, allow the virus to replicate anew, increase the risk of drug resistance and disease progression, and are not recommended.

The expected outcome of initial therapy in a previously untreated patient is an undetectable viral load (plasma HIV RNA <50 copies/mL) within 24 weeks of starting treatment. Mathematical models of HIV replication suggested that 3 is the minimum number of agents required to guarantee effective long-term suppression of HIV replication without resistance. In treatment-naive patients, a regimen containing a non-nucleoside plus 2 nucleoside reverse transcriptase inhibitors is as effective as a regimen containing an additional nucleoside, indicating the equivalence of these 3-drug and 4-drug regimens. Four or more drugs may be used simultaneously in pretreated patients harboring drug-resistant virus, but the number of agents a patient can take is limited by toxicity and inconvenience.

Failure of an antiretroviral regimen is defined as a persistent increase in plasma HIV RNA concentrations in a patient with previously undetectable virus, despite continued treatment with that regimen. This indicates resistance to 1 or more drugs in the regimen and necessitates a change in treatment. The selection of new agents is therefore informed by the patient’s treatment history and viral resistance testing. Treatment failure generally requires implementation of a completely new combination of drugs. Adding a single active agent to a failing regimen is functional monotherapy if the patient is resistant to all drugs in the regimen. The risk of failing a regimen depends on the percentage of prescribed doses taken during any given period of treatment.
As antiretroviral therapy becomes more effective and easier to take, long-term toxicity of these drugs is of greater concern. An important consequence of long-term therapy is the development of a metabolic syndrome (*HIV lipodystrophy syndrome*) characterized by insulin resistance, fat redistribution, and hyperlipidemia, that occurs in 10-40% of treated patients. Clinical features include peripheral fat wasting (lipoatrophy), central fat accumulation including enlarged breasts and buffalo hump, insulin resistance and hyperglycemia, and elevations in serum cholesterol and triglycerides. Lipodystrophy has been associated with an increased risk of myocardial infarction in virologically controlled patients. A potential concern that applies to all protease inhibitors and NNRTIs is clinically significant pharmacokinetic drug interactions. All agents in these 2 drug classes can act as inhibitors and/or inducers of hepatic CYPs and other drug metabolizing enzymes, as well as drug transport proteins.

An increasingly recognized complication of initiating antiretroviral therapy is accelerated inflammatory reaction to overt or subclinical opportunistic infections or malignancies. This *immune reconstitution inflammatory syndrome (IRIS)* is most commonly seen when initiating therapy in individuals with low CD4 counts and/or advanced HIV disease. Infections commonly associated with IRIS include tuberculosis and other mycobacterial diseases, cryptococcosis, hepatitis virus infections, and Pneumocystis pneumonia.

**Drugs Used to Treat HIV Infection**

**NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS**

The HIV-encoded, RNA-dependent DNA polymerase, also called *reverse transcriptase*, converts viral RNA into proviral DNA that is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogs or non-nucleoside inhibitors (*Table 59–1*). Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) prevent infection of susceptible cells but do not eradicate the virus from cells that already harbor integrated proviral DNA. Nearly all patients starting antiretroviral treatment do
so with at least 1 agent from this class. **Figure 59–2** shows the mechanism of action of NRTIs, which involves phosphorylation by host cells to the active inhibitory form.

*| A number of fixed-dose co-formulations are available: zidovudine + lamivudine (Combivir); zidovudine + lamivudine + abacavir (Triziv); abacavir + lamivudine (Epzicom); tenofovir + emtricitabine (Truvada); tenofovir + efavirenz + emtricitabine (Atripla).  

*| Lopinavir is available only as part of a fixed-dose co-formulation with ritonavir (Kaletra/Arista).  

*| No longer marketed worldwide.
Figure 59–2 Mechanism of nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs). Zidovudine is depicted; Table 59–1 lists other agents in the NRTI class. Nucleoside and nucleotide analogs must enter cells and be phosphorylated to generate synthetic substrates for reverse transcriptase. The fully phosphorylated analogs block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3′-hydroxyl group.

All but 1 of the drugs in this class are nucleosides that must be triphosphorylated at the 5′-hydroxyl to exert activity. The sole exception, tenofovir, is a nucleotide monophosphate analog that requires 2 additional phosphates to acquire full activity. These compounds inhibit both HIV-1 and HIV-2, and several have broad-spectrum activity against other human and animal retroviruses; emtricitabine, lamivudine, and tenofovir are active against hepatitis B virus (HBV), and tenofovir also has activity against herpesviruses (see Chapter 58).

The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA polymerases. Although the intracellular triphosphates for all these drugs have low affinity for human DNA polymerase-α and polymerase-β, some do inhibit human DNA polymerase-
γ, which is the mitochondrial enzyme. As a result, the important toxicities common to this class of drugs result in part from the inhibition of mitochondrial DNA synthesis. These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with stavudine, zidovudine, and didanosine. Phosphorylated emtricitabine, lamivudine, and tenofovir have low affinity for DNA polymerase-γ and are largely devoid of mitochondrial toxicity.

Table 59–2 summarizes the pharmacokinetic properties of NRTIs approved for treating HIV infection. A notable pharmacological feature of these agents is the elimination of the intracellular nucleoside di- or tri-phosphate, which is the active form. In general, the phosphorylated anabolites are eliminated from cells much more gradually than the parent drug is eliminated from the plasma. As a result, available NRTIs are dosed once or twice daily.

</table>

These drugs are not major substrates for hepatic CYPs. Pharmacokinetic drug interactions involving tenofovir and protease inhibitors are likely to be explained by inhibition of OATP drug transporters (see Chapter 5). High-level resistance to NRTIs, especially thymidine analogs, occurs slowly by comparison to non-NRTIs and first-generation protease inhibitors. High-level resistance can occur rapidly with lamivudine and emtricitabine. Cross-resistance is common but often
confined to drugs having similar chemical structures. Several nucleoside analogs have favorable safety and tolerability profiles and are useful in suppressing the emergence of HIV isolates resistant to the more potent drugs in combination regimens.

**ZIDOVUDINE.** Zidovudine (AZT) is a synthetic thymidine analog (see structure in Figure 59–2) with potent activity against a broad spectrum of retroviruses including HIV-1, HIV-2, and human T-cell lymphotrophic viruses (HTLVs) I and II. Zidovudine is active in lymphoblastic and monocytic cell lines but has no impact on cells already infected with HIV. Zidovudine appears to be more active in activated than in resting lymphocytes because the phosphorylating enzyme, thymidine kinase, is S-phase-specific. Zidovudine is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission; it also is recommended for post-exposure prophylaxis in HIV-exposed healthcare workers. Zidovudine (RETROVIR) is marketed in oral tablets, capsules, and solution as well as a solution for intravenous injection. Zidovudine is available in coformulated tablets with lamivudine (COMBIVIR) or with lamivudine and abacavir (TRIZIVIR).

**MECHANISMS OF ACTION AND RESISTANCE.** Intracellular zidovudine is phosphorylated to zidovudine 5’-triphosphate. Zidovudine 5’-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3’-hydroxyl group. The monophosphate competitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate. Zidovudine 5’-triphosphate only weakly inhibits cellular DNA polymerase-α but is a more potent inhibitor of mitochondrial polymerase-γ. Because the conversion of zidovudine 5’-monophosphate to diphosphate is very inefficient, high concentrations of the monophosphate accumulate inside cells and may serve as a precursor depot for formation of triphosphate. As a consequence, there is little correlation between extracellular concentrations of parent drug and intracellular concentrations of triphosphate, and higher plasma concentrations of zidovudine do not increase intracellular triphosphate concentrations proportionately.
Resistance to zidovudine is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219. These mutations are referred to as \textit{thymidine analog mutations} (TAMs) because of their ability to confer cross-resistance to other thymidine analogs such as stavudine. The M184V substitution in the reverse transcriptase gene associated with the use of lamivudine or emtricitabine greatly restores sensitivity to zidovudine. The combination of zidovudine and lamivudine produces greater long-term suppression of plasma HIV RNA than does zidovudine alone.

\textbf{ADME.} Zidovudine is absorbed rapidly and reaches peak plasma concentrations within 1 h. Table 59–2 summarizes the drug’s pharmacokinetic profile, which is not altered significantly during pregnancy; drug concentrations in the newborn approach those of the mother. Parent drug crosses the blood-brain barrier relatively well and also is detectable in breast milk, semen, and fetal tissue.

\textbf{UNTOWARD EFFECTS.} Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia; these symptoms usually resolve within a few weeks. Erythrocytic macrocytosis is seen in \textasciitilde90\% of patients but usually is not associated with anemia. Chronic zidovudine administration has been associated with nail hyperpigmentation. Skeletal muscle myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase-$\gamma$. Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal.

\textbf{PRECAUTIONS AND INTERACTIONS.} Zidovudine is not a substrate or inhibitor of CYPs. However, probenecid, fluconazole, atovaquone, and valproic acid may increase plasma concentrations of zidovudine, probably through inhibition of glucuronosyl transferases. Zidovudine can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly.

\textbf{STAVUDINE.} Stavudine (d4T) is a synthetic thymidine analog that is active in vitro against HIV-1 and HIV-2. Stavudine (ZERIT) is approved for use in HIV-infected adults and children, including
neonates.

MECHANISMS OF ACTION AND RESISTANCE. Intracellular stavudine is sequentially phosphorylated stavudine 5′-triphosphate. Like zidovudine, stavudine is most potent in activated cells, probably because thymidine kinase, which produces the monophosphate, is an S-phase-specific enzyme. Stavudine resistance is seen most frequently with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219, which are mutations associated with zidovudine resistance. Resistance mutations for stavudine appear to accumulate slowly. Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy.

ADME. Table 59–2 summarizes the agent's PK data. Stavudine is well absorbed and reaches peak plasma concentrations within 1 h; bioavailability is not affected by food. The drug penetrates well into the CSF, achieving concentrations that are ~40% of those in plasma. Placental concentrations of stavudine are about half those of zidovudine. The drug undergoes active tubular secretion, and renal elimination accounts for ~40% of parent drug; thus, dose should be adjusted in patients with renal insufficiency.

UNTOWARD EFFECTS. The most common serious toxicity of stavudine is peripheral neuropathy. Although this may reflect mitochondrial toxicity, stavudine is a less potent inhibitor of DNA polymerase-γ than either didanosine or zalcitabine, suggesting that other mechanisms may be involved. Stavudine is also associated with a progressive motor neuropathy characterized by weakness and in some cases respiratory failure, similar to Guillain-Barré syndrome.

Lactic acidosis and hepatic steatosis are associated with stavudine use, and may be more common when stavudine and didanosine are combined. Acute pancreatitis is not highly associated with stavudine but is more common when stavudine is combined with didanosine than when didanosine is given alone. Of all nucleoside analogs, stavudine use is associated most strongly with fat wasting (lipoatrophy). Stavudine has fallen out of favor in the developed world largely because of this toxicity.

PRECAUTIONS AND INTERACTIONS. Stavudine is mainly renally cleared and is not subject to metabolic drug interactions. The incidence and severity of peripheral neuropathy may be increased when stavudine is combined with other
neuropathic medications; thus, drugs such as ethambutol, isoniazid, phenytoin, and vincristine should be avoided. Combining stavudine with didanosine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis; therefore, these 2 drugs should not be used together. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly.

**LAMIVUDINE.** Lamivudine is a cytidine analog reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and HBV. Lamivudine (EPIVIR) is approved for HIV in adults and children ≥3 months of age. Lamivudine has been effective in combination with other antiretroviral drugs in both treatment-naive and experienced patients and is a common component of therapy, given its safety, convenience, and efficacy. Lamivudine (EPIVIR-HBV) is approved for treatment of chronic hepatitis B.

**MECHANISMS OF ACTION AND RESISTANCE.** Lamivudine enters cells by passive diffusion and is sequentially phosphorylated to lamivudine 5′-triphosphate, which is the active anabolite. Lamivudine has low affinity for human DNA polymerases, explaining its low toxicity to the host. High-level resistance to lamivudine occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce in vitro sensitivity to lamivudine as much as 1000-fold. The M184V mutation restores zidovudine susceptibility in zidovudine-resistant HIV and also partially restores tenofovir susceptibility in tenofovir-resistant HIV harboring the K65R mutation. This effect may contribute to the sustained virologic benefits of zidovudine and lamivudine combination therapy.

**ADME.** Table 59–2 summarizes the PK parameters for this drug. Lamivudine is excreted primarily unchanged in the urine; dose adjustment is recommended for patients with a creatinine clearance <50 mL/min. Lamivudine freely crosses the placenta into the fetal circulation.

**UNTOWARD EFFECTS.** Lamivudine is one of the least toxic antiretroviral drugs. Neutropenia, headache, and nausea have been reported at higher than recommended doses. Pancreatitis has been reported in pediatric patients.

**PRECAUTIONS AND INTERACTIONS.** Because lamivudine also has activity against
HBV, caution is warranted in using this drug in patients coinfected with HBV or in HBV-endemic areas: discontinuation of lamivudine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

**ABACAVIR.** Abacavir (ZIAGEN), a synthetic purine analog, is approved for the treatment of HIV-1 infection, in combination with other antiretroviral agents. Abacavir is available in a co-formulation with zidovudine and lamivudine (TRIZIVIR) for twice-daily dosing and in a co-formulation with lamivudine (EPZICOM) for once-daily dosing. Abacavir is approved for use in adult and pediatric patients ≥3 months of age, with dosing in the latter based on body weight.

**MECHANISMS OF ACTION AND RESISTANCE.** Abacavir is the only approved antiretroviral that is active as a guanosine analog. It is sequentially phosphorylated in the host cell to carbovir 5′-triphosphate, which terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3′-hydroxyl group. Clinical resistance to abacavir is associated with 4 specific substitutions: K65R, L74V, Y115F, and M184V. In combination, these substitutions can reduce susceptibility by up to 10-fold. K65R confers cross-resistance to all nucleosides except zidovudine. An alternate pathway for abacavir resistance involves mutations at codons 41, 210, and 215.

**ADME.** Table 59–2 summarizes the PK parameters for this agent. The presence of food does not affect the oral bioavailability of abacavir. Abacavir is neither a substrate nor an inhibitor of CYPs. Its CSF/plasma AUC ratio is ~0.3.

**UNTOWARD EFFECTS.** The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity syndrome characterized by fever, abdominal pain, and other GI complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea), musculoskeletal complaints, headache, and paresthesias are less common. The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate discontinuation of the drug. *Abacavir must never be restarted once discontinued for hypersensitivity.*

The hypersensitivity syndrome (in 2-9% of patients) results from a genetically mediated immune response linked to both the HLA-B*5701 locus and the M493T allele in the heat-shock locus Hsp70-Hom. The latter gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor
necrosis factor-α release after exposure of human lymphocytes to abacavir ex vivo.

PRECAUTIONS AND INTERACTIONS. Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of ethanol (0.7 g/kg) increased the abacavir plasma AUC by 41% and prolonged the elimination $t_{1/2}$ by 26% possibly owing to competition for alcohol dehydrogenase, which produces the dehydro metabolite of the drug (see Table 59–2).

TENOFOVIR. Tenofovir disoproxil is a derivative of adenosine 5’-monophosphate that lacks a complete ribose ring; it is the only nucleotide analog currently marketed for the treatment of HIV infection. Tenofovir is available as the disoproxil prodrug, which substantially improves oral absorption. It is active against HIV-1, HIV-2, and HBV. Tenofovir (VIREAD) is FDA-approved for treating HIV infection in adults in combination with other antiretroviral agents and for the treatment of chronic hepatitis B in adults.

MECHANISMS OF ACTION AND RESISTANCE. Tenofovir disoproxil is hydrolyzed rapidly to tenofovir, which is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate (which is actually a triphosphate: the parent drug is a monophosphate). Tenofovir diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerase-α, polymerase-β, and polymerase-γ, which is the basis for its selective toxicity.

Specific resistance occurs with a K65R substitution that has been associated with clinical failure of tenofovir-containing regimens. Tenofovir sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to zidovudine or stavudine. The M184V mutation associated with lamivudine or emtricitabine resistance partially restores susceptibility in tenofovir-resistant HIV harboring the K65R mutation.

ADME. Table 59–2 shows PK data for tenofovir. Following an intravenous dose,
70-80% of the drug is recovered unchanged in the urine; thus, doses should be decreased in those with renal insufficiency. Tenofovir is not known to inhibit or induce CYPs.

**UNTOWARD EFFECTS.** Tenofovir generally is well tolerated, with few significant adverse effects reported except for flatulence. Rare episodes of acute renal failure and Fanconi syndrome have been reported, and this drug should be used with caution in patients with preexisting renal disease. Tenofovir use is associated with small declines in estimated creatinine clearance after months of treatment in some patients; because the dose needs to be reduced in renal insufficiency, renal function (creatinine and phosphorus) should be monitored regularly. Since tenofovir also has activity against HBV, caution is warranted in using this drug in patients coinfected with HBV: discontinuation of tenofovir may be associated with a rebound of HBV replication and exacerbation of hepatitis. Tenofovir can increase the AUC of didanosine and the 2 drugs probably should not be used together.

**EMTRICITABINE.** Emtricitabine (EMTRIVA) is a cytidine analog that is chemically related to lamivudine and shares many of its properties. Emtricitabine is active against HIV-1, HIV-2, and HBV. The drug is FDA-approved for treating HIV infection in adults in combination with other antiretroviral agents and is available co-formulated with tenofovir ± efavirenz.

**MECHANISMS OF ACTION AND RESISTANCE.** Emtricitabine enters cells by passive diffusion and is sequentially phosphorylated to its active metabolite, emtricitabine 5'-triphosphate. High-level resistance to emtricitabine occurs with the same mutations affecting lamivudine (mainly M184V), although these appear to occur less frequently with emtricitabine. The M184V mutation restores sensitivity to zidovudine and in zidovudine-resistant HIV partially restores sensitivity to tenofovir in tenofovir-resistant HIV harboring the K65R mutation. The same K65R mutation confers resistance to emtricitabine and the other cytidine analog lamivudine, as well as didanosine, stavudine, and abacavir.

**ADME.** Table 59–2 summarizes pharmacokinetic data for emtricitabine. Orally administered drug is absorbed rapidly and well; the drug can be taken without regard to meals. Emtricitabine is excreted primarily unchanged in the urine, thus,
the dose should be reduced in patients with creatinine clearances of <50 mL/min.

**UNTOWARD EFFECTS.** Emtricitabine is one of the least toxic antiretroviral drugs and has few significant adverse effects. Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Because emtricitabine also has in vitro activity against HBV, caution is warranted in using this drug in patients co-infected with HBV and in regions with high HBV seroprevalence.

**PRECAUTIONS AND INTERACTIONS.** Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to any known metabolic drug interactions.

**DIDANOSINE.** Didanosine (2’,3’-dideoxyinosine; ddI) is a purine nucleoside analog that is active against HIV-1, HIV-2, and other retroviruses including HTLV-1. The drug (VIDEX, VIDEX EC) is FDA-approved for adults and children with HIV infection in combination with other antiretroviral agents. This drug is no longer widely prescribed in the developed world because of the availability of agents with less toxicity.

**MECHANISMS OF ACTION AND RESISTANCE.** Didanosine enters cells via a nucleoside transporter and is sequentially phosphorylated by cellular enzymes to the triphosphate, the active anabolite that functions as an antiviral adenosine analog. Resistance to didanosine is associated with mutations at reverse transcriptase codons 65 and 74. The L74V substitution, which reduces susceptibility 5- to 26-fold in vitro, is seen most commonly in patients failing to respond to didanosine. Other nucleoside analog mutations, including TAMs, can contribute to didanosine resistance even though the drug does not appear to select for these mutations de novo. The reverse transcriptase insertion mutations at codon 69 produce cross-resistance to all current nucleoside analogs, including didanosine.

**ADME.** Table 59–2 summarizes some major pharmacokinetic parameters for didanosine. The drug is acid labile, and thus is administered with an antacid buffer. Food decreases didanosine bioavailability. All formulations of didanosine must be administered at least 30 min before or 2 h after eating. This complicates dosing of didanosine in combination with antiretroviral drugs that must be given
with food, as is the case for most HIV protease inhibitors. Didanosine is excreted both by glomerular filtration and by tubular secretion; doses therefore must be adjusted in patients with renal insufficiency.

**UNTOWARD EFFECTS.** The most serious toxicities associated with didanosine include peripheral neuropathy and pancreatitis, both of which are thought to be a consequence of mitochondrial toxicity. Didanosine should be avoided in patients with a history of pancreatitis or neuropathy. Patients complain of pain, numbness, and tingling in the affected extremities. If the drug is stopped as soon as symptoms appear, the neuropathy should improve or resolve. However, irreversible neuropathy can occur with continued use. Retinal changes and optic neuritis also have been reported. Coadministration of other drugs that cause pancreatitis or neuropathy (i.e., stavudine) also will increase the risk and severity of these symptoms. Ethambutol, isoniazid, vincristine, cisplatin, and pentamidine also should be avoided. Serious hepatic toxicity occurs very rarely but can be fatal. Other reported adverse effects include elevated hepatic transaminases, headache, and asymptomatic hyperuricemia and portal hypertension.

**PRECAUTIONS AND INTERACTIONS.** Buffering agents included in didanosine formulations can interfere with the bioavailability of some coadministered drugs because of altered pH or chelation with cations in the buffer. For example, didanosine greatly reduces the AUCs of ciprofloxacin and indinavir; concentrations of ketoconazole and itraconazole, whose absorption is pH dependent, also are diminished. These interactions generally can be avoided by separating administration of didanosine from that of other agents by at least 2 h after or 6 h before the interacting drug. The enteric-coated formulation of didanosine does not alter ciprofloxacin or indinavir absorption. Didanosine is excreted renally, and shared renal excretory mechanisms provide a basis for interactions with oral ganciclovir, allopurinol, and tenofovir. Methadone decreases the didanosine AUC by ~60%.

**NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS**

NNRTIs include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase, in a site distant from the active site (Figure 59–3). These
compounds induce a conformational change in the 3-dimensional structure of the enzyme that greatly reduces its activity, and thus they act as noncompetitive inhibitors. Because the binding site for NNRTIs is virus-strain-specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection. These compounds also have no activity against host cell DNA polymerases. The 4 approved NNRTIs are nevirapine, efavirenz, etravirine, and delavirdine. Table 59–3 summarizes their pharmacokinetic properties.

Figure 59–3 Mechanism of non-nucleoside reverse transcriptase inhibitors (NNRTIs).

Table 59–3

Pharmacokinetic Properties of Non-nucleoside Reverse Transcriptase
Agents in this class share a number of properties. All approved NNRTIs are eliminated from the body by hepatic metabolism. Efavirenz, etravirine, and nevirapine are moderately potent inducers of hepatic drug-metabolizing enzymes including CYP3A4; delavirdine is mainly a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds. All NNRTIs except etravirine are susceptible to high-level drug resistance caused by single-amino-acid changes in the NNRTI-binding pocket (usually in codons 103 or 181). Exposure to even a single dose of nevirapine in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients. These agents are potent and highly effective but must be combined with at least 2 other active agents to avoid resistance.

The use of efavirenz or nevirapine in combination with other antiretroviral drugs is associated with favorable long-term suppression of viremia and elevation of CD4+ lymphocyte counts. Efavirenz is a common component of first regimens for treatment-naive patients due to its convenience, tolerability, and potency. Rashes occur frequently with all NNRTIs, usually during the first 4 weeks of therapy. Rare cases of potentially fatal Stevens-Johnson syndrome have been reported with nevirapine, efavirenz, and etravirine. Fat accumulation can be seen after long-term use of NNRTIs, and fatal hepatitis has been associated with nevirapine use.

**NEVIRAPINE.** Nevirapine (VIRAMUNE) is a dipyridodiazepinone NNRTI with potent activity against HIV-1. The drug is FDA-approved for the treatment of HIV-1 infection in adults and children in

*Values at steady state after multiple oral doses.*
combination with other antiretroviral agents. *Nevirapine should never be used as a single agent or as the sole addition to a failing regimen.* Nevirapine is approved for use in infants and children ≥15 days old, with dosing based on body surface area. Single-dose nevirapine has been used commonly in pregnant HIV-infected women to prevent mother-to-child transmission.

**ADME.** Table 59–3 summarizes the PK data for this agent. Nevirapine is well absorbed and its bioavailability is not altered by food or antacids. The drug readily crosses the placenta and has been found in breast milk. Nevirapine is a moderate inducer of CYPs and induces its own metabolism. To compensate for this, it is recommended that the drug be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have occurred.

**UNTOWARD EFFECTS.** The most frequent adverse events associated with nevirapine are rash (in ~16% of patients) and pruritus. In most patients the rash resolves with continued administration of drug; administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with nevirapine use, and this may be more common in women with CD4 counts >250 cells/mm³, especially during pregnancy. Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

**PRECAUTIONS AND INTERACTIONS.** Because nevirapine induces CYP3A4, this drug may lower plasma concentrations of coadministered CYP3A4 substrates. Methadone withdrawal has been reported in patients receiving nevirapine, presumably as a consequence of enhanced methadone clearance. Plasma ethinyl estradiol and norethindrone concentrations decrease by 20% with nevirapine; alternative methods of birth control are advised.

**EFAVIRENZ.** Efavirenz (SUSTIVA) (see structure in Figure 59–3) is an NNRTI with potent activity against HIV-1. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Efavirenz is used
widely in the developed world because of its convenience, effectiveness, and long-term tolerability. Especially popular is the once-daily single pill co-formulation of efavirenz, tenofovir, and emtricitabine (ATRIPLA). Efavirenz plus 2 nucleoside reverse transcriptase inhibitors remains a preferred regimen for treatment-naive patients. Efavirenz can be safely combined with rifampin and is useful in patients also being treated for tuberculosis. Efavirenz is approved for adult and pediatric patients ≥3 years of age and weighing at least 10 kg.

ADME. Table 59–3 summarizes the PK data for this agent. Efavirenz is well absorbed from the GI tract, but there is diminished absorption of the drug with increasing doses. Bioavailability (AUC) is increased by 22% with a high-fat meal. Efavirenz is >99% bound to plasma proteins and, as a consequence, has a low CSF-to-plasma ratio of 0.01. The drug should be taken initially on an empty stomach at bedtime to reduce side effects. Efavirenz is cleared mainly by CYP2B6 and to a lesser extent by CYP3A4. The parent drug is not excreted renally to a significant degree. The long elimination t1/2 permits once-daily dosing.

UNTOWARD EFFECTS. The most important adverse effects of efavirenz involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but <5% discontinue the drug for this reason. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy. Rash occurs frequently with efavirenz (27%), usually in the first few weeks of treatment, resolving spontaneously and rarely requiring drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome are rare. Other side effects reported with efavirenz include headache, increased hepatic transaminases, and elevated serum cholesterol. Efavirenz is the only antiretroviral drug that is unequivocally teratogenic in primates. Women of childbearing potential therefore should use 2 methods of birth control and avoid pregnancy while taking efavirenz.

PRECAUTIONS AND INTERACTIONS. Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4, but also a weak to moderate CYP inhibitor.
Efavirenz decreases concentrations of phenobarbital, phenytoin, and carbamazepine; the methadone AUC is reduced by 33-66% at steady state. Efavirenz reduces the rifabutin AUC by 38% on average. Efavirenz has a variable effect on HIV protease inhibitors: indinavir, saquinavir, and amprenavir concentrations are reduced; ritonavir and nelfinavir concentrations are increased. Drugs that induce CYPs 2B6 or 3A4 (e.g., phenobarbital, phenytoin, and carbamazepine) would be expected to increase the clearance of efavirenz and should be avoided.

**ETRAVIRINE.** Etravirine is a diarylpyrimidine NNRTI that is active against HIV-1. Etravirine is unique in its ability to inhibit reverse transcriptase that is resistant to other NNRTIs. The drug appears to have conformational and positional flexibility in the NNRTI binding pocket that allow it to inhibit the function of the HIV-1 reverse transcriptase in the presence of common NNRTI resistance mutations. Etravirine (INTELENCE) is approved for use only in treatment-experienced HIV-infected adults. NNRTI-experienced patients should not receive etravirine plus NRTIs alone. Etravirine has not yet been approved for pediatric use.

**ADME.** Table 59–3 summarizes the PK data for this agent. Food increases the etravirine AUC by 50%, and it is recommended that the drug be administered with food. Methyl- and dimethyl-hydroxylated metabolites are produced in the liver primarily by CYPs 3A4, 2C9, and 2C19, accounting for most of the elimination of this drug. No unchanged drug is detected in the urine.

**UNTOWARD EFFECTS.** The only notable side effect of etravirine is rash (17% vs. placebo value of 9%), usually occurring within a few weeks of starting therapy and resolving within 1-3 weeks. Severe rash including Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported.

**PRECAUTIONS AND INTERACTIONS.** Etravirine is an inducer of CYP3A4 and glucuronosyl transferases, and an inhibitor of CYPs 2C9 and 2C19, and can therefore be involved in a number of clinically significant pharmacokinetic drug interactions. Etravirine can be combined with darunavir/ritonavir, lopinavir/ritonavir, and saquinavir/ritonavir without the need for dose
adjustments. The dose of maraviroc should be doubled when these 2 drugs are combined. Etravirine should not be administered with tipranavir/ritonavir, fosamprenavir/ritonavir, or atazanavir/ritonavir in the absence of better data to guide dosing. Etravirine should not be combined with efavirenz, nevirapine, or delavirdine. Unlike other NNRTIs, etravirine does not appear to alter the clearance of methadone.

**DELAVIDINE**
Delavirdine is a bisheteroarylpiperazine NNRTI that selectively inhibits HIV-1. This agent shares resistance mutations with efavirenz and nevirapine. Delavirdine is well absorbed, especially at pH <2. Antacids, histamine H₂-receptor antagonists, proton pump inhibitors, and achlorhydria may decrease its absorption. The drug can be administered irrespective of food. Delavirdine clearance is primarily through oxidative metabolism by CYP3A4, with <5% of a dose recovered unchanged in the urine. At the recommended dose of 400 mg 3 times daily, the elimination $t_{1/2}$ is 5.8 h.

The most common side effect of delavirdine is rash (18-36%), usually in the first few weeks of treatment and often resolving despite continued therapy. Severe dermatitis, including erythema multiforme and Stevens-Johnson syndrome, is rare. Elevated hepatic transaminases and hepatic failure also have been reported, as has neutropenia (rare). Delavirdine is both a substrate for and an inhibitor of CYP3A4 and can alter the metabolism of other CYP3A4 substrates. Delavirdine increases the plasma concentrations of most HIV protease inhibitors.

**HIV PROTEASE INHIBITORS**
HIV protease inhibitors (PIs) are peptide-like chemicals that competitively inhibit the action of the virus aspartyl protease (Figure 59–4). This protease is a homodimer consisting of two 99-amino acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis. The preferred cleavage site for this enzyme is the N-terminal side of proline residues, especially between phenylalanine and proline. Human aspartyl proteases (i.e., renin, pepsin, gastricsin, and cathepsins D and E) contain only 1 polypeptide chain and are not significantly inhibited by HIV PIs.
Figure 59–4 Mechanism of action of the HIV protease inhibitor saquinavir. Shown here is a phenylalanine-proline target peptide sequence (in blue) for the protease enzyme (in golden brown) with chemical structures of the native amino acids (in lower box) to emphasize homology of their structures to that of saquinavir (at top).

Table 59–4 summarizes pharmacokinetic data for these agents. Clearance is mainly through hepatic oxidative metabolism. All except nelfinavir are metabolized predominantly by CYP3A4 (and nelfinavir’s major metabolite is cleared by CYP3A4). All approved HIV PIs have the potential for metabolic drug interactions. Most of
these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with ritonavir by far the most potent. It is now a common practice to combine HIV PIs with a low dose of ritonavir to take advantage of that drug’s remarkable capacity to inhibit CYP3A4 metabolism. Doses of 100 or 200 mg once or twice daily are sufficient to inhibit CYP3A4 and increase (“boost”) the concentrations of most concurrently administered CYP3A4 substrates. The enhanced pharmacokinetic profile of HIV PIs administered with ritonavir reflects inhibition of both first-pass and systemic clearance, resulting in improved oral bioavailability and a longer elimination $t_{1/2}$ of the coadministered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations. Combinations of darunavir, lopinavir, fosamprenavir, and atazanavir with ritonavir are approved for once-daily administration.

*All results under plasma concentration-time curve; $t_{1/2}$, half-life of elimination; ↑, increase; ↓, decrease; +, no effect; CYP, cytochrome P450; ND, not determined; <, weak; ++, moderate; ++++, substantial.

*Reported mean values in adults with normal renal and hepatic function.

*Parameters reported for the respective soft-gel capsule formulation.

*Values for lopinavir, tipranavir, and dasaponavir reflect coadministration with ritonavir.

Most HIV PIs are substrates for the P-glycoprotein efflux pump (P-gp) (see Chapter 5). These agents generally penetrate less well into semen than do NRTIs and NNRTIs. HIV PIs have a high interindividual variability that may reflect differential activity of intestinal and hepatic CYPs. The speed with which HIV
develops resistance to unboosted PIs is intermediate between that of nucleoside analogs and NNRTIs. Initial (primary) resistance mutations in the enzymatic active site confer only a 3- to 5-fold drop in sensitivity to most drugs; these are followed by secondary mutations often distant from the active site that compensate for the reduction in proteolytic efficiency. Accumulation of secondary resistance mutations increases the likelihood of cross-resistance to other PIs.

GI side effects including nausea, vomiting, and diarrhea are common, although symptoms resolve within 4 weeks of starting treatment. With potent activity and favorable resistance profiles, these drugs are a common component of regimens for treatment-experienced patients. However, the virologic benefits of these drugs must be balanced against short- and long-term toxicities, including the risk of insulin resistance and lipodystrophy.

SAQUINAVIR. Saquinavir is a peptidomimetic hydroxyethylamine that inhibits both HIV-1 and HIV-2 replication (Figure 59–4). Typical of HIV PIs, high-level resistance requires accumulation of multiple resistance mutations. The drug is available as a hard-gelatin capsule (INVIrase). When combined with ritonavir and nucleoside analogs, saquinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens.

ADME. Table 59–4 summarizes the pharmacokinetic profile of this agent. Fractional oral bioavailability is low owing mainly to first-pass metabolism, and so this drug should always be given in combination with ritonavir. Low doses of ritonavir increase the saquinavir steady-state AUC by 20- to 30-fold. Substances that inhibit intestinal but not hepatic CYP3A4 (e.g., grapefruit juice) can increase the saquinavir AUC by ~3-fold.

UNTOWARD EFFECTS. The most frequent side effects of saquinavir are GI: nausea, vomiting, diarrhea, and abdominal discomfort. Most side effects of saquinavir are mild and short lived, although long-term use is associated with lipodystrophy.

PRECAUTIONS AND INTERACTIONS. Saquinavir clearance is increased with CYP3A4 induction. Coadministration of inducers of CYP3A4 such as rifampin,
phenytoin, or carbamazepine lowers saquinavir concentrations and should be avoided. The effect of nevirapine or efavirenz on saquinavir may be reversed with ritonavir.

**RITONAVIR.** Ritonavir (NORVIR) is a peptidomimetic HIV protease inhibitor designed to complement the C<sub>2</sub> axis of symmetry of the enzyme active site. Ritonavir is active against both HIV-1 and HIV-2 (perhaps slightly less active against HIV-2). Ritonavir is mostly used as a pharmacokinetic enhancer (CYP3A4 inhibitor); the low doses used for this purpose are not known to induce ritonavir resistance mutations. The drug is used infrequently as the sole protease inhibitor in combination regimens because of GI toxicity.

**ADME.** *Table 59–4* summarizes the pharmacokinetic profile of this agent. Interindividual variability in pharmacokinetics is high, with variability exceeding 6-fold in trough concentrations among patients given 600 mg ritonavir every 12 h as capsules.

**UNTOWARD EFFECTS.** The major side effects of ritonavir are GI and include dose-dependent nausea, vomiting, diarrhea, anorexia, abdominal pain, and taste perversion. GI toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias can occur at the therapeutic dose of 600 mg twice daily. These side effects generally abate within a few weeks of starting therapy. Ritonavir also causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy.

**PRECAUTIONS AND INTERACTIONS.** Ritonavir is one of the most potent known inhibitors of CYP3A4. Thus, ritonavir should be used with caution in combination with any CYP3A4 substrate and should not be combined with drugs that have a narrow therapeutic index such as midazolam, triazolam, fentanyl, and ergot derivatives. Ritonavir is a mixed competitive and irreversible inhibitor of CYP 3A4 and its effects can persist for 2-3 days after the drug is discontinued. Ritonavir is also a weak inhibitor of CYP2D6. Potent inducers of CYP3A4 activity such as rifampin may lower ritonavir concentrations and should be avoided or their dosage adjusted. Capsule and solution formulations of ritonavir contain alcohol and should not be administered with disulfiram or metronidazole. Ritonavir is also a moderate inducer of CYP3A4, glucuronosyl S-
transferase, and possibly other hepatic enzymes and drug transport proteins. The concentrations of some drugs therefore will be decreased in the presence of ritonavir. Ritonavir reduces the ethinyl estradiol AUC by 40%, and alternative forms of contraception should be used.

*Use of Ritonavir as a CYP3A4 Inhibitor.* Ritonavir inhibits the metabolism of all current HIV PIs and is frequently used in combination with most of these drugs, with the exception of nelfinavir, to enhance their pharmacokinetic profile and allow a reduction in dose and dosing frequency of the coadministered drug. Ritonavir also overcomes the deleterious effect of food on indinavir bioavailability. Low doses of ritonavir (100 or 200 mg once or twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600 mg twice-daily.

**FOSAMPRENAVIR.** Fosamprenavir (LEXIVA) is a phosphonooxy prodrug of amprenavir that has increased water solubility and improved oral bioavailability. Fosamprenavir is as effective, and generally better tolerated than amprenavir, and as a result, amprenavir is no longer marketed. The drug is active against both HIV-1 and HIV-2. Fosamprenavir has long-term virologic benefit in treatment-naive and treatment-experienced patients, with or without ritonavir, in combination with nucleoside analogs. Twice-daily fosamprenavir/ritonavir produces virologic outcomes equivalent to lopinavir/ritonavir in both treatment-naive and treatment-experienced patients. Fosamprenavir is approved for use in treatment-naive pediatric patients ≥2 years of age and treatment-experienced patients ≥6 years of age, at a dose of 30 mg/kg twice daily or 18 mg/kg plus ritonavir 3 mg/kg twice daily.

Amprenavir’s primary resistance mutation occurs at HIV protease codon 50. Primary resistance occurs less frequently at codon 84.

**ADME.** *Table 59–4* summarizes the pharmacokinetic profile of this agent. The phosphorylated prodrug is ~2000 times more water soluble than amprenavir. Fosamprenavir is dephosphorylated rapidly to amprenavir in the intestinal mucosa. Meals have no significant effect on fosamprenavir pharmacokinetics.
UNTOWARD EFFECTS. The most common adverse effects associated are GI and include diarrhea, nausea, and vomiting. Hyperglycemia, fatigue, paresthesias, and headache also have been reported. Fosamprenavir can produce skin eruptions; moderate to severe rash (in up to 8% of recipients) may occur within 2 weeks of starting therapy. Fosamprenavir has fewer effects on plasma lipid profiles than lopinavir-based regimens.

PRECAUTIONS AND INTERACTIONS. Inducers of hepatic CYP3A4 activity (e.g., rifampin and efavirenz) may lower plasma amprenavir concentrations. Because amprenavir is both a CYP3A4 inhibitor and inducer, pharmacokinetic drug interactions can occur and may be unpredictable, especially if the drug is given without ritonavir.

LOPINAVIR. Lopinavir is structurally similar to ritonavir but is 3- to 10-fold more potent against HIV-1. This agent is active against both HIV-1 and HIV-2. Lopinavir is available only in co-formulation with low doses of ritonavir (KALETRA) as a CYP3A4 inhibitor. Lopinavir has antiretroviral activity comparable with that of other potent HIV PIs and better than that of nelfinavir. Lopinavir also has considerable and sustained antiretroviral activity in patients who failed previous HIV protease inhibitor–containing regimens.

Treatment-naive patients who fail a first regimen containing lopinavir generally do not have HIV protease mutations but may have genetic resistance to the other drugs in the regimen. For treatment-experienced patients, accumulation of 4 or more HIV protease inhibitor resistance mutations is associated with a reduced likelihood of virus suppression after starting lopinavir.

ADME. Table 59–4 summarizes the pharmacokinetic profile of this agent. The adult lopinavir/ritonavir dose is 400/100 mg (2 tablets) twice daily, or 800/200 mg (4 tablets) once daily. Lopinavir/ritonavir should not be dosed once daily in treatment-experienced patients. Lopinavir/ritonavir is approved for use in pediatric patients ≥14 days, with dosing based on either weight or body surface area. A pediatric tablet formulation is available for use in children >6 months of age. Lopinavir is absorbed rapidly after oral administration. Food has a minimal effect on bioavailability. Although the tablets contain lopinavir/ritonavir in a fixed 4:1 ratio, the observed plasma concentration ratio for these 2 drugs
following oral administration is nearly 20:1, reflecting the sensitivity of lopinavir to the inhibitory effect of ritonavir on CYP3A4. Both lopinavir and ritonavir are highly bound to plasma proteins, mainly to α1-acid glycoprotein, and have a low fractional penetration into CSF and semen.

**UNTOWARD EFFECTS.** The most common adverse events reported with the lopinavir/ritonavir co-formulation are GI: loose stools, diarrhea, nausea, and vomiting. Laboratory abnormalities include elevated total cholesterol and triglycerides. It is unclear whether these side effects are due to ritonavir, lopinavir, or both.

**PRECAUTIONS AND INTERACTIONS.** Concomitant administration of agents that induce CYP3A4, such as rifampin, may lower plasma lopinavir concentrations considerably. St. John’s wort is a known inducer of CYP3A4, leading to lower concentrations of lopinavir and possible loss of antiviral effectiveness. Coadministration of other antiretrovirals that can induce CYP3A4, including amprenavir, nevirapine or efavirenz, may require increasing the dose of lopinavir. The liquid formulation of lopinavir contains 42% ethanol and should not be administered with disulfiram or metronidazole. Ritonavir is also a moderate CYP inducer at the dose employed in the co-formulation and can adversely decrease concentrations of some coadministered drugs (e.g., oral contraceptives). There is no direct proof that lopinavir is a CYP inducer in vivo; however, concentrations of some coadministered drugs (e.g., amprenavir and phenytoin) are lower with the lopinavir/ritonavir co-formulation than would have been expected with low-dose ritonavir alone.

**ATAZANAVIR.** Atazanavir is an azapeptide protease inhibitor that is active against both HIV-1 and HIV-2.

**THERAPEUTIC USE.** In treatment-experienced patients, atazanavir (Reyataz) 400 mg once daily without ritonavir was inferior to the lopinavir/ritonavir co-formulation given twice daily. The combination of atazanavir and low-dose ritonavir had a similar viral-load effect as the lopinavir/ritonavir co-formulation in 1 study, suggesting that this drug should be combined with ritonavir in treatment-experienced patients and perhaps in treatment-naive patients with high baseline viral load. Atazanavir, in combination with ritonavir, is approved for treatment of pediatric patients >6 years of age, with dosing based on weight. The
primary atazanavir resistance mutation occurs at HIV protease codon 50 and confers ~9-fold decreased susceptibility. High-level resistance is more likely if 5 or more additional mutations are present.

ADME. Table 59–4 summarizes the pharmacokinetic profile of this agent. Atazanavir is absorbed rapidly after oral administration. A light meal increases the AUC by 70%; a high-fat meal increases the AUC by 35%. It is therefore recommended that the drug be administered with food. Absorption is pH dependent, and proton pump inhibitors or other acid-reducing agents substantially reduce atazanavir concentrations after oral dosing. The mean elimination $t_{1/2}$ of atazanavir increases with dose, from 7 h at the standard 400-mg once-daily dose to nearly 10 h at a dose of 600 mg. The drug is present in CSF at <3% of plasma concentrations but has excellent penetration into seminal fluid.

UNTOWARD EFFECTS. Like indinavir, atazanavir frequently causes unconjugated hyperbilirubinemia, although this is not associated with hepatotoxicity. Postmarketing reports include hepatic adverse reactions of cholecystitis, cholelithiasis, cholestasis, and other hepatic function abnormalities. Other side effects reported with atazanavir include diarrhea and nausea, mainly during the first few weeks of therapy. Overall, 6% of patients discontinue atazanavir because of side effects during 48 weeks of treatment. Patients treated with atazanavir have significantly lower fasting triglyceride and cholesterol concentrations than patients treated with nelfinavir, lopinavir, or efavirenz. Atazanavir is not known to cause glucose intolerance or changes in insulin sensitivity.

PRECAUTIONS AND INTERACTIONS. Because atazanavir is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., rifampin) is contraindicated. Atazanavir is also a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Atazanavir is a moderate UGT1A1 inhibitor and increases the raltegravir AUC by 41–72%. Ritonavir significantly increases the atazanavir AUC and reduces atazanavir systemic clearance. Proton pump inhibitors (PPIs) reduce atazanavir concentrations substantially with concomitant administration. PPIs and H$_2$ blockers should be avoided in patients receiving atazanavir without ritonavir.
DARUNAVIR. Darunavir is a nonpeptidic protease inhibitor that is active against both HIV-1 and HIV-2. Darunavir binds tightly but reversibly to the active site of HIV protease but has also been shown to prevent protease dimerization. At least 3 darunavir-associated resistance mutations are required to confer resistance. Darunavir (PREZISTA) in combination with ritonavir is approved for use in HIV-infected adults.

ADME. Table 59–4 summarizes the pharmacokinetic profile of this agent. Darunavir/ritonavir can be used as a once-daily (800/100 mg) or twice-daily (600/100 mg) regimen with nucleosides in treatment-naive adults and as a twice-daily regimen (with food) in treatment-experienced adults. Darunavir/ritonavir twice daily is approved for use in pediatric patients >6 years of age, with dosing based on weight. Darunavir is absorbed rapidly after oral administration with ritonavir, with peak concentrations occurring 2-4 h. Ritonavir increases darunavir bioavailability by up to 14-fold. When combined with ritonavir, the mean elimination $t_{1/2}$ of darunavir is ~15 h and the AUC is increased by an order of magnitude.

UNTOWARD EFFECTS. Because darunavir must be combined with a low dose of ritonavir, drug administration can be accompanied by all of the side effects caused by ritonavir, including GI complaints in up to 20% of patients. Darunavir, like fosamprenavir, contains a sulfa moiety, and rash has been reported in up to 10% of recipients. Darunavir/ritonavir is associated with increases in plasma triglycerides and cholesterol, although the magnitude of increase is lower than that seen with lopinavir/ritonavir. Darunavir has been associated with episodes of hepatotoxicity.

PRECAUTIONS AND INTERACTIONS. Because darunavir is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., rifampin) is contraindicated. The drug interaction profile of darunavir/ritonavir is dominated by those expected with ritonavir. Darunavir/ritonavir 600/100 twice daily increases the maraviroc AUC by 340%; the maraviroc dose should be reduced to 150 mg twice daily when combined with darunavir.

INDINAVIR. Indinavir is a peptidomimetic HIV protease inhibitor.
Indinavir (CRIXIVAN) lacks significant advantages over other HIV PIs and is no longer widely prescribed because of problems with nephrolithiasis and other nephrotoxicities.

**ADME.** Table 59–4 summarizes the pharmacokinetic profile of this agent. Indinavir is absorbed rapidly after oral administration, with peak concentrations achieved in ~1 h. High-calorie, high-fat meals reduce plasma concentrations by 75%; thus, indinavir must be taken with ritonavir or while fasting or with a light low-fat meal. Indinavir has the lowest protein binding of the HIV PIs, with only 60% of drug bound to plasma proteins. As a consequence, indinavir has higher fractional CSF penetration than other drugs in this class. The short $t_{1/2}$ of indinavir makes thrice-daily (every 8 h) dosing necessary unless the drug is combined with ritonavir, which reduces indinavir clearance, allowing twice-daily dosing regardless of meals.

**UNTOWARD EFFECTS.** A unique and common adverse effect of indinavir is crystalluria and nephrolithiasis, stemming from the poor solubility of the drug (lower at pH 7.4 than at pH 3.5). Nephrolithiasis occurs in ~3% of patients. Patients must drink sufficient fluids to maintain dilute urine and prevent renal complications. Risk of nephrolithiasis is related to higher plasma drug concentrations. Indinavir frequently causes unconjugated hyperbilirubinemia. This is generally asymptomatic and not associated with serious long-term sequelae. Prolonged administration of indinavir is associated with the HIV lipodystrophy syndrome. Indinavir has been associated with hyperglycemia and can induce a state of relative insulin resistance. Dermatologic complications have been reported, including hair loss, dry skin, dry and cracked lips, and ingrown toenails.

**PRECAUTIONS AND INTERACTIONS.** Patients taking indinavir should drink at least 2 L of water daily to prevent renal complications. *This is especially problematic for those who live in warm climates.* Because indinavir solubility decreases at higher pH, antacids or other buffering agents should not be taken at the same time. Didanosine formulations containing an antacid buffer should not be taken within 2 h before or 1 h after indinavir. Indinavir is metabolized by CYP3A4 and is a moderately potent CYP3A4 inhibitor. Indinavir should not be coadministered with other CYP3A4 substrates that have a narrow therapeutic index.
NELFINAVIR. Nelfinavir is a nonpeptidic protease inhibitor that is active against both HIV-1 and HIV-2. Nelfinavir (VIRACEPT) is approved for the treatment of HIV infection in adults and children in combination with other antiretroviral drugs. Long-term virologic suppression with nelfinavir-based combination regimens is significantly inferior to lopinavir/ritonavir, atazanavir, or efavirenz-based regimens. Nelfinavir is well tolerated in pregnant HIV-infected women but detection of a potentially carcinogenic contaminant led to a recommendation that the drug not be used pregnant women.

The primary nelfinavir resistance mutation (D30N) is unique to this drug and results in a 7-fold decrease in susceptibility. Isolates with only this mutation retain full sensitivity to other HIV PIs. Less commonly, a primary resistance mutation occurs at position 90, which can confer cross-resistance. Secondary resistance mutations can accumulate and these are associated with further resistance to nelfinavir, as well as cross-resistance to other HIV PIs.

ADME. Table 59–4 summarizes the pharmacokinetic profile of this agent. A moderate-fat meal increases the AUC 2- to 3-fold; higher concentrations are achieved with high-fat meals. Intraindividual and interindividual variabilities in plasma nelfinavir concentrations are large as a consequence of variable absorption. Nelfinavir is the only HIV protease inhibitor whose pharmacokinetics are not substantially improved with ritonavir. Its major hydroxy-t-butylamide metabolite, M8, is formed by CYP2C19 and has antiretroviral activity similar to that of the parent drug. This is the only known active metabolite of any HIV protease inhibitor. Nelfinavir induces its own metabolism.

UNTOWARD EFFECTS. The most important side effect of nelfinavir is diarrhea and loose stools, which resolve in most patients within the first 4 weeks of therapy. Otherwise, nelfinavir is generally well tolerated. It has been associated with glucose intolerance, elevated cholesterol levels, and elevated triglycerides.

PRECAUTIONS AND INTERACTIONS. Because nelfinavir is metabolized by CYPs 2C19 and 3A4, concomitant administration of agents that induce these enzymes may be contraindicated (as with rifampin) or may necessitate an increased nelfinavir dose (as with rifabutin). Nelfinavir is a moderate inhibitor of CYP3A4
and may alter plasma concentrations of other CYP3A4 substrates. Nelfinavir also induces hepatic drug-metabolizing enzymes, reducing the AUC of ethinyl estradiol by 47% and norethindrone by 18%. Combination oral contraceptives therefore should not be used as the sole form of contraception in patients taking nelfinavir. Nelfinavir reduces the zidovudine AUC by 35%.

**TIPRANAVIR.** Tipranavir is a non-peptidic protease inhibitor that is active against both HIV-1 and HIV-2. Tipranavir (APTIVUS) is approved for use only in treatment-experienced adult and pediatric patients whose HIV is resistant to 1 or more PIs. Combining tipranavir/ritonavir with at least 1 other active antiretroviral drug, usually enfuvirtide, greatly improves virologic responses. Tipranavir/ritonavir is approved for use in adults and pediatric patients >2 years of age, with pediatric dosing based on weight or body surface area.

Because most HIV strains sensitive to tipranavir are also sensitive to darunavir, darunavir is preferred for most treatment-experienced patients because of its better tolerability and toxicity profile.

**ADME.** Table 59–4 summarizes the pharmacokinetic profile of this agent. Tipranavir must be administered with ritonavir because of poor oral bioavailability. The recommended regimen of tipranavir/ritonavir 500/200 mg twice daily includes a ritonavir dose higher than that of other boosted HIV PIs; lower doses of ritonavir should not be used. Food does not alter pharmacokinetics in the presence of ritonavir but may reduce GI side effects.

**UNTOWARD EFFECTS.** Tipranavir use has been associated rarely with fatal hepatotoxicity and also with intracranial hemorrhage (including fatalities) and bleeding episodes in patients with hemophilia. The drug has anticoagulant properties in vitro and in animal models that are potentiated by vitamin E. Tipranavir is more likely to cause elevation in lipids and triglycerides than other boosted PIs, possibly due to the higher dose of ritonavir. Tipranavir contains a sulfa moiety, and ~10% of treated patients report a transient rash. The current formulation contains a high amount of vitamin E; patients should not take supplements containing this vitamin.
PRECAUTIONS AND INTERACTIONS. Like ritonavir, tipranavir is a substrate, inhibitor, and inducer of CYP enzymes. Tipranavir/ritonavir reduces the concentrations (AUC) of all coadministered PIs by 44-76% and should not be administered with any of these agents. This reflects the combined effect of the increased ritonavir dose, as well as tipranavir’s unique capacity among PIs to induce expression of the P-glycoprotein drug transporter.

ENTRY INHIBITORS

The 2 drugs available in this class, enfuvirtide and maraviroc, have different mechanisms of action (see Figure 59–1). Enfuvirtide inhibits fusion of the viral and cell membranes mediated by gp41 and CD4 interactions. Maraviroc is a chemokine receptor antagonist and binds to the host cell CCR5 receptor to block binding of viral gp120.

MARAVIROC. Maraviroc blocks the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine receptor (Figure 59–5). Maraviroc (SELZENTRY) is approved for use in HIV-infected adults who have baseline evidence of predominantly CCR5-tropic virus. The drug has no activity against viruses that are CXCR4-tropic or dual-tropic. Maraviroc retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.
Figure 59–5 *Mechanism of action of the HIV entry inhibitor maraviroc.*

HIV can develop resistance to this drug through 2 distinct pathways. A patient starting maraviroc therapy with HIV that is predominantly CCR5-tropic may experience a shift in tropism to CXCR4- or dual/mixed-tropism predominance. This is especially likely in patients harboring low-level but undetected CXCR4- or dual/mixed-tropic virus prior to initiation of maraviroc. Alternatively, HIV can retain its CCR5-tropism but gain resistance to the drug through specific mutations in the V3 loop of gp 120 that allow virus binding in the presence of inhibitor.

ADME. Maraviroc is the only antiretroviral drug approved at 3 different starting doses, depending on concomitant medications. When combined with most CYP3A inhibitors, the starting dose is 150 mg twice daily; when combined with most CYP3A inducers, the starting dose is 600 mg twice daily; for other
concomitant medications, the starting dose is 300 mg twice daily. The oral bioavailability of maraviroc, 23-33%, is dose-dependent. Food decreases bioavailability, but there are no food requirements for drug administration. Elimination is mainly via CYP3A4 with an elimination $t_{1/2}$ of 10.6 h.

UNTOWARD EFFECTS. Maraviroc is generally well tolerated. One case of serious hepatotoxicity with allergic features has been reported, but in controlled trials significant (grade 3 or 4) hepatotoxicity was no more frequent with maraviroc than with placebo.

PRECAUTIONS AND INTERACTIONS. Maraviroc is a CYP3A4 substrate and susceptible to pharmacokinetic drug interactions involving CYP3A4 inhibitors or inducers. Maraviroc is not itself a CYP inhibitor or inducer in vivo, although high-dose maraviroc (600 mg daily) can increase concentrations of the CYP2D6 substrate debrisoquine.

ENFUVIRTIDE. Enfuvirtide is a 36-amino-acid synthetic peptide that is not active against HIV-2 but is broadly effective against laboratory and clinical isolates of HIV-1. Enfuvirtide (FUZEON) is FDA-approved for use only in treatment-experienced adults who have evidence of HIV replication despite ongoing antiretroviral therapy. The drug’s cost and route of administration (subcutaneous injection twice daily) limit its use to those with no other treatment options.

MECHANISMS OF ACTION AND RESISTANCE. The amino acid sequence of enfuvirtide is derived from the transmembrane gp41 region of HIV-1 that is involved in fusion of the virus membrane lipid bilayer with that of the host cell membrane. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a 6-helix bundle critical for membrane fusion and viral entry into the host cell. Enfuvirtide inhibits infection of CD4+ cells by free virus particles. Enfuvirtide retains activity against viruses that have become resistant to antiretroviral agents of other classes. HIV can develop resistance to this drug through specific mutations in the enfuvirtide-binding domain of gp41.

ADME. Enfuvirtide is the only approved antiretroviral drug that must be administered parenterally. The bioavailability of subcutaneous enfuvirtide is
84% compared with an intravenous dose. Pharmacokinetics of the subcutaneous drug are not affected by site of injection. The major route of elimination for enfuvirtide has not been determined. The mean elimination $t_{1/2}$ of parenteral drug is 3.8 h, necessitating twice-daily administration.

**UNTOWARD EFFECTS.** The most prominent adverse effects of enfuvirtide are injection-site reactions. Most patients (98%) develop local side effects including pain, erythema, and induration at the site of injection; 80% of patients develop nodules or cysts. Use of enfuvirtide has been associated with a higher incidence of lymphadenopathy and pneumonia. Enfuvirtide is not known to alter the concentrations of any coadministered drugs.

**INTEGRASE INHIBITORS**

Chromosomal integration is a defining characteristic of retrovirus life cycles and allows viral DNA to remain in the host cell nucleus for a prolonged period of inactivity or latency (see Figure 59–1). Because human DNA is not known to undergo excision/reintegration, this process is an excellent target for antiviral intervention. The HIV integrase inhibitor, raltegravir, prevents the formation of covalent bonds between host and viral DNA—a process known as strand transfer—presumably by interfering with essential divalent cations in the enzyme’s catalytic core.

**RALTEGRAVIR.** Raltegravir blocks the catalytic activity of the HIV-encoded integrase, thus preventing integration of viral DNA into the host chromosome (Figure 59–6). Raltegravir has potent activity against both HIV-1 and HIV-2. Raltegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action. Raltegravir (ISENTERRES) is approved for use in HIV-infected adults.
ADME. Peak concentrations of raltegravir occur ~1 h after oral dosing. Elimination is biphasic, with an α-phase $t_{1/2}$ of ~1 h and a terminal β-phase $t_{1/2}$ of 12 h, with the α-phase predominating. The pharmacokinetics of raltegravir are highly variable. Moderate- and high-fat meals increase raltegravir apparent bioavailability (AUC) by as much as 2-fold; a low-fat meal decreases AUC modestly (46%); however, there are no food requirements for raltegravir administration. The drug is 83% protein bound in human plasma. Raltegravir is eliminated mainly via glucuronidation by UGT1A1.

UNTOWARD EFFECTS. Raltegravir is generally well tolerated, with little clinical toxicity. The most common complaints are headache, nausea, asthenia, and fatigue. Creatine kinase elevations, myopathy, and rhabdomyolysis have been reported, as has exacerbation of depression.

PRECAUTIONS AND INTERACTIONS. As a UGT1A1 substrate, raltegravir is susceptible to pharmacokinetic drug interactions involving inhibitors or inducers of this enzyme. Atazanavir, a moderate UGT1A1 inhibitor, increases the raltegravir AUC 41-72%. Tenofovir increases the raltegravir AUC by 49%, but the mechanism for this interaction is unknown. When raltegravir is combined with the CYP inducer rifampin, the raltegravir dose should be doubled to 800 mg twice daily. Raltegravir has little effect on the pharmacokinetics of the usual coadministered drugs.

Current treatment recommendations center around making 2 important clinical decisions:

- **When to start therapy in treatment-naive individuals**
- **When to change therapy in individuals who are failing their current regimen**

The specific drugs recommended may change as new choices become available and clinical research data accumulate. Selection of drugs in the developed world will be driven by genotypic and phenotypic resistance testing. However, future treatment guidelines will likely continue to be driven by 3 principles:

- **Use of combination therapy to prevent the emergence of resistant virus**
- **Emphasis on regimen convenience, tolerability, and adherence to chronically suppress HIV replication**
- **Realization of the need for lifelong treatment under most circumstances**

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training.
Section VIII
Chemotherapy of Neoplastic Diseases
INTRODUCTION. Cancer pharmacology has changed dramatically as curative treatments have been identified for many previously fatal malignancies such as testicular cancer, lymphomas, and leukemia. Adjuvant chemotherapy and hormonal therapy can extend life and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers, soft-tissue sarcomas, and pediatric solid tumors, thereby allowing for more limited surgery and even cure in these formerly incurable cases. Colony-stimulating factors restore bone marrow function and expand the utility of high-dose chemotherapy. Chemotherapeutic drugs are increasingly used in nonmalignant diseases: cytotoxic antitumor agents have become standard in treating autoimmune diseases, including rheumatoid arthritis (methotrexate and cyclophosphamide), Crohn disease (6-mercaptopurine), organ transplantation (methotrexate and azathioprine), sickle cell anemia (hydroxyurea), and psoriasis (methotrexate). Despite these therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than the cytotoxic antineoplastic drugs. A thorough understanding of their pharmacology, including drug interactions and clinical pharmacokinetics, is essential for their safe and effective use in humans.

The compounds used in the chemotherapy of neoplastic disease are quite varied in structure and mechanism of action, including alkylating agents; antimetabolite analogs of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of agents directed at specific molecular targets. Tables 60–1
through 60–5 summarize of the main classes and examples of these drugs. Figure 60–1 depicts the cellular targets of chemotherapeutic agents.

</table>
The rapidly expanding knowledge of cancer biology has led to the discovery of entirely new and more cancer-specific targets (e.g., growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity, DNA repair defects, and cell death pathways). For example, in many tumors, proliferation and survival depends on the constitutive activity of a single growth factor pathway, or so-called oncogene addiction (i.e., the “Achilles heel”), and inhibition of that pathway leads to cell death. Thus, imatinib (GLEEVEC) attacks the unique and specific bcr-abl translocation in chronic myelocytic leukemia. Imatinib also inhibits c-kit and produces extended control of GI stromal tumors that express a mutated and constitutively activated form of c-kit. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified her-2/neu receptor in breast cancer cells. These examples emphasize that entirely
new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology.

New clinical trial designs, aimed at determining effects of new drugs at the molecular level, increasingly employ biomarkers derived from samples of biological fluids or tumors to assess the effects of these new agents on signaling pathways, tumor proliferation and cell death, and angiogenesis. Imaging of molecular, metabolic, and physiological effects of drugs will become increasingly important in establishing that drugs effectively engage their targets.

New therapies are not likely to replace cytotoxics in the foreseeable future. Rather, the targeted drugs and cytotoxics will continue to be used in combination. For instance, monoclonal antibodies or small targeted molecules, used as single agents against solid tumors, produce low response rates and modest benefits; however, in combination with cytotoxics and in early stages of disease, monoclonal antibodies such as trastuzumab (HERCEPTIN) and bevacizumab (AVASTIN) are dramatically effective. At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better anti-nausea medications (see Chapters 13 and 46) and with granulocyte colony-stimulating factor and erythropoietin to restore bone marrow function (see Chapters 37 and 62). Finally, targeted drugs are helping to overcome resistance to chemotherapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting pro-survival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., bevacizumab) normalize blood flow and interstitial pressure, improve drug delivery, and are thus synergistic with cytotoxic drugs in the treatment of lung, breast, and other cancers.

*Drug resistance* remains a major obstacle to successful cancer treatment.

Resistance results from a variety of pharmacokinetic and molecular changes that can defeat the best designed treatments, including poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets. The resistance process is best understood for targeted agents. Tumors developing
resistance to *bcr-abl* inhibitors and to inhibitors of the epidermal growth factor receptor (EGFR) express mutations in the target enzyme. Cells exhibiting drug-resistant mutations exist in the patient prior to drug treatment and are selected by drug exposure. Resistance to inhibitors of the EGFR may develop through expression of an alternative receptor, *c-met*, which bypasses EGFR blockade and stimulates proliferation. Defects in recognition of DNA breaks and overexpression of specific repair enzymes may also contribute to resistance to cytotoxic drugs, and a loss of apoptotic pathways can lead to resistance to both cytotoxic and targeted agents.

Drugs in combination can negate the effects of a resistance mechanism specific for a single agent, and they may be synergistic because of their biochemical interactions.

Ideally, drug combinations should not overlap in their major toxicities. In general, cytotoxic drugs are used as close as possible to their maximally tolerated individual doses and should be given as frequently as tolerated to discourage tumor regrowth. Because the tumor cell population in patients with clinically detectable disease exceeds 1 g, or $10^9$ cells, and each cycle of therapy kills <99% of the cells, it is necessary to repeat treatments in multiple, carefully timed cycles to achieve cure.

**THE CELL CYCLE.** An understanding of the life cycle of tumors is essential for the rational use of antineoplastic agents (*Figure 60–2*).
Many cytotoxic agents act by damaging DNA. Their toxicity is greatest during the S, or DNA synthetic, phase of the cell cycle. Others, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human neoplasms most susceptible to chemotherapeutic measures are those having a high percentage of proliferating cells. Normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus highly susceptible to damage from cytotoxic drugs.

Slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or non–small cell lung cancer) are less responsive to cycle-specific drugs. More effective are agents that inflict high levels of DNA damage (e.g., alkylating agents) or those that remain at high concentrations inside the cell for extended periods of time (e.g., fluoropyrimidines).
The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size; newer “targeted” agents, however, may simply slow or halt tumor growth so their effects may best be measured in the assessment of time to disease progression. More recently, there is growing interest in designing drugs that selectively kill the stem cell component of tumors because these cells are believed to be responsible for the continuous proliferation and repopulation of tumors after a toxic exposure to chemotherapy or targeted therapy. For example, bone marrow and epithelial tissues contain a compartment of normal non-dividing stem cells that display resistance to cytotoxic drugs and retain the capacity to regenerate the normal cell population. Tumor stem cells exhibit the same resistance to chemotherapy, radiotherapy, and oxidative insults, and thus they may represent a significant barrier to the cure of neoplasms.

Although cells from different tumors display differences in the duration of their transit through the cell cycle and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression (see Figure 60–2):

- A phase that precedes DNA synthesis (G₁)
- A DNA synthetic phase (S)
- An interval following the termination of DNA synthesis (G₂)
- The mitotic phase (M) in which the cell, containing a double complement of DNA, divides into 2 daughter G₁ cells
- A probability of moving into a quiescent state (G₀) and failing to move forward for long periods of time

At each transition point in the cell cycle, specific proteins such as p53 and chk-1 and 2, monitor the integrity of DNA and, upon detection of DNA damage, may initiate DNA repair processes or, in the presence of massive damage, direct cells down a cell death (apoptosis) pathway. Some cancer chemotherapeutic drugs act at specific phases, in the cell cycle, mainly at the S phase and M phase; other agents are cytotoxic at any point in the cell cycle and are termed cell cycle phase nonspecific agents.
Each transition point in the cell cycle requires the activation of specific *cyclin-dependent kinases (CDKs)*, which, in their active forms, couple with corresponding regulatory proteins called *cyclins*. The proliferative impact of CDKs is, in turn, dampened by inhibitory proteins such as *p16*. Tumor cells often exhibit changes in cell-cycle regulation that lead to relentless proliferation (e.g., mutations or loss of *p16* or other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin or CDK activity). Consequently, CDKs and their effector proteins have become attractive targets for discovery of anti-neoplastic agents.

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms (“checkpoints”) have evolved to monitor DNA integrity. If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the G₁/S or G₂/M boundary. If the *p53* gene product or other checkpoint proteins are mutated or absent and the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will emerge as a mutated and potentially drug-resistant population. Thus, alterations in the regulation of cell-cycle kinetics and checkpoint controls are critical factors in determining sensitivity to cytotoxic drugs and understanding the success or failure of new agents.

**ACHIEVING THERAPEUTIC INTEGRATION AND EFFICACY**

The treatment of cancer patients requires a skillful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and irradiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drugs and irradiation. Furthermore, individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic
plan. Other less quantifiable considerations, such as the natural history of the tumor, the patient’s willingness to undergo difficult and potentially dangerous treatments, and the patient’s physical and emotional tolerance for side effects, enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient.

One of the great challenges of therapeutics is to adjust drug regimens to achieve a therapeutic but nontoxic outcome. Orally administered drugs are now frequently prescribed using uniform dosing for all adult patients. Dose adjustment based on renal function, on hepatic function, or on pharmacokinetic monitoring does facilitate meeting specific targets such as desired drug concentration in plasma or area under the concentration-time curve (AUC). There are few good guidelines for adjusting dose on the basis of obesity or age. Elderly patients, particularly those >70 years of age, exhibit less tolerance for chemotherapy because of decreased renal and hepatic drug clearance, lower protein binding, and less bone marrow reserve. Drug clearance decreases in morbidly obese patients, and dosage should probably be capped for these patients at no more than 150% of the dosage for patients of average body surface area (1.73 m²), with adjustment upward for tolerance after each subsequent dose.

Even patients with normal renal and hepatic function exhibit significant variability in pharmacokinetics of anticancer drugs that can reduce efficacy or cause excess toxicity. The following examples illustrate the potential of using pharmacokinetic targeting to improve therapy:

- The thrombocytopenia caused by carboplatin is a direct function of AUC, which in turn is determined by renal clearance of the parent drug. One can target a desired AUC based on creatinine clearance.
- Monitoring of 5-fluorouracil levels in plasma allows dose adjustment to improve response rates in patients with rapid drug clearance, and to avoid toxicity in those with slow drug clearance.
- High-dose methotrexate therapy requires drug-level monitoring to detect patients at high risk for renal failure and severe myelosuppression. Patients with inappropriately high concentrations of methotrexate at specific time points can be rescued from toxicity by the administration of leucovorin, and in extreme cases, by dialysis or administration of a methotrexate-cleaving enzyme and orphan drug, glucarpidase (VORAXAZE; recombinant
MOLECULAR TESTING TO SELECT PATIENTS FOR CHEMOTHERAPY. Molecular tests are increasingly employed to identify patients likely to benefit from treatment and those at highest risk of toxicity.

Pretreatment testing has become standard practice to select patients for hormonal therapy of breast cancer and for treatment with antibodies such as trastuzumab (*her-2/neu receptor*) and rituximab (*CD20*). The presence of a mutated *k-ras* gene indicates that a colorectal cancer patient’s tumor will not respond to anti-EGFR antibodies; mutations of EGFR signal a 70% likelihood of response to erlotinib (*TARCEVA*) and gefitinib (*IRESSA*), both inhibitors of this receptor. Although not yet routinely employed in traditional cytotoxic therapy, molecular testing of tumors could improve outcomes by pairing patients with drugs likely to be effective against mutations that drive tumor proliferation or survival. Mutations of the *b-Raf, HER 2/neu*, and *Alk*, which are found in subsets of solid tumors in human subjects, represent examples of promising targets for solid tumor chemotherapy.

Inherited differences in protein sequence polymorphisms or levels of RNA expression influence toxicity and anti-tumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer. Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes. Other polymorphisms appear to affect the clearance and therapeutic activity of cancer drugs, including tamoxifen, methotrexate, irinotecan, and 6-mercaptopurine.

Gene expression profiling, in which the levels of messenger RNA from thousands of genes are randomly surveyed using gene arrays, has revealed tumor profiles that are highly associated with metastasis. The expression of the
transcription factor HOX B13 correlates with disease recurrence in patients receiving adjuvant hormonal therapy in breast cancer. Gene expression profiles also predict the benefit of adjuvant chemotherapy for breast cancer patients and the response of ovarian cancer patients to platinum-based therapy. New molecular tests and their more widespread use likely will shorten the time for drug development and approval, help to avoid the costs and toxicity of ineffective drugs, and improve patient outcome.

A CAUTIONARY NOTE. Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves emphasis. The pharmacokinetics and toxicities of cancer drugs vary among individual patients. It is imperative to recognize toxicities early, to alter doses or discontinue offending medication to relieve symptoms and reduce risk, and to provide vigorous supportive care (platelet transfusions, antibiotics, and hematopoietic growth factors). Toxicities affecting the heart, lungs, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for drug use.
In 1942, Louis Goodman and Alfred Gilman, the originators of this text, began clinical studies of intravenous nitrogen mustards in patients with lymphoma, launching the modern era of cancer chemotherapy. Six major types of alkylating agents are used in the chemotherapy of neoplastic diseases:

- Nitrogen mustards
- Ethyleneimines
- Alkyl sulfonates
- Nitrosoureas
- The triazenes
- DNA-methylating drugs, including procarbazine, temozolomide, and dacarbazine

In addition, because of similarities in their mechanisms of action and resistance, platinum complexes are discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA.

The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryl, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The general mechanisms actions of alkylating agents on DNA are illustrated in Figure 61–1 with mechlorethamine (nitrogen mustard). The extreme cytotoxicity of bifunctional alkylators correlates very closely with interstrand cross-linkage of DNA.
Figure 61–1 Mechanism of action of alkylating agents. A. Activation reaction. B. Alkylation of N7 of guanine.

The ultimate cause of cell death related to DNA damage is not known. Specific cellular responses include cell-cycle arrest and attempts to repair DNA. The specific repair enzyme complex utilized will depend on 2 factors: the chemistry of the adduct formed and the repair capacity of the cell involved. The process of recognizing and repairing DNA generally requires an intact nucleotide excision repair (NER) complex, but may differ with each drug and with each tumor. Alternatively, recognition of extensively damaged DNA by p53 can trigger apoptosis. Mutations of p53 lead to alkylating agent resistance.

Structure-Activity Relationships. Although these alkylating agents share the
capacity to alkylate biologically important molecules, modification of the basic chloroethylamino structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which determine drug activity in vivo. With several of the most valuable agents (e.g., cyclophosphamide, ifosfamide), the active alkylating moieties are generated in vivo through hepatic metabolism (Figure 61–2). Consult Chapter 61 of the 12th edition of the parent text for details on metabolic activation and structure-activity relationships among these compounds.

![Figure 61–2 Metabolic activation of cyclophosphamide.](image)

Cyclophosphamide is activated (hydroxylated) by CYP2B, with subsequent transport of the activated
intermediate to sites of action. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways. Ifosfamide is structurally similar to cyclophosphamide: whereas cyclophosphamide has 2 chloroethyl groups on the exocyclic nitrogen atom, 1 of the 2-chloroethyl groups of ifosfamide is on the cyclic phosphoramide nitrogen of the oxazaphosphorine ring. Ifosfamide is activated by hepatic CYP3A4. The activation of ifosfamide proceeds more slowly, with greater production of de-chlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and perhaps differences in the antitumor spectra of cyclophosphamide and ifosfamide.

The newest approved alkylating agent, bendamustine, has the typical chloroethyl reactive groups attached to a benzimidazole backbone. The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators, and has significant activity in chronic lymphocytic leukemia (CLL) and large-cell lymphomas refractory to standard alkylators. One class of alkylating agents transfers methyl rather than ethyl groups to DNA. The triazene derivative 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide, usually called dacarbazine or DTIC, is prototypical of methylation agents. Dacarbazine requires initial activation by hepatic CYPs through an N-demethylation reaction. In the target cell, spontaneous cleavage of the metabolite, methyl-triazeno-imidazole-carboxamide (MTIC), yields an alkylating moiety, a methyl diazonium ion. A related triazene, temozolomide, undergoes spontaneous, nonenzymatic activation to MTIC and has significant activity against gliomas.

The nitrosoureas, which include compounds such as 1,3-bis-(2-chloroethyl)-1-nitrosourea (carmustine [BCNU]), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine [CCNU]), and its methyl derivative (semustine [methyl-CCNU]), as well as the antibiotic streptozocin (streptozotocin), exert their cytotoxicity through the spontaneous breakdown to an alkylating intermediate, the 2-chloroethyl diazonium ion. As with the nitrogen mustards, interstrand cross-linking appears to be the primary lesion responsible for the cytotoxicity of
nitrosoureas. The reactions of the nitrosoureas with macromolecules are shown in Figure 61–3.

**Figure 61–3** Generation of alkylating and carbamylating intermediates from carmustine (BCNU). The 2-chloroethyl diazonium ion, a strong electrophile, can alkylate guanine, cytidine, and adenine bases. Displacement of the halogen atom that can then lead to interstrand or intrastrand cross-linking of DNA. The formation of cross-links after the initial alkylation reaction proceeds slowly and can be reversed by the DNA repair enzyme O⁶-alkyl, methyl guanine methyltransferase (MGMT), which displaces the chloroethyl adduct from its binding to guanine in a suicide reaction. The same enzyme, when expressed in human gliomas, produces resistance to nitrosoureas and to other methylating agents, including DTIC, temozolomide, and procarbazine.

**Stable ethyleneimine derivatives** have antitumor activity; triethylene melamine (TEM) and triethylenethiophosphoramide (thiotepa) have been used clinically. In standard doses, thiotepa produces little toxicity other than myelosuppression; it also is used for high-dose chemotherapy regimens, in which it causes both
mucosal and CNS toxicity. Altretamine (hexamethylmelamine [HMM]) is chemically similar to TEM. The methylmelamines are N-demethylated by hepatic microsomes with the release of formaldehyde; there is a direct relationship between the degree of the demethylation and their antitumor activity in model systems.

**Esters of alkane sulfonic acids** alkylate DNA through the release of methyl radicals. Busulfan is of value in high-dose chemotherapy.

**GENERAL PHARMACOLOGICAL ACTIONS**

*Cytotoxic Actions.* The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes); effects in these tissues usually are delayed. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. In non-dividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G1/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and exhibit resistance to these drugs.

Although DNA is the ultimate target of all alkylating agents, there is a crucial distinction between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylating agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and single-chain scission. Conversely, simple methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify DNA sequence. These new sequences are transmitted to subsequent generations and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.
Adduct recognition systems and DNA repair systems play important roles in removing adducts, and thereby determine the selectivity of action against particular cell types and the acquisition of resistance to alkylating agents. Alkylation of a single strand of DNA (mono-adducts) is repaired by the nucleotide excision repair pathway; the less frequent cross-links require participation of nonhomologous end joining, an error-prone pathway, or the error-free homologous recombination pathway. After drug infusion in humans, mono-adducts appear rapidly and peak within 2 h of drug exposure, while cross-links peak at 8 h. The $t_{1/2}$ for repair of adducts varies among normal tissues and tumors; in peripheral blood mononuclear cells, both mono-adducts and cross-links disappear with a $t_{1/2}$ of 12-16 h.

The repair process depends on the presence and accurate functioning of multiple proteins. Their absence or mutation, as in Fanconi anemia or ataxia telangiectasia, leads to extreme sensitivity to DNA cross-linking agents such as mitomycin, cisplatin, or classical alkylators. Other repair enzymes are specific for removing methyl and ethyl adducts from the O-6 of guanine (MGMT) and for repair of alkylation of the N-3 of adenine and N-7 of guanine (3-methyladenine-DNA glycosylase). High expression of MGMT protects cells from cytotoxic effects of nitrosoureas and methylating agents and confers drug resistance, while methylation and silencing of the gene in brain tumors are associated with clinical response to BCNU and temozolomide. Bendamustine differs from classical chloroethyl alkylators in activating base excision repair, rather than the more complex double-strand break repair or MGMT. It impairs physiological arrest of adduct-containing cells at mitotic checkpoints and leads to mitotic catastrophe rather than apoptosis, and does not require an intact p53 to cause cytotoxicity.

Recognition of DNA adducts is an essential step in promoting attempts at repair and ultimately leading to apoptosis. The Fanconi pathway, consisting of 12 proteins, recognizes adducts and signals the need for repair of a broad array of DNA-damaging drugs and irradiation. Absence or inactivation of components of this pathway leads to increased sensitivity to DNA damage. Conversely, for the methylating drugs, nitrosoureas, cisplatin and carboplatin, and thiopurine analogs, the mismatch repair (MMR) pathway is essential for cytotoxicity, causing strand breaks at sites of adduct formation, creating mispairing of thymine residues, and triggering apoptosis.
**Mechanisms of Resistance to Alkylating Agents.** Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include:

- Decreased permeation of actively transported drugs (mechlorethamine and melphalan).
- Increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates.
- Increased activity of DNA repair pathways, which may differ for the various alkylating agents.
- Increased rates of metabolic degradation of the activated forms of cyclophosphamide and ifosfamide to their inactive keto and carboxy metabolites by aldehyde dehydrogenase (see Figure 61–2), and detoxification of most alkylating intermediates by glutathione transferases.
- Loss of ability to recognize adducts formed by nitrosoureas and methylating agents, as the result of defective mismatch repair (MMR) proteins capability, confers resistance, as does defective checkpoint function, for virtually all alkylating drugs.
- Impaired apoptotic pathways, with overexpression of bcl-2 as an example, confer resistance.

**TOXICITIES OF ALKYLATING AGENTS**

**BONE MARROW.** Alkylating agents differ in their patterns of antitumor activity and in the sites and severity of their side effects. Most cause dose-limiting toxicity to bone marrow elements and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause acute myelosuppression, with a nadir of the peripheral blood granulocyte count at 6-10 days and recovery in 14-21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogenic bone marrow transplantation. Carmustine and other chloroethylnitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4-6 weeks after drug administration.
and reversing slowly thereafter. Both cellular and humoral immunity are suppressed by alkylating agents, which have been used to treat various autoimmune diseases. Immunosuppression is reversible at usual doses, but opportunistic infections may occur with extended treatment.

**MUCOSA.** Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia. Mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow reconstitution, as they predispose to bacterial sepsis arising from the GI tract. In these protocols, cyclophosphamide, melphalan, and thiopeta have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, however, other toxicities become limiting (Table 61–1).

*CNS, central nervous system; GI, gastrointestinal; PN, peripheral neuropathy; VOD, veno-occlusive disease. *Maximum tolerated dose (MTD; cumulative) in treatment protocols.

**NERVOUS SYSTEM.** Nausea and vomiting commonly follow agent administration of nitrogen mustard or BCNU. Ifosfamide is the most neurotoxic agent of this class and may produce altered mental status, coma, generalized seizures, and cerebellar ataxia. These side effects result from the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of ifosfamide. High-dose busulfan can cause seizures; in addition, it accelerates the clearance of phenytoin, an antiseizure medication.

**OTHER ORGANS.** All alkylating agents, including temozolomide, have caused pulmonary fibrosis, usually several months after treatment. In high-dose
regimens, particularly those employing busulfan or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver, an often fatal side effect that is successfully reversed by the investigational drug defibrotide. The nitrosoureas and ifosfamide, after multiple cycles of therapy, may lead to renal failure. Cyclophosphamide and ifosfamide release a nephrotoxic and urotoxic metabolite, acrolein, which causes a severe hemorrhagic cystitis in high-dose regimens. This adverse effect can be prevented by coadministration of 2-mercaptopoethanesulfonate (mesna [MESNE]), which conjugates acrolein in urine. Ifosfamide in high doses for transplant causes a chronic, and often irreversible, renal toxicity. Nephrotoxicity correlates with the total dose of drug received and increases in frequency in children <5 years of age. The syndrome may be due to chloroacetaldehyde and/or acrolein excreted in the urine.

The more unstable alkylating agents (e.g., mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use and, if extravasated, produce ulceration. All alkylating agents have toxic effects on the male and female reproductive systems, causing an often permanent amenorrhea, particularly in perimenopausal women, and an irreversible azoospermia in men.

**Leukemogenesis.** Alkylating agents are highly leukemogenic. Acute nonlymphocytic leukemia, often associated with partial or total deletions of chromosome 5 or 7, peaks in incidence ~4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs. Leukemia often is preceded by a period of neutropenia or anemia and by bone marrow morphology consistent with myelodysplasia. Melphalan, the nitrosoureas, and the methylating agent procarbazine have the greatest propensity to cause leukemia, while it is less common after cyclophosphamide.

**CLINICAL PHARMACOLOGY**

**MECHLORETHAMINE**

Mechlorethamine HCl (MUSTARGEN) was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It is used topically for treatment of cutaneous T-cell lymphoma (CTCL) as a solution that is rapidly mixed and applied to affected areas. It has been largely replaced by cyclophosphamide, melphalan, and other, more stable alkylating agents.
Severe local reactions of exposed tissues necessitate rapid intravenous injection of mechlorethamine for most uses. Mechlorethamine, rapidly and within minutes, undergoes chemical degradation (affected markedly by pH) as it combines with either water or cellular nucleophiles. The major acute toxic manifestations of mechlorethamine are nausea and vomiting, lacrimation, and myelosuppression. Leukopenia and thrombocytopenia limit the amount of drug that can be given in a single course.

**CYCLOPHOSPHAMIDE**

*ADME.* Cyclophosphamide is well absorbed orally and is activated to the 4-hydroxy intermediate (see Figure 61–2). Its rate of metabolic activation exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at infusion rates of >4 g/90 min and concentrations of the parent compound >150 μM. 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. The hydroxyl metabolite of ifosfamide similarly is inactivated by aldehyde dehydrogenase. 4-Hydroxycyclophosphamide and its tautomer, aldophosphamide, travel in the circulation to tumor cells where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramidate mustard and acrolein. Phosphoramidate mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide. Patients should receive vigorous intravenous hydration during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage can become life-threatening and may require cystectomy for control of bleeding. Inappropriate secretion of antidiuretic hormone has been observed, usually at doses >50 mg/kg (see Chapter 25). It is important to be aware of the possibility of water intoxication, because these patients usually are vigorously hydrated.

Pretreatment with CYP inducers such as phenobarbital enhances the rate of activation of the azoxyphosphorenes but does not alter total exposure to active metabolites over time and does not affect toxicity or efficacy. Cyclophosphamide can be used in full doses in patients with renal dysfunction, because it is eliminated by hepatic metabolism. Patients with significant hepatic dysfunction (bilirubin <3 mg/dL) should receive reduced doses. Maximal $C_P$ is achieved 1 hour after oral administration; the $t_{1/2}$ of parent drug in plasma is ~7 h.
Therapeutic Uses. Cyclophosphamide (LYOPHILIZED CYTOXAN) is administered orally or intravenously. Recommended doses vary widely, and standard protocols for determining the schedule and dose of cyclophosphamide in combination with other chemotherapeutic agents should be consulted. As a single agent, a daily oral dose of 100 mg/m² for 14 days has been recommended for patients with lymphomas and CLL. Higher doses of 500 mg/m² intravenously every 2-4 weeks are used in combination with other drugs in the treatment of breast cancer and lymphomas. The neutrophil nadir of 500-1000 cells/mm³ generally serves as a lower limit for dosage adjustments in prolonged therapy. In regimens associated with bone marrow or peripheral stem cell rescue, cyclophosphamide may be given in total doses of 5-7 g/m² over a 3-5-day period. GI ulceration, cystitis (counteracted by mesna and diuresis), and, less commonly, pulmonary, renal, hepatic, and cardiac toxicities (hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses >200 mg/kg.

The clinical spectrum of activity for cyclophosphamide is very broad. It is an essential component of many effective drug combinations for non-Hodgkin lymphomas, other lymphoid malignancies, breast and ovarian cancers, and solid tumors in children. Complete remissions and presumed cures have been reported when cyclophosphamide was given as a single agent for Burkitt lymphoma. It frequently is used in combination with doxorubicin and a taxane as adjuvant therapy after surgery for breast cancer. Because of its potent immunosuppressive properties, cyclophosphamide has been used to treat autoimmune disorders, including Wegener granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for non-neoplastic conditions, not only because of its acute toxic effects but also because of its potential for inducing sterility, teratogenic effects, and leukemia.

IFOSFAMIDE
Ifosfamide (IFEX, others) is an analog of cyclophosphamide. Severe urinary tract and CNS toxicity initially limited the use of ifosfamide, but adequate hydration and coadministration of mesna have reduced its bladder toxicity.

Therapeutic Uses. Ifosfamide is approved for treatment of relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric and adult sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue; in these regimens, in total doses of 12-14 g/m², it may cause severe neurological toxicity, including hallucinations, coma,
and death, with symptoms appearing 12 h to 7 days after beginning the ifosfamide infusion. This toxicity may result from a metabolite, chloroacetaldehyde. Ifosfamide also causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver. In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 min at a dose of ≤1.2 g/m²/day for 5 days. Intravenous mesna is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and an additional 20% again 4 and 8 h later, for a total mesna dose of 60% of the ifosfamide dose. Alternatively, mesna may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3-4 weeks.

**Pharmacokinetics.** Ifosfamide has a plasma elimination $t_{1/2} \sim 1.5$ h after doses of 3.8-5 g/m² and a somewhat shorter $t_{1/2}$ at lower doses; its pharmacokinetics are highly variable due to variable rates of hepatic metabolism (see legend to Figure 61–2).

**Toxicity.** Ifosfamide has virtually the same toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and in the absence of mesna, urothelial damage.

**MELPHALAN**

This alkylating agent primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation. The general pharmacological and cytotoxic actions of melphalan are similar to those of other bifunctional alkylators. The drug is not a vesicant.

**ADME.** Oral melphalan is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a plasma $t_{1/2} \sim 45$-90 min; 10-15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

**Therapeutic Uses.** Melphalan (ALKERAN) for multiple myeloma is given in doses of 4-10 mg orally for 4-7 days every 28 days, with dexamethasone or thalidomide. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. Melphalan also may be used in myeloablative regimens followed by bone marrow or
peripheral blood stem cell reconstitution, at a dose of 180-200 mg/m². The toxicity of melphalan is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction.

**CHLORAMBUCIL**
The cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of ≥20 mg.

**ADME.** Oral absorption of chlorambucil is adequate and reliable. The drug has a $t_{1/2}$ in plasma of ~1.5 h and is hydrolyzed to inactive products.

**Therapeutic Uses.** Chlorambucil is almost exclusively used in treating CLL, for which it has largely been replaced by fludarabine and cyclophosphamide. In treating CLL, the initial daily dose of chlorambucil (Leukeran) is 0.1-0.2 mg/kg, given once daily and continued for 3-6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy (usually 2 mg daily) often is required to maintain clinical response. Chlorambucil treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow. Marked hypoplasia of the bone marrow may be induced with excessive doses, but the myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of acute myelocytic leukemia (AML) and other tumors was noted in the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy.

**BENDAMUSTINE**
This drug is approved for treatment of CLL and non-Hodgkin lymphoma. Bendamustine is given as a 30-min intravenous infusion in dosages of 100 mg/m²/day on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pretreated patients. Bendamustine is rapidly degraded through sulfhydryl interaction and adduct formation with macromolecules; <5% of the parent drug
is excreted in the urine intact. N-demethylation and oxidation produces metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a plasma $t_{1/2}$ \sim 30 min. The clinical toxicity pattern of bendamustine is typical of alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable.

**MISCELLANEOUS ALKYLATING DRUGS**

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, alternative alkylators with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.

**ETHYLENEIMINES AND METHYLMELAMINES**

**ALTRETAMINE**

Altretamine (hexamethylmelamine [Hexalen]) is structurally similar to TEM (tretamine). Its precise mechanism of cytotoxicity is unknown. It is a palliative treatment for persistent or recurrent ovarian cancer following cisplatin-based combination therapy. The usual dosage of altretamine as a single agent in ovarian cancer is 260 mg/m$^2$/day in 4 divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

**ADME.** Altretamine is well absorbed from the GI tract; its elimination $t_{1/2}$ is 4-10 h. The drug undergoes rapid demethylation in the liver; the principal metabolites are pentamethylmelamine and tetramethyl melamine.

**Clinical Toxicities.** The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate upon discontinuation of therapy. Peripheral blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage of 200 mg/m$^2$/day if the white cell count falls to <2000 cells/mm$^3$ or the platelet count falls to <75,000 cells/mm$^3$ or if neurotoxic or intolerable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule,
altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive MAO-inhibitors, amitriptyline, imipramine, or phenelzine concurrently with altretamine.

**THIOTEPA**

Thiotepa (Thioplex, others) consists of 3 ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use is primarily for high-dose chemotherapy regimens. Both thiotepa and its desulfurated primary metabolite, triethylene phosphoramide (TEPA), to which it is rapidly converted by hepatic CYPs, form DNA cross-links.

**ADME.** TEPA becomes the predominant form of the drug present in plasma within hours of thiotepa administration. The parent compound has a plasma $t_{1/2}$ of 1.2-2 h, TEPA has a longer $t_{1/2}$, 3-24 h. Thiotepa pharmacokinetics essentially are the same in children as in adults at conventional doses (<80 mg/m²), and drug and metabolite $t_{1/2}$ are unchanged in children receiving high-dose therapy of 300 mg/m²/day for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite.

**Clinical Toxicities.** Toxicities include myelosuppression and, to a lesser extent, mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high-doses, thiotepa may cause neurotoxic symptoms, including coma and seizures.

**ALKYL SULFONATES**

**BUSULFAN**

Busulfan (Myleran, Busulfex) exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of imatinib mesylate (Gleevec), was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. Busulfan now is primarily used in high-dose regimens, in which pulmonary fibrosis, GI mucosal damage, and hepatic veno-occlusive disease (VOD) are important toxicities.
ADME. Busulfan is well absorbed after oral administration in dosages of 2-6 mg/day and has a plasma $t_{1/2}$ of 2-3 h. The drug is conjugated to GSH by GSTA1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is methane sulfonic acid. In high doses, children <18 years of age clear the drug 2-4 times faster than adults and tolerate higher doses. Busulfan clearance varies considerably among patients. VOD is associated with high area under the curve (AUC) (AUC > 1500 1M × min) peak drug levels and slow clearance, leading to recommendations for dose adjustment based on drug level monitoring. A target steady-state concentration of 600-900 ng/mL in plasma in adults or AUC <1000 1M × min in children achieves an appropriate balance between toxicity and therapeutic benefit.

Therapeutic Uses. In treating chronic myelogenous leukemia (CML), the initial oral dose of busulfan varies with the total leukocyte count and the severity of the disease; daily doses of 2-8 mg for adults (~60 μg/kg or 1.8 mg/m² for children) are used to initiate therapy and are adjusted appropriately to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to ≤10,000 cells/mm³. A decrease in the leukocyte count usually is not seen during the first 10-15 days of treatment, and the leukocyte count may actually increase during this period. Because the leukocyte count may fall for >1 month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to ~15,000 cells/mm³. A normal leukocyte count usually is achieved within 12-20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches ~50,000 cells/mm³. Daily maintenance doses are 1-3 mg.

In high-dose therapy, doses of 1 mg/kg are given every 6 h for 4 days, with adjustment based on pharmacokinetics. Anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures that may occur several hours after each dose. Although phenytoin is a frequent choice, phenytoin induces the GSTs that metabolize busulfan, reducing its AUC by ~20%. In patients requiring concomitant anti-seizure medication, non-enzyme-inducing benzodiazepines such as lorazepam and clonazepam are recommended as an alternative to phenytoin. If phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted accordingly.
**Clinical Toxicity.** The toxic effects of busulfan are related to its myelosuppressive properties; prolonged thrombocytopenia may occur. Occasionally, patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension. High-dose busulfan causes VOD of the liver in ≤10% of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and metronidazole, possibly through inhibition of the clearance of busulfan and/or its toxic metabolites.

**NITROSOUREAS**

The nitrosoureas have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and lomustine (CCNU) are highly lipophilic and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression with recovery 4-6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamylating moieties (see Figure 61–3).

**CARMUSTINE (BCNU)**

Carmustine’s major action is its alkylation of DNA at the O6-guanine position, an adduct repaired by MGMT. Methylation of the MGMT promoter inhibits its expression in ~30% of primary gliomas and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, carmustine produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia.

**ADME.** Carmustine is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable $t_{1/2}$ of
≥15-90 min. Approximately 30-80% of the drug appears in the urine within 24 h as degradation products. The alkylating metabolites enter rapidly into the cerebrospinal fluid (CSF), and their concentrations in the CSF reach 15-30% of the concurrent plasma values.

**Therapeutic Uses.** Carmustine (BCNU) is administered intravenously at doses of 150-200 mg/m², given by infusion over 1-2 h and repeated every 6 weeks. Because of its ability to cross the blood-brain barrier, carmustine has been used in the treatment of malignant gliomas. An implantable carmustine wafer (GLIADEL) is available for use as an adjunct to surgery and radiation in newly diagnosed high-grade malignant glioma patients and as an adjunct to surgery for recurrent glioblastoma multiforme.

**STREPTOZOCIN**

Streptozocin (or streptozotocin) has a methylnitrosourea (MNU) moiety attached to the 2-carbon of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

**ADME.** Streptozocin is rapidly degraded following intravenous administration. The t₁/₂ of the drug is ~15 min. Only 10-20% of a dose is recovered intact in the urine.

**Therapeutic Uses.** Streptozocin (ZANOSAR) is used in the treatment of human pancreatic islet cell carcinoma and malignant carcinoid tumors. It is administered intravenously, 500 mg/m² once daily for 5 days; this course is repeated every 6 weeks. Alternatively, 1000 mg/m² can be given weekly for 2 weeks, and the weekly dose then can be increased to a maximum of 1500 mg/m² as tolerated. Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in <10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicities (anemia, leukopenia, thrombocytopenia) occur in 20% of patients.

**TRIAZENES**

**DACARBAZINE (DTIC)**

Dacarbazine functions as a methylating agent after metabolic activation to the
monomethyl triazeno metabolite, MTIC. It kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the O6– guanine bases in DNA by MGMT.

ADME. Dacarbazine is administered intravenously. After an initial rapid phase ($t_{1/2}$ of ~20 min), dacarbazine is cleared from plasma with a terminal $t_{1/2}$ of ~5 h. The $t_{1/2}$ is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion.

Therapeutic Uses. The primary clinical indication for dacarbazine (DTIC-DOME) is in the chemotherapy of Hodgkin disease. In combination with other drugs for Hodgkin disease, dacarbazine is given in dosages of 150 mg/m\(^2\)/day for 5 days, repeated every 4 weeks; it can be used alone as a single dose of 375 mg/m\(^2\), repeated every 15 days. It is modestly effective against malignant melanoma and adult sarcomas. Dacarbazine (DTIC-DOME) for malignant melanoma is given in dosages of 2-4.5 mg/kg/day for a 10-day period, repeated every 28 days; alternatively, 250 mg/m\(^2\) can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain.

Toxicity. DTIC induces nausea and vomiting in >90% of patients; vomiting usually develops 1-3 h after treatment and may last up to 12 h. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1-2 weeks. A flu-like syndrome may occur. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

TEMZOLOMIDE
Temozolomide (Temodar) is the standard agent in combination with radiation therapy for patients with malignant glioma and for astrocytoma. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle.

ADME. Temozolomide is administered orally or intravenously in dosages of ~200 mg/day; it has a bioavailability approaching 100%. Plasma levels of the parent drug decline with a $t_{1/2}$ of 1-2 h. The primary active metabolite MTIC reaches a maximum plasma concentration (150 ng/mL) 90 min after a dose and declines with a $t_{1/2}$ of 2 h. Little intact drug is recovered in the urine, the primary
urinary metabolite being the inactive imidazole carboxamide.

**Toxicity.** The toxicities of temozolomide mirror those of DTIC. Hematological monitoring is necessary to guide dosing adjustments.

**METHYLHYDRAZINES**

**PROCARBAZINE**

Procarbazine is employed for second-line therapy in malignant brain tumors.

**Cytotoxic Action.** The antineoplastic activity of procarbazine results from its conversion by CYP-mediated hepatic oxidative metabolism to highly reactive alkylating species that methylate DNA. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Resistance to procarbazine develops rapidly when it is used as a single agent; one mechanism of resistance results from increased expression of MGMT, which repairs methylation of guanine.

**Pharmacokinetics.** The pharmacokinetic behavior of procarbazine has not yet been thoroughly defined. The drug is extensively metabolized by CYP isoenzymes to azo, methylazoxy, and benzylazoxy intermediates, which are found in the plasma and yield the alkylating metabolites in tumor cells. In brain cancer patients, the concurrent use of anti-seizure drugs that induce hepatic CYPs does not significantly alter the pharmacokinetics of the parent drug.

**Therapeutic Uses.** The recommended dosage of procarbazine (Matulane) for adults is 100 mg/m²/day for 10-14 days in combination regimens such as MOPP (nitrogen mustard, Oncovin, procarbazine, and prednisone) for Hodgkin disease. The drug rarely is used in current practice.

**Toxicity.** The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; diarrhea and rash are noted in 5-10% of cases. Behavioral disturbances also have been reported. Because procarbazine augments sedative effects, the concomitant use of CNS depressants should be avoided. The drug is
a weak MAO inhibitor; it blocks the metabolism of catecholamines, sympathomimetics, and dietary tyramine and may provoke hypertension in patients concurrently exposed to these. Procarbazine has disulfiram-like actions, and therefore the ingestion of alcohol should be avoided. The drug is highly carcinogenic, mutagenic, and teratogenic and is associated with a 5-10% risk of acute leukemia in patients treated with MOPP. The highest risk is for patients who also receive radiation therapy. Procarbazine is a potent immunosuppressive agent. It causes infertility, particularly in males.

**PLATINUM COORDINATION COMPLEXES**

Platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. Although cisplatin and other platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.

**MECHANISM OF ACTION.** Cisplatin, carboplatin, and oxaliplatin enter cells by an active Cu\(^{2+}\) transporter, CTR1, and in doing so rapidly degrade the transporter. The compounds are actively extruded from cells by ATP7A and ATP7B copper transporters and by multidrug resistance protein 1 (MRP1); variable expression of these transporters may contribute to clinical resistance. Inside the cell, the chloride, cyclohexane, or oxalate ligands of the analogs are displaced by water molecules, yielding a positively charged molecule that reacts with nucleophilic sites on DNA and proteins.

Aquation of cisplatin is favored at the low concentrations of Cl\(^{-}\) inside the cell and in the urine. High concentrations of Cl\(^{-}\) stabilize the drug, explaining the effectiveness of Cl\(^{-}\) diuresis in preventing nephrotoxicity. The activated platinum complexes can react with electron-rich regions, such as sulfhydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The DNA-platinum adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and if recognized by p53 and other checkpoint proteins, cause induction of apoptosis. Adduct formation is an important predictor of clinical response. The analogs differ in the conformation
of their adducts and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and less readily repaired, create a different pattern of distortion of the DNA helix, and differ from cisplatin adducts in the pattern of hydrogen bonding to adjacent segments of DNA.

Unlike the other platinum analogs, oxaliplatin exhibits a cytotoxicity that does not depend on an active MMR system, which may explain its greater activity in colorectal cancer. It also seems less dependent on the presence of high mobility group (HMG) proteins that are required by the other platinum derivatives. Testicular cancers have a high concentration of HMG proteins and are quite sensitive to cisplatin. Basal-type breast cancers, such as those with *BRCA1* and *BRCA2* mutations, lack *Her 2* amplification and hormone-receptor expression and appear to be uniquely susceptible to cisplatin through their upregulation of apoptotic pathways governed by p63 and p73. The cell cycle specificity of cisplatin differs among cell types; the effects of cross-linking are most pronounced during the S phase. The platinum analogs are mutagenic, teratogenic, and carcinogenic. Cisplatin- or carboplatin-based chemotherapy for ovarian cancer is associated with a 4-fold increased risk of developing secondary leukemia.

**Resistance to Platinum Analogs.** Resistance to the platinum analogs likely is multifactorial; the compounds differ in their degree of cross-resistance. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin does not. A number of factors influence sensitivity to platinum analogs in experimental cells, including intracellular drug accumulation and intracellular levels of glutathione and other sulfhydryls such as metallothionein that bind to and inactivate the drug and rates of repair of DNA adducts. Repair of platinum-DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in ovarian cancer patients, while overexpression of NER components is associated with poor response to cisplatin or oxaliplatin-based therapy in lung, colon, and gastric cancer.

Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the MMR proteins. In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. Some DNA polymerases can bypass adducts, possibly contributing to resistance. Overexpression of copper efflux transporters, ATP7A
and ATP7B, correlates with poor survival after cisplatin-based therapy for ovarian cancer.

**CISPLATIN ADME.** After intravenous administration, cisplatin has an initial plasma elimination $t_{1/2}$ of 25-50 min; concentrations of total (bound and unbound) drug fall thereafter, with a $t_{1/2}$ of $\geq 24$ h. More than 90% of the platinum in the blood is covalently bound to plasma proteins. High concentrations of cisplatin are found in the kidney, liver, intestine, and testes; cisplatin penetrates poorly into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 h; by 24 h, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

**Therapeutic Uses.** Cisplatin (PLATINOL) is given only intravenously. The usual dosage is 20 mg/m$^2$/day for 5 days, 20-30 mg weekly for 3-4 weeks, or 100 mg/m$^2$ given once every 4 weeks. *To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1-2 L of normal saline prior to treatment.* The appropriate amount of cisplatin then is diluted in a solution containing dextrose, saline, and mannitol and administered intravenously over 4-6 h. Because aluminum inactivates cisplatin, the drug should not come in contact with needles or other infusion equipment that contain aluminum during its preparation or administration.

Cisplatin, in combination with bleomycin, etoposide, ifosfamide, or vinblastine, cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin or carboplatin induces complete response in the majority of patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. The drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

**TOXICITY.** Cisplatin-induced nephrotoxicity has been largely abrogated by adequate pretreatment hydration and chloride diuresis. Amifostine (ETHYOL), a thiophosphate cytoprotective agent, reduces renal toxicity associated with repeated administration of cisplatin. Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss.
Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5HT\textsubscript{3} antagonists, NK1-receptor antagonists, and high-dose corticosteroids (see Table 46–6).

At higher doses or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy that may worsen after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild to moderate myelosuppression, with transient leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to tubular damage and renal electrolyte wasting may produce tetany if untreated. Routine measurement of Mg\textsuperscript{2+} concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchoconstriction, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with corticosteroids or anti-histamines. Cisplatin has been associated with the development of AML, usually ≥4 years after treatment.

**CARBOPLATIN**

The mechanisms of action and resistance and the spectrum of clinical activity of carboplatin (PARAPLATIN; CBDCA, JIM-8) are similar to cisplatin. However, the 2 drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

**ADME.** Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated via renal excretion, with a $t_{1/2}$ ~2 h. A small fraction of platinum binds irreversibly to plasma proteins and disappears slowly, with a $t_{1/2}$ ≥5 days.

**Therapeutic Uses.** Carboplatin and cisplatin are equally effective in the treatment of suboptimally debulked ovarian cancer, non–small cell lung cancer, and extensive-stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in germ cell, head and neck, and esophageal cancers. Carboplatin is an effective alternative for responsive tumors in patients unable to
tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. Carboplatin is administered as an intravenous infusion over at least 15 min and is given once every 21-28 days; the dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance (CrCl) for patients with a CrCl <60 mL/min.

**Toxicity.** Carboplatin is relatively well tolerated clinically, causing less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than cisplatin. The dose-limiting toxicity of carboplatin is myelosuppression, primarily thrombocytopenia. It may cause a hypersensitivity reaction; in patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

**OXALIPLATIN**

**ADME.** Oxaliplatin has a short t½ in plasma, probably as a result of its rapid uptake by tissues and its reactivity; the initial t½ ~17 min. No dose adjustment is required for hepatic dysfunction or for patients with a CrCl ≥20 mL/min.

**Therapeutic Uses.** Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents. Oxaliplatin’s effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects. It also suppresses expression of thymidylate synthase (TS), the target enzyme of 5-fluorouracil (5-FU) action, which may promote synergy of these 2 drugs. In combination with 5-FU, it is approved for treatment of patients with colorectal cancer.

**Toxicity.** The dose-limiting toxicities of oxaliplatin are peripheral neuropathies. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias and/or dysesthessias in the upper and lower extremities, mouth, and throat. A second type relates to cumulative dose and has features similar to cisplatin neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m² experience some progressive sensory neurotoxicity, with dysesthessias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias; nausea is well controlled with 5HT₃-receptor antagonists. Oxaliplatin causes leukemia and pulmonary fibrosis months to years after administration. Oxaliplatin may cause
an acute allergic response with urticaria, hypotension, and bronchoconstriction.

II. Antimetabolites

FOLIC ACID ANALOGS

Folic acid is an essential dietary factor that is converted by enzymatic reduction to a series of tetrahydrofolate (FH₄) cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines). Interference with FH₄ metabolism reduces the cellular capacity for one-carbon transfer and the necessary methylation reactions in the synthesis of purine ribonucleotides and thymidine monophosphate (TMP), thereby inhibiting DNA replication.

Antifolate chemotherapy produced the first striking, although temporary, remissions in leukemia and the first cure of a solid tumor, choriocarcinoma. Recognition that methotrexate (MTX), an inhibitor of dihydrofolate reductase (DHFR), also directly inhibits the folate-dependent enzymes of de novo purine and thymidylate synthesis led to development of antifolate analogs that specifically target these other folate-dependent enzymes (Figure 61–4). New congeners have greater capacity for transport into tumor cells (pralatrexate) and exert their primary inhibitory effect on TS (raltitrexed, TOMUDEX), early steps in purine biosynthesis (lometrexol), or both (the multitargeted antifolate, pemetrexed, ALIMTA).

Mechanism of Action. The primary target of MTX is the enzyme DHFR (see Figure 61–4). To function as a cofactor in 1-carbon transfer reactions, folate must be reduced by DHFR to FH₄. Inhibitors such as MTX, with a high affinity for DHFR ($K_i$ 0.01-0.2 nM), cause partial depletion of the FH₄ cofactors (5-10 methylene tetrahydrofolic acid and N-10 formyl tetrahydrofolic acid) required for the synthesis of thymidylate and purines. In addition, MTX, like cellular folates, undergoes conversion to a series of polyglutamates (MTX-PGs) in both normal and tumor cells. These MTX-PGs constitute an intracellular storage form of folates and folate analogs and dramatically increase inhibitory potency of the analog for additional sites, including TS and 2 early enzymes in the purine
biosynthetic pathway. The dihydrofolic acid polyglutamates that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (see Figure 61–4).

**Figure 61–4** Actions of methotrexate and its polyglutamates. AICAR, aminoimidazole carboxamide; dUMP, deoxyuridine monophosphate; FH4Gluₙ/FH₂Gluₙ, dihydro-/tetrahydro-folate polyglutamates; GAR, glycaminamide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate; TMP, thymidine monophosphate.

**Selective Toxicity; Rescue.** As with most antimetabolites, MTX is only partially
selective for tumor cells and kills rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly. The toxic effects of MTX may be terminated by administering leucovorin, a fully reduced folate coenzyme that repletes the intracellular pool of FH₄ cofactors.

**Cellular Entry and Retention.** Because folic acid and many of its analogs are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells: (1) a folate receptor, which has high affinity for folic acid but much reduced ability to transport MTX and other analogs; (2) the reduced folate transporter, the major transit protein for MTX, raltitrexed, pemetrexed, and most analogs; and (3) a transporter that is active at low pH. The reduced folate transporter is highly expressed in the hyperdiploid subtype of acute lymphoblastic leukemia (ALL), which has extreme sensitivity to MTX. Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Because these higher polyglutamates are strongly charged and cross cellular membranes poorly, polyglutamation serves as a mechanism of entrapment and may account for the prolonged retention of MTX in chorionic epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamyl folates and analogs have substantially greater affinity than the monoglutaform for folate-dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

**Newer Congeners.** New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate (NEUTREXIN), a lipid-soluble analog that lacks a terminal glutamate, has modest antitumor activity, primarily in combination with leucovorin rescue. However, it is beneficial in the treatment of Pneumocystis jiroveci (*Pneumocystis carinii*) pneumonia where leucovorin provides differential rescue of the host but not the parasite. The most important new folate analog, MTA or pemetrexed (ALIMTA), is a pyrrole–pyrimidine structure. It is avidly transported into cells via the
reduced folate carrier and is converted to polyglutamates that inhibit TS and glycine amide ribonucleotide transformylase, as well as DHFR. It has activity against ovarian cancer, mesothelioma, and non–small cell adenocarcinomas of the lung. Pemetrexed and its polyglutamates have a somewhat different spectrum of biochemical actions. Like MTX, pemetrexed inhibits DHFR, but as a polyglutamate, it even more potently inhibits glycaminamide ribonucleotide formyltransferase (GART) and TS. Unlike MTX, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion also differs; it causes a greater fall in thymidine triphosphate (TTP) than in other triphosphates. Like MTX, it induces p53 and cell-cycle arrest, but this effect does not depend on induction of p21. A newer congener, pralatrexate, is more effectively taken up and polyglutamated than MTX and is approved for treatment of cutaneous T-cell lymphoma.

**MECHANISMS OF RESISTANCE TO ANTIFOLATES.** Resistance to MTX can involve alterations in each known step in MTX action, including:

- Impaired transport of MTX into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize MTX polyglutamates
- Increased expression of a drug efflux transporter of the MRP class (see Chapter 5)

DHFR levels in leukemic cells increase within 24 h after treatment of patients with MTX, probably as a result of induction of DHFR synthesis. Unbound DHFR protein may bind to its own message and reduce its own translation, while the DHFR-MTX complex is ineffective in blocking the DHFR translation. With longer periods of drug exposure, tumor cell populations that contain markedly increased levels of DHFR emerge. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements) or in stably integrated, homogeneously staining chromosomal regions or amplicons. Similar gene amplification target proteins have been implicated in the resistance to many antitumor agents, including 5-FU
and pentostatin (2’-deoxycoformycin).

High doses of MTX may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of MTX in concentrations that inactivate high levels of DHFR. The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance to this agent seems to arise from loss of influx transport, TS amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

**ADME.** MTX is readily absorbed from the GI tract at doses of M25 mg/m²; larger doses are absorbed incompletely and are routinely administered intravenously. After intravenous administration, the drug disappears from plasma in a triphasic fashion. The rapid distribution phase is followed by a second phase, which reflects renal clearance ($t_{1/2}$ of 2-3 h). A third phase has a $t_{1/2}$ of ~8-10 h. This terminal phase of disappearance, if unduly prolonged by renal failure, may be responsible for major toxic effects of the drug on the marrow, GI epithelium, and skin. Distribution of MTX into body spaces, such as the pleural or peritoneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of the drug, resulting in prolonged elevation of plasma concentrations and more severe bone marrow toxicity.

Approximately 50% of MTX binds to plasma proteins and may be displaced from plasma albumin by myriad agents (e.g., sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin); caution should be used if these drugs are given concomitantly. Up to 90% of a given dose is excreted unchanged in the urine, mostly within the first 8-12 h. Metabolism of MTX usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-MTX, which is potentially nephrotoxic. Renal excretion of MTX occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., NSAIDs), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin, piperacillin) can delay drug excretion and lead to severe myelosuppression. In patients with renal insufficiency, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided. Concentrations of MTX in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably
are not killed by standard dosage regimens. When high doses of MTX are given, cytotoxic concentrations of MTX reach the CNS. MTX is retained in the form of polyglutamates for long periods (e.g., weeks in the kidneys, several months in the liver).

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates methylenetetrahydrofolate, the cofactor for TS, and thereby increases MTX toxicity. The presence of this polymorphism in leukemic cells confers increased sensitivity to MTX and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS affect its expression, and by altering the intracellular levels of TS, modulate the response and toxicity of both antifolates and fluoropyrimidines.

**Therapeutic Uses.** MTX is a critical drug in the management of childhood ALL. High-dose MTX is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-h infusion of relatively large doses of MTX may be employed every 2-4 weeks (≥1-7.5 g/m²) but only when leucovorin rescue follows within 24 h of the MTX infusion. For maintenance therapy, it is administered weekly, 20 mg/m² orally. Outcome of treatment in children correlates inversely with the rate of drug clearance. During MTX infusion, high steady-state levels are associated with a lower leukemia relapse rate. MTX is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis. The intrathecal administration of MTX has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of MTX in the CSF and also is effective in patients whose systemic disease has become resistant to MTX. The recommended intrathecal dose in all patients >3 years of age is 12 mg. The dose is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the potential toxicity of MTX that escapes into the systemic circulation, although this generally is not necessary. Because MTX administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular Ommaya reservoir in the treatment of active intrathecal disease. MTX is of established value in choriocarcinoma and related trophoblastic tumors.
of women; cure is achieved in ~75% of advanced cases treated sequentially with MTX and dactinomycin and in >90% when early diagnosis is made. For choriocarcinoma, 1 mg/kg of MTX is administered intramuscularly every other day for 4 doses, alternating with leucovorin (0.1 mg/kg every other day). Courses are repeated at 3-week intervals, toxicity permitting, and urinary β-human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt and other non-Hodgkin lymphomas. MTX is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. High-dose MTX with leucovorin rescue (HDM-L) is a standard agent for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalization of urine pH are required prior to drug administration. If MTX values measured 48 h after drug administration are 1 μM or higher, higher doses (100 mg/m²) of leucovorin must be given until the plasma concentration of MTX falls to <50 nM. With appropriate hydration and urine alkalization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is <2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing MTX levels. Continuous-flow hemodialysis can eliminate MTX at ~50% of the clearance rate in patients with intact renal function. Alternatively, a MTX-cleaving enzyme, carboxypeptidase G2, can be obtained from the Cancer Therapy Evaluation Program at the National Cancer Institute. MTX concentrations in plasma fall by >99% within 5-15 min following enzyme administration, with insignificant rebound. Systemically administered carboxypeptidase G2 has little effect on MTX levels in the CSF.

MTX (amethopterin; Rheumatrex, Trexall, others) is used in the treatment of severe, disabling psoriasis (see Chapter 65) in doses of 2.5 mg orally for 5 days, followed by a rest period of at least 2 days, or 10-25 mg intravenously weekly. It also is used at low dosage to induce remission in refractory rheumatoid arthritis. MTX inhibits cell-mediated immune reactions and is employed to suppress graft-versus-host disease in allogenic bone marrow and organ transplantation and for the treatment of dermatomyositis, Wegener granulomatosis, and Crohn
disease (see Chapters 35 and 47). MTX is also used as an abortifacient, generally in combination with a prostaglandin (see Chapter 66).

**CLINICAL TOXICITIES.** The primary toxicities of antifolates are on the bone marrow and the intestinal epithelium. Patients may be at risk for spontaneous hemorrhage or life-threatening infection, and may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed drug excretion. The dosage of MTX (and likely pemetrexed) must be reduced in proportion to any reduction in CrCL. Additional toxicities of MTX include alopecia, dermatitis, an allergic interstitial pneumonitis, nephrotoxicity (after high-dose therapy), defective oogenesis or spermatogenesis, abortion, and teratogenesis. Low-dose MTX may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of MTX often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Leucovorin does not reverse neurotoxicity.

Pemetrexed toxicity mirrors that of MTX, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. Dexamethasone, 4 mg twice daily on days ~1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with preexisting homocystinemia, largely is eliminated by concurrent administration of low dosages of folic acid, 350-1000 mg/day, beginning 1-2 weeks prior to pemetrexed and continuing while the drug is administered. Patients should receive intramuscular vitamin B\textsubscript{12} (1 mg) with the first dose of pemetrexed to correct possible B\textsubscript{12} deficiency. These small doses of folate and B\textsubscript{12} do not compromise the therapeutic effect.

**PYRIMIDINE ANALOGS**

The pyrimidine antimetabolites encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogs (6-mercaptopurine and 6-thioguanine) inhibit the synthesis of essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogs, become incorporated into DNA and block its further elongation and function. Other inhibitory
effects of these analogs may contribute to their cytotoxicity and their capacity to induce differentiation.

**Cellular Actions of Pyrimidine Antimetabolites.** Four bases (Figure 61–5) form DNA: 2 pyrimidines (thymine and cytosine) and 2 purines (guanine and adenine). RNA differs in that it incorporates uracil instead of thymine as one of its bases. Strategies for inhibiting DNA synthesis are based on the ability to create analogs of these precursors that readily enter tumor cells and become activated by intracellularly. As an example, the pyrimidine analog, 5-FU, is converted to a deoxynucleotide, fluorodeoxyuridine monophosphate (FdUMP), which in turn blocks the enzyme, TS, required for the physiological conversion of dUMP to dTMP, a component of DNA. Other analogs incorporate into DNA itself and thereby block its function.

Cells can make the purine and pyrimidine bases de novo and convert them to their active triphosphates (dNTPs), providing substrates for DNA polymerase. Alternatively, cells can salvage free bases or their deoxynucleosides from the bloodstream. Thus, cells can take up uracil, guanine, and their analogs and convert them to (deoxy) nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogs of these bases (5-FU, 6-thioguanine) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine, and their analogs can only be used as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinase. Thus, cytarabine (cytosine arabinoside; Ara-C), gemcitabine, 5-azacytidine, and adenosine analogs (cladribine) (Figures 61–5 and 61–6) are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA.
Figure 61–5 Structural modification of base and deoxyribonucleoside analogs. Yellow ellipses indicate sites modified to create antimetabolites. Specific substitutions are noted in red for each drug. Modifications occur in the base ring systems, in their amino or hydroxyl side groups, and in the deoxyribose sugar found in deoxyribonucleosides. See structures in Figure 61–6.
Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogs may differ from the physiological bases in a variety of ways: by altering in the purine or pyrimidine ring; by altering the sugar attached to the base, as in the arabinoside, Ara-C; or by altering both the base and sugar, as in fludarabine phosphate (see Figure 61–5). These alterations produce inhibitory effects on vital enzymatic pathways and prevent DNA synthesis.

**FLUOROURACIL, CAPECITABINE, AND FLOXURIDINE (FLUORODEOXYURIDINE)**

Fluorouracil is available as 5-FU, as the derivative fluorodeoxyuridine (FUdR, not often used in clinical practice), and as a prodrug, capecitabine, which is ultimately converted to 5-FU.

**Mechanisms of Action.** 5-FU requires enzymatic conversion (ribosylation and phosphorylation) to the nucleotide form to exert its cytotoxic activity. As the triphosphate FUTP, the drug is incorporated into RNA. Alternative reactions can produce the deoxy derivative FdUMP; FdUMP inhibits TS and blocks the
synthesis of TTP, a necessary constituent of DNA (Figure 61–7). The folate cofactor, 5,10-methylenetetrahydrofolate, and FdUMP form a covalently bound ternary complex with TS. The physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and 2 hydrogen atoms from folate to dUMP, but this reaction is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results.

![Figure 61–7](image)

**Figure 61–7 Actions of 5-fluoro-2'-deoxyuridine-5'-phosphate (5-FdUMP) and 5-FU nucleotides.** 5-FU, 5-fluorouracil; dUMP FdUMP, deoxyuridine monophosphate/fluoro dUMP; FH2Gluₙ/FH₄Gluₙ, dihydro-/tetrahydro-folate polyglutamates; TMP/TTP, thymidine monophosphate/triphosphate.

5-FU is incorporated into both RNA and DNA. In 5-FU-treated cells, both FdUTP and dUTP (that accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological TTP. Presumably, such incorporation into DNA calls into action the excision-repair process, which can lead to DNA strand breakage because DNA repair requires TTP, which is lacking as a result of TS inhibition. 5-FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and functions of RNA.

**Mechanisms of Resistance.** Resistance to the cytotoxic effects of 5-FU or FUdR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5-FU, amplification of TS, mutation of TS to a form that is not inhibited by FdUMP, and high levels of the degradative enzymes dihydouracil dehydrogenase and thymidine phosphorylase. TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts
with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved, and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5-FU.

Some malignant cells appear to have insufficient concentrations of 5,10-methylenetetrahydrofolate, and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of leucovorin increases formation of the complex and enhances responses to 5-FU. A number of other agents have been combined with 5-FU in attempts to enhance the cytotoxic activity through biochemical modulation. MTX, by inhibiting purine synthesis and increasing cellular pools of 5-phosphoribosyl-1-pyrophosphate (PRPP), enhances the activation of 5-FU and increases antitumor activity of 5-FU when given prior to but not following 5-FU. The combination of cisplatin and 5-FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is unclear. Oxaliplatin, which downregulates TS expression, is commonly used with 5-FU and leucovorin for treating metastatic colorectal cancer. A most important interaction is the enhancement of irradiation by fluoropyrimidines, the basis for which is unclear. 5-FU with simultaneous irradiation cures anal cancer and enhances local tumor control in head, neck, cervical, rectal, gastroesophageal, and pancreatic cancer.

**ADME.** 5-FU is administered parenterally because absorption after oral ingestion of the drug is unpredictable and incomplete. 5-FU is inactivated by reduction of the pyrimidine ring in a reaction carried out by dihydropyrimidine dehydrogenase (DPD), which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug. DPD deficiency can be detected either by enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5-FU to its metabolite, 5-fluoro-5,6-dihydrouracil.

Plasma clearance is rapid ($t_{1/2} \sim 10$-20 min). Only 5-10% of a single intravenous dose of 5-FU is excreted intact in the urine. The dose does not have to be modified in patients with hepatic dysfunction, presumably because of sufficient degradation of the drug at extrahepatic sites. 5-FU enters the CSF in minimal amounts.
THERAPEUTIC USES

5-FLUOROURACIL. 5-FU produces partial responses in 10-20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5-FU in combination with leucovorin and oxaliplatin or irinotecan in the adjuvant setting is associated with a survival advantage for patients with colorectal cancers. For average-risk patients in good nutritional status with adequate hematopoietic function, the weekly dosage regimen employs 500-600 mg/m² with leucovorin once each week for 6 of 8 weeks. Other regimens use daily doses of 500 mg/m² for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5-FU for 5 days must be reduced to 375-425 mg/m² because of mucositis and diarrhea. 5-FU increasingly is used as a biweekly infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer.

FLOXURIDINE (FUDR). FUdR (fluorodeoxyuridine [FUDR]) is converted directly to FdUMP by thymidine kinase. The drug is administered primarily by continuous infusion into the hepatic artery for treatment of metastatic carcinoma of the colon or following resection of hepatic metastases; the response rate to such infusion is 40-50%, double that observed with intravenous administration. Intrahepatic arterial infusion for 14-21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7-14.

CAPECITABINE (Xeloda). Capecitabine, an orally administered prodrug of 5-FU, is approved for the treatment of (1) metastatic breast cancer in patients who have not responded to a regimen of paclitaxel and an anthracycline antibiotic; (2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer. The recommended dosage is 2500 mg/m²/day, given in 2 divided doses with food, for 2 weeks, followed by a rest period of 1 week. Capecitabine is well absorbed orally. It is rapidly de-esterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5′-deoxyfluorodeoxyuridine (5′-dFdU), which disappears with a $t_{1/2}$ of 1 h. The
conversion of 5′-dFdU to 5-FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5-FU levels are <10% of those of 5′-dFdU, reaching a maximum of 0.3 mg/L or 1 μM at 2 h. Liver dysfunction delays the conversion of the parent compound to 5′-dFdU and 5-FU, but there is no consistent effect on toxicity.

**Combination Therapy.** Higher response rates are seen when 5-FU or capecitabine is used in combination with other agents (e.g., with cisplatin in head and neck cancer, with oxaliplatin or irinotecan in colon cancer). The combination of 5-FU and oxaliplatin or irinotecan has become the standard first-line treatment for patients with metastatic colorectal cancer. The use of 5-FU in combination regimens has improved survival in the adjuvant treatment for breast cancer and, with oxaliplatin and leucovorin, for colorectal cancer. 5-FU also is a potent radiation sensitizer. Beneficial effects also have been reported when combined with irradiation as primary treatment for locally advanced cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5-FU produces very favorable results for the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

**Clinical Toxicities.** The clinical manifestations of toxicity caused by 5-FU and floxuridine are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5-FU. The nadir of leukopenia usually occurs 9-14 days after the first injection of drug. Thrombocytopenia and anemia also may occur, as may loss of hair (occasionally progressing to total alopecia), nail changes, dermatitis, and increased pigmentation and atrophy of the skin may. Hand-foot syndrome, a particularly prominent adverse effect of capecitabine, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5-FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional than with bolus regimens, while hand-foot syndrome occurs more often with infusional than with bolus regimens. The significant risk of toxicity with fluoropyrimidines
emphasizes the need for very skillful supervision by physicians familiar with the action and possible hazards.

Capecitabine causes a similar spectrum of toxicities as 5-FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

**CYTIDINE ANALOGS**

**CYTARABINE (CYTOSINE ARABINOSIDE; Ara-C)**

Cytarabine (1-β-d-arabinofuranosylcytosine; Ara-C [CYTOSAR-U, TARABINE PFS, others]) is the most important antimetabolite used in the therapy of AML; it is the single most effective agent for induction of remission in this disease.

**MECHANISM OF ACTION.** Ara-C is an analog of 2′-deoxycytidine; the 2′-hydroxyl in a position trans to the 3′-hydroxyl of the sugar (see Figures 61–5 and 61–6) hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via nucleoside transporters; hENT1 appears to be the primary mediator of Ara-C influx. In the cell, Ara-C is converted to its active form, the 5′-monophosphate ribonucleotide, by deoxycytidine kinase (CdK), an enzyme that shows polymorphic expression among patients (see below). Ara-CMP then reacts with deoxynucleotide kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with deoxycytidine 5′-triphosphate (dCTP) for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, both in replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytotoxicity correlates with the total Ara-C incorporated into DNA; incorporation of ~5 molecules of Ara-C per 10^4 bases of DNA decreases cellular clonogenicity by ~50%.

In infants and adults with ALL and t(4;11) mixed-lineage leukemia (MLL) translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter, hENT1, is highly expressed, and its expression correlates with sensitivity to Ara-C. At extracellular drug concentrations >10 1M (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate
limiting. Particular subtypes of AML derive benefit from high-dose Ara-C treatment; these include t(8;21), inv(16), t(9;16), and del(16). Approximately 20% of AML patients have leukemic cells with a k-RAS mutation, and these patients seem to derive greater benefit from high dose Ara-C regimens than do patients with wild type k-RAS.

**MECHANISMS OF RESISTANCE.** Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme, CdK, produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, ara-uridine (Ara-U). Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite, Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells lead to a longer duration of complete remission in patients with AML. The capacity of cells to transport Ara-C also may affect response. Clinical studies have implicated a loss of CdK as the primary mechanism of resistance to Ara-C in AML.

**ADME.** Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only ~20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2-50 μM are measurable in plasma after intravenous injection of 30-300 mg/m² but fall rapidly (t₁/₂ ≈ 10 min). Less than 10% of the injected dose is excreted unchanged in the urine within 12-24 h; most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection, but are ≤10% of concentrations in plasma. After intrathecal administration of the drug at a dose of 50 mg/m², deamination proceeds slowly, with a t₁/₂ of 3-4 h, and peak concentrations of 1-2 μM are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4 μM) for ≥24 h. A depot liposomal formulation of Ara-C (DEPOCYT) provides sustained release into the CSF. After a standard 50-mg dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures.

**Therapeutic Uses.** Continuous inhibition of DNA synthesis for a duration
equivalent to at least 1 cell cycle or 24 h is necessary to expose most tumor cells during the S, or DNA-synthetic, phase of the cycle. The optimal interval between bolus doses of Ara-C is ~8-12 h, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multi-day cycle of treatment. Typical schedules for administration of Ara-C employ bolus doses every 12 h or continuous drug infusion for 5-7 days. Two dosage schedules are recommended: (1) rapid intravenous infusion of 100 mg/m² every 12 h for 5-7 days or (2) continuous intravenous infusion of 100-200 mg/m²/day for 5-7 days. In general, children tolerate higher doses than adults. Intrathecal doses of 30 mg/m² every 4 days have been used to treat meningeal or lymphomatous leukemia. The intrathecal administration of liposomal cytarabine (DEPOCYT), 50 mg for adults, 35 mg for children, every 2 weeks seems equally effective as the every-4-days regimen with the standard drug. Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of other leukemias, such as ALL, CML in the blast phase, acute promyelocytic leukemia, and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate transport and intercellular activation, clinicians have employed high-dose regimens (2-3 g/m² every 12 h for 6-8 doses) to achieve 20-50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

**CLINICAL TOXICITIES.** Cytarabine is a potent myelosuppressive agent capable of producing acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis. The onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomography scans may follow 1-2 weeks after high-dose Ara-C and may be fatal in 10-20% of patients, especially in patients being treated for relapsed leukemia. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy, or coma, especially if given concomitantly with systemic high-dose MTX or systemic Ara-C. Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients >40
years of age and/or patients with poor renal function.

AZACITIDINE (5-AZACYTIDINE)

5-Azacytidine (see Figure 61–6) and decitabine (2′-deoxy-5-azacytidine) have antileukemic activity and induce differentiation by inhibiting DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15-20% of patients and reduce transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

Mechanism of Action. The aza-nucleosides enter cells by the human equilibrative transporter. The drugs incorporate into DNA, where they become covalently bound to the methyltransferase, depleting intracellular enzyme and leading to global demethylation of DNA, tumor cell differentiation, and apoptosis. Decitabine also induces double-strand DNA breaks, perhaps as a consequence of the effort to repair the protein-DNA adduct.

Pharmacokinetics. After subcutaneous administration of the standard dose of 75 mg/m², 5-azacytidine undergoes rapid deamination by cytidine deaminase (plasma $t_{1/2}$ 20-40 min). Due to the formation of intracellular nucleotides, which become incorporated into DNA, the effects of the aza-nucleosides persist for many hours.

Therapeutic Use. The usual regimen for 5-azacytidine in myelodysplastic syndrome (MDS) is 75 mg/m²/day for 7 days every 28 days, while decitabine is given in a dose of 20 mg intravenously every day for 5 days every 4 weeks. Best responses may become apparent only after 2-5 courses of treatment.

Toxicity. The major toxicities of the aza-nucleosides include myelosuppression and mild GI symptoms. 5-Azacytidine produces rather severe nausea and vomiting when given intravenously in large doses (150-200 mg/m²/day for 5 days).

GEMCITABINE

Gemcitabine (2′,2′-difluorodeoxycytidine; dFdC) (see Figure 61–6), a difluoro analog of deoxycytidine, is used for patients with metastatic pancreatic; non-
squamous, non–small cell lung; ovarian; and bladder cancer.

**Mechanism of Action.** Gemcitabine enters cells via 3 distinct nucleoside transporters: hENT (the major route), hCNT, and a nucleobase transporter found in malignant mesothelioma cells. Intracellularly, CdK phosphorylates gemcitabine to the monophosphate (dFdCMP), which is converted to di- and triphosphates (dFdCDP and dFdCTP). Although gemcitabine’s anabolism and effects on DNA in general mimic those of cytarabine, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike that of cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle. The cytotoxic activity may reflect several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP is a stoichiometric inhibitor of ribonucleotide reductase (RNR), resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis. Incorporation of dFdCTP into DNA causes DNA strand termination and appears resistant to repair. The capacity of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis. Gemcitabine is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

**ADME.** Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is dFdU. In patients with significant renal dysfunction, dFdU and its triphosphate accumulate to high and potentially toxic levels. Gemcitabine has a short plasma $t_{1/2}$ (~15 min); women and elderly patients clear the drug more slowly.

**Therapeutic Uses.** The standard dosing schedule for gemcitabine (GEMZAR) is a 30-min intravenous infusion of 1-1.25 g/m² on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication. Conversion of gemcitabine to dFdCMP by CdK is saturated at infusion rates of ~10 mg/m²/min. To increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100-150 min at a fixed rate of 10 mg/min. The 150-min infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression but does not
improve antitumor activity. The inhibition of DNA repair by gemcitabine may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy.

**Clinical Toxicities.** The principal toxicity is myelosuppression. Longer-duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild, reversible elevation in liver transaminases may occur in ≥40% of patients. Interstitial pneumonitis, at times progressing to acute respiratory distress syndrome (ARDS), may occur within the first 2 cycles of treatment and usually responds to corticosteroids. Rarely, patients treated for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. Gemcitabine is a very potent radiosensitizer and should not be used with radiotherapy.

**PURINE ANALOGS**

The pioneering studies of Hitchings and Elion identified analogs of naturally occurring purine bases with antileukemic and immunosuppressant properties. Figure 61–8 shows structural formulas of several of these, with adenosine for comparison.
Other purine analogs that have valuable roles in leukemia and lymphoid malignancies include cladribine (standard therapy for hairy cell leukemia), fludarabine phosphate (standard treatment for CLL), nelarabine (pediatric ALL), and clofarabine (T-cell leukemia/lymphoma). The apparent selectivity of these agents may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

**6-THIOPURINE ANALOGS**

6-Mercaptopurine (6-MP) and 6-thioguanine (6-TG) are approved agents for human leukemias and function as analogs of the natural purines, hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6-MP and 6-TG inhibit de novo purine synthesis and also become incorporated into nucleic acids.
**Mechanism of Action.** Hypoxanthine guanine phosphoribosyl transferase (HGPRT) converts 6-TG and 6-MP to the ribonucleotides 6-thioguanosine-5′-monophosphate (6-thioGMP) and 6-thioinosine-5′-monophosphate (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase (the enzyme that converts GMP to GDP), T-IMP accumulates intracellularly. T-IMP inhibits the new formation of ribosyl-5-phosphate, as well as conversion of IMP to adenine and guanine nucleotides. The most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the de novo pathway. 6-Thioguanine nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing.

**Mechanisms of Resistance.** The most common mechanism of 6-MP resistance observed in vitro is deficiency or complete lack of the activating enzyme, HGPRT, or increased alkaline phosphatase activity. Other mechanisms for resistance include (1) decreased drug uptake, or increased efflux due to active transporters; (2) alteration in allosteric inhibition of ribosylamine 5-phosphate synthase; and (3) impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6) of MMR.

**Pharmacokinetics and Toxicity.** Absorption of oral mercaptopurine is incomplete (10-50%); the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when mercaptopurine is combined with high-dose MTX. After an intravenous dose, the $t_{1/2}$ of the drug is ~50 min in adults, due to rapid metabolic degradation by xanthine oxidase and by thiopurine methyltransferase (TPMT). Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier. In addition to the HGPRT-catalyzed anabolism of mercaptopurine, there are 2 other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse. In patients with autoimmune disease treated with mercaptopurine, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population.
A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate. The second major pathway for 6-MP metabolism involves its oxidation by xanthine oxidase to 6-thiourate, an inactive metabolite. Oral doses of 6-MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor, allopurinol; no dose adjustment is required for intravenous dosing.

**Therapeutic Uses.** In the maintenance therapy of ALL, the initial daily oral dose of 6-MP (PURINETHOL) is 50-100 mg/m² and is thereafter adjusted according to white blood cell and platelet count. The combination of MTX and 6-MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, MTX elevates the intracellular concentration of PRPP, a cofactor required for 6-MP activation.

**CLINICAL TOXICITIES.** The principal toxicity of 6-MP is bone marrow depression; thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. When depression of normal bone marrow elements occurs, dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in ~25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6-MP and usually resolve upon discontinuation of therapy. 6-MP and its derivative, azathioprine, predispose to opportunistic infection (e.g., reactivation of hepatitis B, fungal infection, and *Pneumocystis* pneumonia), and an increased incidence of squamous cell malignancies of the skin. 6-MP is teratogenic during the first trimester of pregnancy, and AML has been reported after prolonged 6-MP therapy for Crohn disease.

**FLUDARABINE PHOSPHATE**

Fludarabine phosphate is a fluorinated, deamination-resistant, phosphorylated analog of the antiviral agent vidarabine (9-β-D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas and is also effective as a potent immunosuppressant.

**Mechanisms of Action and Resistance.** The drug is dephosphorylated
extracellularly to the nucleoside fludarabine, which enters the cell and is rephosphorylated by CdK to the active triphosphate. This antimetabolite inhibits DNA polymerase, DNA primase, DNA ligase, and RNR, and becomes incorporated into DNA and RNA. The nucleotide is an effective chain terminator when incorporated into DNA. Incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation.

In experimental tumors, resistance to fludarabine is associated with decreased activity of CdK (the enzyme that phosphorylates the drug), increased drug efflux, and increased RNR activity. Its mechanism of immunosuppression and paradoxical stimulation of autoimmunity stems from the particular susceptibility of lymphoid cells to purine analogs and the specific effects on the CD4+ subset of T cells, as well as its inhibition of regulatory T-cell responses.

**ADME.** Fludarabine phosphate is administered both intravenously and orally and is rapidly converted to fludarabine in the plasma. The median time to reach maximal concentrations of drug in plasma after oral administration is 1.5 h, and oral bioavailability averages 55-60%. The $t_{1/2}$ of fludarabine in plasma is ~10 h. The compound is eliminated primarily by renal excretion.

**THERAPEUTIC USES.** Fludarabine phosphate (FLUDARA, OFORTA) is approved for intravenous and oral use and is equally active by both routes. The recommended dose is 25 mg/m$^2$ daily for 5 days by intravenous infusion, or 40 mg/m$^2$ daily for 5 days by mouth. The drug is administered intravenously over 30-120 min. Dosage should be reduced in patients with renal impairment in proportion to the reduction in CrCl. Treatment may be repeated every 4 weeks, and gradual improvement in CLL usually occurs within 2-3 cycles. Fludarabine phosphate is highly active alone or with rituximab and cyclophosphamide for the treatment of patients with CLL; overall response rates in previously untreated patients approximate 80% and the duration of response averages 22 months. The synergy of fludarabine with alkylators may stem from the observation that it blocks the repair of double-strand DNA breaks and interstrand cross-links induced by alkylating agents. It also is effective in follicular B-cell lymphomas refractory to standard therapy. It is increasingly used as a potent immunosuppressive agent in nonmyeloablative allogeneic bone marrow transplantation.

**CLINICAL TOXICITIES.** Oral and intravenous therapy cause
myelosuppression in ~50% of patients, nausea and vomiting in a minor fraction, and, uncommonly, chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of CD4+ T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a rare complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Autoimmune events may occur after fludarabine treatment. CLL patients may develop an acute hemolytic anemia or pure red cell aplasia during or following fludarabine treatment. Prolonged cytopenias, probably mediated by autoimmunity, also complicate fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications. Pneumonitis is an occasional side effect and responds to corticosteroids. In patients with compromised renal function, the initial doses should be reduced in proportion to the reduction in CrCl.

**CLADRIBINE**

Cladribine (2-chlorodeoxyadenosine [2-CdA]) is an adenosine deaminase-resistant purine analog that has potent and probably curative activity in hairy cell leukemia, CLL, and low-grade lymphomas.

**Mechanisms of Action and Resistance.** Cladribine enters cells via active nucleoside transport. After phosphorylation by CdK and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme, CdK; increased expression of RNR; or increased active efflux by ABCG2 or other members of the ABC cassette family of transporters.

**ADME.** Cladribine is moderately well absorbed orally (55%) but is routinely administered intravenously. It is excreted by the kidneys, with a terminal $t_{1/2}$ in plasma of 6.7 h. Cladribine crosses the blood-brain barrier and reaches CSF concentrations of ~25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

**Therapeutic Uses.** Cladribine (Leustatin, others) is administered as a single course of 0.09 mg/kg/day for 7 days by continuous intravenous infusion. It is the
drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

**Clinical Toxicities.** The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased CD4+ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

**CLOFARABINE (2-CHLORO-2′-FLUORO-ARABINOSYLADENINE)**
This analog incorporates the 2-chloro, glycosylase-resistant substituent of cladribine and a 2′-fluoro-arabinosyl substitution, which adds stability and enhances uptake and phosphorylation. The resulting compound is approved for pediatric ALL after failure of 2 prior therapies. Clofarabine produces complete remissions in 20-30% of these patients. It has activity as well in pediatric and adult AML and in myelodysplasia. The uptake and metabolic activation of clofarabine in tumor cells follow the same path as cladribine and the other purine nucleosides, although clofarabine is more readily phosphorylated by dCK. Clofarabine triphosphate has a long intracellular t½ (24 h). It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis; clofarabine also inhibits RNR.

**Clinical Pharmacology.** In children, it is administered in doses of 52 mg/m² given as a 2-h infusion daily for 5 days. The primary elimination t½ in plasma is 6.5 h. Most of the drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in CrCl. The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachyphemia, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release that necessitate immediate discontinuation of the drug; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hypokalemia and hypophosphatemia.

**NELARABINE (6-METHOXY-ARABINOSYL-GUANINE)**
Nelarabine is the only guanine nucleoside in clinical use. It has selective activity against acute T-cell leukemia (20% complete responses) and the closely related
T-cell lymphoblastic lymphoma and is approved for use in relapsed/refractory patients. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis.

**ADME.** Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by adenosine deaminase–mediated cleavage of the methyl group, yielding the phosphorylase resistant Ara-G, which has a plasma $t_{1/2}$ of 3 h. The active metabolite is transported into tumor cells, where it is activated by CdK to Ara-G triphosphate (Ara-GTP) that incorporates into DNA and terminates DNA synthesis. The drug and its metabolite, Ara-G, are primarily eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The dose should be used with close clinical monitoring in patients with severe renal impairment (CrCL <50 mg/mL). Adults are given a dose of 1500 mg/m$^2$ intravenously as a 2-h infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose of 650 mg/m$^2$/day intravenously for 5 days and repeated every 21 days.

**Clinical Toxicity.** Side effects include myelosuppression and liver function test abnormalities, as well as frequent, serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological side effects may not be reversible.

**PENTOSTATIN (2’-DEOXYCOFORMYCIN)**

Pentostatin (2’-deoxycoformycin; see Figure 61–8), a transition-state analog of the intermediate in the adenosine deaminase (ADA) reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting both T- and B-cell functions).

**Mechanism of Action.** Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR. Deoxyadenosine also inactivates S-adenosyl homocysteine hydrolase. The resulting accumulation of S-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.
**ADME.** Pentostatin is administered intravenously and has a mean terminal $t_{1/2}$ of 5.7 h. The recommended dose is 4 mg/m$^2$ administered intravenously, every other week. After hydration with 500-1000 mL of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of $\leq$30 min, followed by an additional 500 mL of fluids. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced CrCl.

**Clinical Use.** Pentostatin is effective in producing complete remissions (58%) and partial responses (28%) in hairy cell leukemia. It largely has been superseded by cladribine. Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation. At high doses (10 mg/m$^2$), major renal and neurological complications are encountered. Pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

**III. Natural Products**

**MICROTUBULE-DAMAGING AGENTS**

**VINCA ALKALOIDS**

Purified alkaloids from the periwinkle plant, including *vinblastine* and *vincristine*, were among the earliest clinical agents for treatment of leukemias, lymphomas, and testicular cancer. A closely related derivative, vinorelbine, has important activity against lung and breast cancer.

**Mechanism of Action.** The vinca alkaloids are cell-cycle–specific agents and, in common with other drugs, such as colchicine, podophyllotoxin, the taxanes, and the epothilones, block cells in mitosis. The biological activities of the vincas can be explained by their ability to bind specifically to β tubulin and to block its polymerization with α tubulin into microtubules. The mitotic spindle cannot
form, duplicated chromosomes cannot align along the division plate, and cell division arrests in metaphase. Cells blocked in mitosis undergo changes characteristic of apoptosis. Microtubules are found in high concentration in the brain and contribute to other cellular functions such as movement, phagocytosis, and axonal transport. Side effects of the vinca alkaloids, such as their neurotoxicity, may relate to disruption of these functions.

**Resistance.** Despite their structural similarity, the individual vinca alkaloids have unique patterns of clinical efficacy (see below). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance mediated by the \textit{mdr} gene/P-glycoprotein, which confers resistance to a broad range of agents (the vinca alkaloids, epipodophyllotoxins, anthracyclines, and taxanes). Chromosomal abnormalities consistent with gene amplification and markedly increased levels of P-glycoprotein (a membrane efflux transporter) have been observed in resistant cells in culture. Other membrane transporters, such as the MRP and the closely related breast cancer resistance protein, may contribute to resistance. Other forms of resistance to vinca alkaloids stem from mutations in β tubulin or in the relative expression of isoforms of β tubulin that prevent the inhibitors from effectively binding to their target.

**Cytotoxic Actions.** The very limited myelosuppressive action of vincristine makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes a mild neurotoxicity as well as myelosuppression, has an intermediate toxicity profile.

**Metabolism and Excretion.** The liver cytochromes extensively metabolize all 3 agents, and the metabolites are excreted in the bile. Only a small fraction of a dose (<15%) is found in the urine unchanged. In patients with hepatic dysfunction (bilirubin >3 mg/dL), a 50-75% reduction in dose of any of the vinca alkaloids is advisable. The elimination \( t_{1/2} \) is 20 h for vincristine, 23 h for vinblastine, and 24 h for vinorelbine.

**VINBLASTINE**

**Therapeutic Uses.** Vinblastine sulfate (VELBAN) is given intravenously; special precautions must be taken against subcutaneous extravasation, which may cause
painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose of 0.3 mg/kg of body weight, myelosuppression reaches its maximum in 7-10 days. If a moderate level of leukopenia (~3000 cells/mm\(^3\)) is not attained, the weekly dose may be increased gradually by increments of 0.05 mg/kg of body weight. For testicular cancer, vinblastine is used in doses of 0.3 mg/kg every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin >1.5 mg/dL. Vinblastine is used with bleomycin and cisplatin in the curative therapy of metastatic testicular tumors, although it has been supplanted by etoposide or ifosfamide. It is a component of the standard curative regimen for Hodgkin disease (doxorubicin [ADRIAMYCIN], bleomycin, vinblastine, and dacarbazine [ABVD]). It also is active in Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, bladder cancer, carcinoma of the breast, and choriocarcinoma.

**Clinical Toxicities.** Maximal leukopenia occurs within 7-10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include mild neurological manifestations. GI disturbances including nausea, vomiting, anorexia, and diarrhea may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis.

**VINCristine**

**Therapeutic Uses.** Vincristine is a standard component of regimens for treating pediatric leukemias, lymphomas, and solid tumors, such as Wilms, tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen with cyclophosphamide, doxorubicin, and prednisone. Vincristine sulfate (VINCASARF) used with glucocorticoids is the treatment of choice to induce remissions in childhood leukemia and in combination with alkylating agents and anthracycline for pediatric sarcomas. The common intravenous dosage for vincristine is 2 mg/m\(^2\) of body surface area at weekly or longer intervals. Vincristine is tolerated better by children than by adults, who may experience severe, progressive neurological toxicity and require a lower dose of 1.4 mg/m\(^2\). Administration of the drug more frequently than every 7 days or at higher doses increases the toxic manifestations without proportional improvement in the response rate. Precautions also should be used to avoid
extravasation during intravenous administration. Doses should be reduced for patients with elevated plasma bilirubin.

**Clinical Toxicities.** The clinical toxicity of vincristine is mostly neurological. Severe neurological manifestations may be reversed by suspending therapy or reducing the dosage, upon first evidence of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by a prophylactic program of laxatives and hydrophilic (bulk-forming) agents, and usually is a problem only with doses >2 mg/m². Reversible alopecia occurs in ~20% of patients. Modest leukopenia may occur. Thrombocytopenia, anemia, and the syndrome of inappropriate secretion of ADH are less common. Inadvertent injection of vincristine into the CSF causes a devastating and often fatal irreversible coma and seizures.

**VINORELBINE**
Vinorelbine has activity against non–small cell lung cancer and breast cancer. Vinorelbine (NAVELBINE, others) is administered in normal saline as an intravenous infusion over 6-10 min. When used alone, it is given at doses of 30 mg/m² either weekly or for 2 out of every 3 weeks. When used with cisplatin for the treatment of non–small cell lung cancer, it is given at doses of 25 mg/m² either weekly or for 3 out of every 4 weeks. A lower dose (20-25 mg/m²) may be required for patients who have received prior chemotherapy and for hematological toxicity. Its primary toxicity is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. Vinorelbine may cause allergic reactions and mild, reversible changes in liver enzymes. Doses should be reduced in patients with elevated plasma bilirubin.

**TAXANES**
Paclitaxel (TAXOL, others) was first isolated from the bark of the Western yew tree. Paclitaxel and its congener, the semisynthetic docetaxel (TAXOTERE), exhibit unique pharmacological properties as inhibitors of mitosis, differing from the vinca alkaloids and colchicine derivatives in that they bind to a different β-tubulin site and promote rather than inhibit microtubule formation. The taxanes have a central role in the therapy of ovarian, breast, lung, GI, genitourinary, and head and neck cancers.
Paclitaxel has very limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil (CREMOPHOR EL); this vehicle likely is responsible for a high rate of hypersensitivity reactions. Patients receiving this formulation are protected by pretreatment with an H₁ receptor antagonist such as diphenhydramine, an H₂ receptor antagonist such as cimetidine (see Chapter 32), and a glucocorticoid such as dexamethasone (see Chapter 42).

An albumin-bound nanoparticle solution for infusion (nab-paclitaxel, ABRAXANE) is soluble in aqueous solutions and can be administered safely without prophylactic antihistamines or steroids. This form of paclitaxel has increased cellular uptake via an albumin-specific mechanism. Docetaxel, somewhat more soluble than paclitaxel, is administered in polysorbate 80 and is associated with a lower incidence of hypersensitivity reactions than paclitaxel dissolved in CREMOPHOR. However, pretreatment with dexamethasone for 3 days starting 1 day prior to therapy is required to prevent progressive fluid retention and minimize the severity of hypersensitivity reactions.

Mechanism of Action; Drug Interactions; Resistance. Paclitaxel binds specifically to the β-tubulin subunit of microtubules and antagonizes their disassembly, with the result that bundles of microtubules and aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell death occurs by apoptosis and depends on both drug concentration and duration of drug exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted; the sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule. Paclitaxel decreases doxorubicin clearance and enhances cardiotoxicity, while docetaxel has no apparent effect on anthracycline pharmacokinetics.

The basis of clinical drug resistance is not known. Resistance to taxanes is associated in some cultured tumor cells with increased expression of the mdr-1 gene and its product, P-glycoprotein; other resistant cells have β-tubulin mutations and may display heightened sensitivity to vinca alkaloids. Other resistant cell lines display an increase in survivin, an anti-apoptotic factor, iAurora kinase, that promotes completion of mitosis. The taxanes preferentially
bind to the βIII-tubulin subunit of microtubules; therefore, cells may become resistant by upregulating the βIII-isoform of tubulin.

**ADME.** Paclitaxel is administered as a 3-h infusion of 135-175 mg/m² every 3 weeks or as a weekly 1-h infusion of 80-100 mg/m². Prolonged infusions (96 h) also are active. Hepatic CYPs (primarily CYP2C8, secondarily CYP3A4) extensively metabolize the drug. The primary metabolite is 6-OH paclitaxel, which is inactive; multiple additional hydroxylation products are found in plasma; <10% of a dose is excreted in the urine intact. Dose reductions in patients with abnormal hepatic function have been suggested, and 50-75% doses of taxanes should be used in the presence of hepatic metastases >2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit these CYPs, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate; the plasma $t_{1/2}$ ~10-14 h and clearance is 15-18 L/hr/m². The critical plasma concentration for inhibiting bone marrow elements depends on duration of exposure but likely is 50-100 nM. Paclitaxel clearance is markedly delayed by cyclosporine A and other drugs that inhibit P-glycoprotein.

Nab-paclitaxel achieves a higher serum concentration of paclitaxel compared to Cremophor-solubilized paclitaxel, but the increased clearance of nab-paclitaxel results in a similar drug exposure. Nab-paclitaxel is most often administered intravenously over 30 min at 260 mg/m² every 3 weeks. Like the other taxanes, nab-paclitaxel should not be given to patients with an absolute neutrophil count <1500 cells/mm³.

Docetaxel pharmacokinetics are similar to those of paclitaxel, with an elimination $t_{1/2}$ of ~12 h. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites. In contrast to paclitaxel, the pharmacokinetics of docetaxel are linear for doses ≤115 mg/m².

**Therapeutic Uses.** The taxanes have become central components of regimens for treating metastatic ovarian, breast, lung, GI, genitourinary, and head and neck cancers. These drugs are administered once weekly or once every 3 weeks. The appropriate use of the steroid-sparing nab-paclitaxel still is being evaluated in clinical trials.
**Clinical Toxicities.** Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8-11 days after a dose and reverses rapidly by days 15-21. Used with filgrastim (granulocyte-colony stimulating factor [G-CSF]), doses as high as 250 mg/m² over 24 h are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-h infusions and in the weekly schedule. Hypersensitivity reactions can occur in patients receiving paclitaxel infusions of short duration (1-6 h) but are largely averted by pretreatment with dexamethasone, diphenhydramine, and histamine H₂ receptor antagonists, as noted above. Premedication is not necessary with 96-h infusions. Many patients experience asymptomatic bradycardia; occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-h infusions. Nab-paclitaxel produces increased rates of peripheral neuropathy compared to CREMOPHOR-delivered paclitaxel but rarely causes hypersensitivity reactions.

Docetaxel causes greater degrees of neutropenia than paclitaxel but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of docetaxel therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, 8 mg/day, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause a progressive interstitial pneumonitis and respiratory failure if the drug is not discontinued.

**ESTRAMUSTINE**

Estramustine (EMCYT, estramustine phosphate) combines estradiol and normustine (nornitrogen mustard) through a carbamate link. Although the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not function in vivo as an alkylating agent; rather, it binds to β tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.
**Therapeutic Use.** Estramustine is used solely for the treatment of metastatic or locally advanced hormone refractory prostate cancer at an initial dosage of 14 mg/kg/day in 3 or 4 divided doses.

**ADME.** Following oral administration, at least 75% of a dose of estramustine phosphate is absorbed from the GI tract and rapidly dephosphorylated. The drug undergoes extensive first-pass metabolism by hepatic CYPs to an active 17-keto derivative, estromustine, and to multiple inactive products; the active drug forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have a plasma \( t_{1/2} \) of 10 and 14 h, respectively, and are excreted as inactive metabolites, mainly in the feces.

**Clinical Toxicities; Drug Interactions.** In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention), hypercalcemia, acute attacks of porphyria, impaired glucose tolerance, and hypersensitivity reactions, including angioedema. Estramustine inhibits the clearance of taxanes.

**EPOTHILONES**

The epothilones are 16-membered polyketides discovered as cytotoxic metabolites from a strain of *Sorangium cellulosum*, a myxobacterium originally isolated from soil on the bank of the Zambezi River in southern Africa. These compounds overcome some of the problems of other microtubule disrupting and stabilizing agents, such as difficulties in formulation, drug delivery, and susceptibility to multidrug resistance. Ixabepilone (IXEMPIRA) is approved for breast cancer treatment.

Others in development include the epothilone B analogs patupilone (EPO906) and 21-aminoepothilone B (BMS-310705), the epothilone D analog KOS-1584 (R1645), and the synthetic sagopilone.

**Mechanism of Action; Resistance.** They bind to β tubulin and trigger microtubule nucleation at multiple sites away from the centriole. This chaotic microtubule stabilization triggers cell-cycle arrest at the G2-M interface and
apoptosis. Epothilones bind to a site distinct from that of taxanes. In colon cancer cell lines, p53 and Bax trigger apoptosis in ixabepilone-treated cells. In vitro studies suggest that ixabepilone is less susceptible to P-glycoprotein-mediated multidrug resistance than are taxanes. Other mechanisms implicated in epothilone resistance include mutation of the β-tubulin binding site and upregulation of isoforms of β tubulin.

**ADME.** Ixabepilone is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent, polyoxyethylated castor oil/ethanol (CREMOPHOR EL). CREMOPHOR has been implicated as the cause of infusion reactions; such reactions are infrequent when administration is preceded by premedication with H₁ and H₂ antagonists. The drug is cleared by hepatic CYPs and has a plasma t₁/₂ of 52 h.

**Therapeutic Uses.** In patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes, ixabepilone plus capecitabine provides an improved progression-free survival of 1.6 months compared to capecitabine alone. Ixabepilone also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and capecitabine. The recommended dose of ixabepilone as monotherapy or in combination with capecitabine is 40 mg/m² administered over 3 h every 3 weeks. Because of additive myelosuppression, the phase III trial used an attenuated dose of capecitabine (2000 mg/m²) administered with ixabepilone. Patients should be premedicated with both an H₁ and H₂ antagonist before receiving ixabepilone to minimize hypersensitivity reactions.

The combination of ixabepilone and capecitabine is contraindicated in patients with a baseline neutrophil count <1500 cells/mm³, a platelet count <100,000 cells/mm³, serum transaminases >2.5 × ULN or bilirubin above normal. In patients receiving ixabepilone monotherapy with mild to moderate hepatic dysfunction (bilirubin <1.5 × ULN or 1.5-3 × ULN, respectively), starting doses of 32 and 20 mg/m² are recommended due to delayed drug clearance.

**Toxicities.** Epothilones have toxicities similar to those of the taxanes: neutropenia, peripheral sensory neuropathy, fatigue, diarrhea, and asthenia.
CAMPTOTHECIN ANALOGS

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I. The lead compound in this class, camptothecin, was isolated from the tree Camptotheca acuminata. Irinotecan and topotecan, currently the only camptothecin analogs approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

Chemistry. All camptothecins have a fused 5-ring backbone that includes a labile lactone ring (see Figures 6–5 and 6–6 for examples). The hydroxyl group and S-conformation of the chiral center at C20 in the lactone ring are required for biological activity. Appropriate substitutions on the A and B rings of the quinoline subunit enhance water solubility and increase potency for inhibiting topoisomerase I. Topotecan is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. Irinotecan (CPT-11) differs from topotecan in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bis-piperidine side chain at position C10 (which makes the molecule water soluble) is cleaved by a carboxylesterase to form the active metabolite, SN-38 (see Figure 6–5).

Mechanism of Action. The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled to permit replication, repair, and transcription. Two classes of topoisomerase (I and II) mediate DNA strand breakage and resealing. Camptothecin analogs inhibit the function of topoisomerase I; myriad other chemical entities (e.g., anthracyclines, epipodophyllotoxins, acridines) inhibit topoisomerase II. The camptothecins bind to and stabilize the normally transient DNA-topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the re-ligation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death. The precise sequence of events that leads from drug-induced DNA damage to cell death has not been fully elucidated; one does observe internucleosomal DNA fragmentation, a characteristic of programmed cell death.
Camptothecins are *S phase–specific drugs*, because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. *S phase–specific* cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold for optimal therapeutic efficacy. In fact, low-dose, protracted administration of camptothecin analogs have less toxicity, and equal or greater antitumor activity, than shorter, more intense courses.

**Mechanisms of Resistance.** Decreased intracellular drug accumulation may underlie resistance in cell lines. Topotecan, but not SN-38 or irinotecan, is a substrate for P-glycoprotein; however, compared with other substrates, such as etoposide or doxorubicin, topotecan is a relatively poor substrate. Other reports have associated topotecan and irinotecan resistance with the MRP class of transporters. Cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan, but the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins in vitro and in vivo. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance. Finally, exposure of cells to topoisomerase I–targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

**TOPOTECAN**

**ADME.** Topotecan is approved for intravenous administration. An oral dosage form in development has a bioavailability of 30-40% in cancer patients. Topotecan exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation with a $t_{1/2} \sim 3.5-4.1$ h. Only 20-35% of the total drug in plasma is found to be in the active lactone form. Within 24 h, 30-40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in CrCl. Hepatic metabolism appears to be a relatively minor route of drug elimination. Plasma protein binding of topotecan is low (7-35%), which may explain its relatively greater CNS penetration.

**Therapeutic Uses.** Topotecan (HYCAMTIN) is indicated for previously treated patients with ovarian and small cell lung cancer. Significant hematological toxicity limits its use in combination with other active agents in these diseases.
(e.g., cisplatin). The recommended dosing regimen of topotecan for ovarian cancer and small cell lung cancer is a 30-min infusion of 1.5 mg/m²/day for 5 consecutive days every 3 weeks. For cervical cancer in conjunction with cisplatin, the dose of topotecan is 0.75 mg/m² on days 1, 2, and 3, repeated every 21 days. The dose of topotecan should be reduced to 0.75 mg/m²/day in patients with moderate renal dysfunction (CrCl of 20-40 mL/min); topotecan should not be administered to patients with severe renal impairment (CrCl <20 mL/min). Hepatic dysfunction does not alter topotecan clearance and toxicity. A baseline neutrophil count <1500 cells/mm³ and a platelet count >100,000 is necessary prior to topotecan administration.

**Clinical Toxicities.** The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

**IRINOTECAN**

**ADME.** The conversion of irinotecan to SN-38 is mediated predominantly by carboxylesterases in the liver (see Figure 6–5). Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only ~4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. The $t_{1/2}$ of SN-38 is 11.5 h, 3 times that of topotecan. CSF penetration of SN-38 in humans has not been characterized.

In contrast to topotecan, hepatic metabolism of irinotecan and SN-38 represents an important route of elimination for both. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bis-piperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be 2 times greater in brain cancer patients taking anti-seizure drugs that induce
hepatic CYPs.

UGT1A1 glucuronidates the hydroxyl group at position C10 (resulting from cleavage of the bispiperidine promoiety), producing the inactive metabolite SN-38G (see Figure 6–6). Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and metabolites, although urinary excretion also contributes (14-37%). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after irinotecan therapy. UGT1A1 polymorphisms associated with familial hyperbilirubinemia syndromes may have a major impact on the clinical use of irinotecan. A positive correlation has been found between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38 in patients treated with irinotecan. Severe irinotecan toxicity has been observed in cancer patients with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan’s GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite.

**Therapeutic Uses.** Approved single-agent dosage schedules of irinotecan (Camptosar, others) in the U.S. include 125 mg/m² as a 90-min infusion administered weekly (on days 1, 8, 15, and 22) for 4 out of 6 weeks, and 350 mg/m² given every 3 weeks. In patients with advanced colorectal cancer, irinotecan is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with cetuximab following failure of a 5-FU/oxaliplatin regimen.

**Clinical Toxicities.** The dose-limiting toxicity with all dosing schedules is delayed diarrhea (35%), with or without neutropenia. An intensive regimen of loperamide (4 mg of loperamide starting at the onset of any loose stool beginning more than a few hours after receiving therapy, followed by 2 mg every 2 h; see Chapter 47) reduces this incidence by more than half. However, once severe diarrhea occurs, standard doses of antidiarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14-47% of the patients treated with the every-3-weeks schedule and is less frequently encountered among patients treated with
the weekly schedule. Febrile neutropenia is observed in 3% of patients and may
be fatal, particularly when associated with concomitant diarrhea. A cholinergic
syndrome resulting from the inhibition of acetylcholinesterase activity by
irinotecan may occur within the first 24 h after irinotecan administration.
Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal
cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and less
often, asymptomatic bradycardia. These effects are short lasting and respond
within minutes to atropine. Other common toxicities include nausea and
vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver
transaminases, and alopecia. There have been case reports of dyspnea and
interstitial pneumonitis associated with irinotecan therapy.

ANTIBIOTICS

DACTINOMYCIN (ACTINOMYCIN D)

Actinomycin D has beneficial effects in the treatment of solid tumors
in children and choriocarcinoma in adult women.

Actinomycins are chromopeptides. Most contain the same chromophore, the
planar phenoazone actinosin, which is responsible for their yellow-red color.
The differences among naturally occurring actinomycins are confined to
variations in the structure of the amino acids of the peptide side chains.

Mechanism of Action. The capacity of actinomycins to bind to double-helical
DNA is responsible for their biological activity and cytotoxicity. The planar
phenoazone ring intercalates between adjacent guanine–cytosine base pairs of
DNA, while the polypeptide chains extend along the minor groove of the helix,
resulting in a dactinomycin-DNA complex with stability sufficient to block the
transcription of DNA by RNA polymerase. The DNA-dependent RNA
polymerases are much more sensitive to the effects of dactinomycin than are the
DNA polymerases. In addition, dactinomycin causes single-strand breaks in
DNA, possibly through a free-radical intermediate or as a result of the action of
topoisomerase II. Dactinomycin inhibits rapidly proliferating cells of normal and
neoplastic origin, and is among the most potent antitumor agents known.

ADME. Dactinomycin is administered by intravenous injection. Metabolism of
the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal $t_{1/2}$ of 36 h. Dactinomycin does not cross the blood-brain barrier.

**Therapeutic Uses.** The usual daily dose of dactinomycin (actinomycin D; \textsc{Cosmegen}) is 10-15 μg/kg; given intravenously for 5 days. If no manifestations of toxicity are encountered, additional courses may be given at intervals of 2-4 weeks. In other regimens, 3-6 μg/kg/day, for a total of 125 μg/kg, and weekly maintenance doses of 7.5 μg/kg have been used. The main clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilms, tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide. Ewing, Kaposi, and soft-tissue sarcomas also respond. Dactinomycin and MTX form a curative therapy for choriocarcinoma.

**Clinical Toxicities.** Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation; the drug is extremely corrosive to soft tissues.

**ANTHRACYCLINES AND ANTHRACENEDIONES**

Anthracyclines are derived from the fungus \textit{Streptomyces peucetius} var. \textit{caesius}. \textit{Idarubicin} and \textit{epirubicin} are analogs of the naturally produced anthracyclines \textit{doxorubicin} and \textit{daunorubicin}, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in the acute leukemias, whereas doxorubicin and epirubicin display broader activity against human solid tumors. These agents, which possess potential for generating free radicals, cause an unusual and often irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent
mitoxantrone has less cardiotoxicity and is useful against prostate cancer and AML, and in high-dose chemotherapy.

**Mechanisms of Action and Resistance.** Anthracyclines and anthracenediones can intercalate with DNA, directly affecting transcription and replication. More important is their capacity to form a heterotrimeric complex with topoisomerase II and DNA. Topoisomerase II produces double-strand breaks at the 3′-phosphate backbone, allowing strand passage and uncoiling of super-coiled DNA. Following strand passage, topoisomerase II re-ligates the DNA strands; this enzymatic function is essential for DNA replication and repair. Formation of the ternary complex with anthracyclines or with etoposide inhibits the re-ligation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while overexpression of transcription-linked DNA repair may contribute to resistance.

The quinone moieties of anthracyclines can form radical intermediates that react with O$_2$ to produce superoxide anion radicals, which can generate H$_2$O$_2$ and •OH that attack DNA and oxidize DNA bases, leading to apoptosis. The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron. Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as alpha tocopherol or by an iron chelator, dexrazoxane (ZINECARD, others), which protects against cardiac toxicity. Multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by ABCG2 (the breast cancer resistance protein). Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

**ADME.** Daunorubicin, doxorubicin, epirubicin, and idarubicin usually are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. Each anthracycline is converted to an active alcohol intermediate that plays a variable role in the therapeutic activity. The plasma disappearance curves for doxorubicin and daunorubicin are multiphasic, with a terminal $t_{1/2}$ of 30 h. Idarubicin has a $t_{1/2}$ of 15 h, and its active metabolite, idarubicinol, has a $t_{1/2}$ of 40 h. The drugs rapidly enter the heart,
kidneys, lungs, liver, and spleen; they do not cross the blood-brain barrier. Clearance is delayed in the presence of hepatic dysfunction; at least a 50% initial reduction in dose should be considered in patients with elevated serum bilirubin levels.

**IDARUBICIN AND DAUNORUBICIN**

**Therapeutic Use.** The recommended dosage for idarubicin (IdamyCin PFS) is 12 mg/m²/day for 3 days by intravenous injection in combination with cytarabine. Slow injection over 10-15 min is recommended to avoid extravasation. Idarubicin has less cardiotoxicity than the other anthracyclines.

Daunorubicin (daunomycin, rubidomycin; Cerubidine, others) is available for intravenous use. The recommended dosage is 25-45 mg/m²/day for 3 days. The agent is administered with care to prevent extravasation. Total doses of >1000 mg/m² are associated with a high risk of cardiotoxicity. Daunorubicin may impart a red color to the urine. Daunorubicin and idarubicin also are used in the treatment of AML in combination with Ara-C.

**Clinical Toxicities.** Toxic effects of daunorubicin and idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, rash, and cardiac toxicity. Cardiac toxicity is characterized by tachycardia, arrhythmias, dyspnea, hypotension, pericardial effusion, and congestive heart failure poorly responsive to digitalis.

**DOXORUBICIN**

**Therapeutic Uses.** The recommended dose is 60-75 mg/m², administered as a single rapid intravenous infusion that is repeated after 21 days. A doxorubicin liposomal product (Doxil) is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m² over 60 min and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer at a dose of 50 mg/m² every 4 weeks and as a treatment for multiple myeloma (in conjunction with bortezomib), where it is given as a 30-mg/m² dose on day 4 of each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine. Doxorubicin is effective in malignant lymphomas. In combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant
and metastatic carcinoma of the breast. The drug also is beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

**Clinical Toxicities.** Toxicities of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with maximal leukopenia usually occurring during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, mucositis, diarrhea, and alopecia are common but reversible. Erythematous streaking near the site of infusion (“ADRIAMYCIN flare”) is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa) even when the 2 therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity and may take 2 forms:

- **An acute form, characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias.** This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 h after a single dose, and plasma troponin T may increase in a minority of patients in the first few days following drug administration. Acute myocardial damage, the “pericarditis–myocarditis syndrome,” may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.

- **Chronic, cumulative dose-related toxicity (usually total doses of ≥550 mg/m²) progressing to congestive heart failure.** The mortality rate in patients with congestive failure approaches 50%. The risk increases markedly, with estimates as high as 20% at total doses of 550 mg/m² (a total dose limit of 300 mg/m² is advised for pediatric cases). These total dosages should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent. Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant trastuzumab increases the risk of cardiotoxicity. Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In
children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. Concomitant administration of dexrazoxane may reduce troponin T elevations and avert later cardiotoxicity.

**EPIRUBICIN**
This anthracycline is indicated as a component of adjunctive therapy for treatment of breast cancer. It is administered in doses of 100-120 mg/m² intravenously every 3-4 weeks. Total doses >900 mg/m² sharply increase the risk of cardiotoxicity. Its toxicity profile is the same as that of doxorubicin.

**VALRUBICIN**
Valrubicin is a semi-synthetic analog of doxorubicin, used exclusively for intravesicular treatment of bladder cancer. Once a week for 6 weeks, 800 mg are instilled into the bladder. Less than 10% of instilled drug is absorbed systemically. Side effects relate to bladder irritation.

**MITOXANTRONE**
Mitoxantrone is approved for use in AML, prostate cancer, and late-stage, secondary progressive multiple sclerosis. Mitoxantrone has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. It produces acute myelosuppression, cardiac toxicity (less than doxorubicin), and mucositis as its major toxicities; the drug causes less nausea, vomiting, and alopecia than does doxorubicin. Mitoxantrone (Novantrone, others) is administered by intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m² for 3 days with cytarabine. It also is used in advanced hormone-resistant prostate cancer in a dose of 12-14 mg/m² every 21 days.

**EPIPODOPHYLLOTOXINS**

**ETOPOSIDE AND TENIPOSIDE**
Two synthetic derivatives of podophyllotoxins have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin disease, and large cell lymphomas. These derivatives are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide and teniposide have no effect on microtubular structure or function at usual
concentrations.

**Mechanisms of Action and Resistance.** Etoposide and teniposide form ternary complexes with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G2 phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate (1) amplification of the mdr-1 gene that encodes the P-glycoprotein drug efflux transporter, (2) mutation or decreased expression of topoisomerase II, or (3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway.

**ETOPOSIDE**

**ADME.** Oral administration of etoposide results in variable absorption that averages ~50%. After intravenous injection, there is a biphasic pattern of clearance with a terminal $t_{1/2}$ of 6-8 h in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in CrCl. In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces etoposide from albumin); guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1-10% of those in plasma.

**Therapeutic Uses.** The intravenous dose of etoposide (VEPESID, others) for testicular cancer in combination therapy (with bleomycin and cisplatin) is 50-100 mg/m$^2$ for 5 days, or 100 mg/m$^2$ on alternate days for 3 doses. For small cell carcinoma of the lung, the dosage in combination therapy (with cisplatin and ifosfamide) is 35 mg/m$^2$/day intravenously for 4 days or 50 mg/m$^2$/day intravenously for 5 days. The oral dose for small cell lung cancer is twice the IV dose. Cycles of therapy usually are repeated every 3-4 weeks. When given intravenously, the drug should be administered slowly over a 30- to 60-min period to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide.

Etoposide is also active against non-Hodgkin lymphomas, acute nonlymphocytic
leukemia, and Kaposi sarcoma associated with AIDS. Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it frequently is used for high-dose chemotherapy in total doses of 1500-2000 mg/m$^2$.

**Clinical Toxicities.** The dose-limiting toxicity of etoposide is leukopenia (nadir at 10-14 days, recovery by 3 weeks). Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in ~15% of patients. Alopecia is common but reversible. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug. A disturbing complication of etoposide therapy is the development of an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the MLL gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and the onset of leukemia (1-3 years), compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia. Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses >2000 mg/m$^2$, seem to be at higher risk of leukemia.

**TENIPOSIDE**

Teniposide (VUMON) is administered intravenously. It has a multiphasic pattern of clearance from plasma: after distribution, a $t_{1/2}$ of 4 h and another $t_{1/2}$ of 10-40 h are observed. Approximately 45% of the drug is excreted in the urine; in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure. Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood-brain barrier. Teniposide is available for treatment of refractory ALL in children and is synergistic with cytarabine. Teniposide is administered by intravenous infusion in dosages that range from 50 mg/m$^2$/day for 5 days to 165 mg/m$^2$/day twice weekly. The drug has limited utility and is given primarily for acute leukemia in children and monocytic leukemia in infants, as well as glioblastoma,
neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting are its primary toxic effects.

**DRUGS OF DIVERSE MECHANISM OF ACTION**

**BLEOMYCIN**

The bleomycins, a unusual group of DNA-cleaving antibiotics, are fermentation products of *Streptomyces verticillus*. The drug currently employed clinically is a mixture of the 2 copper-chelating peptides, bleomycins A$_2$ and B$_2$, that differ only in their terminal amino acid. Because their toxicities do not overlap with those of other cytotoxic drugs, and because of their unique mechanism of action, bleomycin maintains an important role in treating Hodgkin disease and testicular cancer.

*Mechanisms of Action and Resistance.* Bleomycin’s cytotoxicity results from its capacity to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA. Bleomycin causes accumulation of cells in the $G_2$ phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, fragments, and translocations. Bleomycin cleaves DNA by generating free radicals. In the presence of $O_2$ and a reducing agent, the metal–drug complex becomes activated and functions as a ferrous oxidase, transferring electrons from Fe$^{2+}$ to molecular oxygen to produce oxygen radicals. Metallobleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-CYP$_{450}$ reductase. Bleomycin binds to DNA, and the activated complex generates free radicals that are responsible for abstraction of a proton at the 3′ position of the deoxyribose backbone of the DNA chain, opening the deoxyribose ring and generating a strand break in DNA. An excess of breaks generates apoptosis.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity. Some bleomycin-resistant cells contain high levels of hydrolase activity. In other cell lines, resistance has been attributed to decreased
uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins.

**ADME.** Bleomycin is administered intravenously, intramuscularly, or subcutaneously, or instilled into the bladder for local treatment of bladder cancer. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly. The elimination $t_{1/2}$ is ~3 h. About two-thirds of the drug is excreted intact in the urine. Concentrations in plasma are greatly elevated in patients with renal impairment and doses of bleomycin should be reduced in the presence of a CrCl <60 mL/min.

**Therapeutic Uses.** The recommended dose of bleomycin (Blenoxane, others) is 10-20 units/m² given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of ≤2 units is recommended for lymphoma patients. Myriad regimens are employed clinically, with bleomycin doses expressed in units. Total courses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity. Bleomycin also may be instilled into the pleural cavity in doses of 5-60 mg to ablate the pleural space in patients with malignant effusions. Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is a component of the standard curative ABVD regimen (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) for Hodgkin lymphoma.

**Clinical Toxicities.** Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation, hyperkeratosis, erythema, and even ulceration, and rarely, Raynaud phenomenon. Skin lesions may recur when patients are treated with other antineoplastic drugs. Rarely, bleomycin causes a flagellate dermatitis consisting of bands of pruritic erythema on the arms, back, scalp, and hands; this rash responds readily to topical corticosteroids.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Approximately 5-10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and
~1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses >250 mg and in patients >40 years of age, in those with a CrCl of <80 mL/min, and in those with underlying pulmonary disease; single doses of ≥30 mg/m² also are associated with an increased risk of pulmonary toxicity. Administration of high O₂ concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and may be related to release of an endogenous pyrogen. This reaction has occurred in ~1% of patients with lymphomas or testicular cancer.

**MITOMYCIN**

Mitomycin has limited clinical utility, having been replaced by less toxic and more effective drugs, with the exception of anal cancers, for which it is curative.

*Mechanisms of Action and Resistance.* After intracellular enzymatic or spontaneous chemical alteration, mitomycin becomes a bifunctional or trifunctional alkylating agent. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O⁶ and N⁷ positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced Q form, and P-glycoprotein-mediated drug efflux.
**ADME.** Mitomycin is administered intravenously. It has a $t_{1/2}$ of 25-90 min. The drug distributes widely throughout the body but is not detected in the CNS. Inactivation occurs by hepatic metabolism or chemical conjugation with sulfhydryls. Less than 10% of the active drug is excreted in the urine or the bile.

**Therapeutic Uses.** Mitomycin (mitomycin-C; MUTAMYCIN, others) is administered at a dose of 6-20 mg/m$^2$, given as a single bolus every 6-8 weeks. Dosage is modified based on hematological recovery. Mitomycin also may be used by direct instillation into the bladder to treat superficial carcinomas. Mitomycin is used in combination with 5-FU and cisplatin for anal cancer. Mitomycin is used off label (as an extemporaneously compounded eye drop) as an adjunct to surgery to inhibit wound healing and reduce scarring.

**Clinical Toxicities.** The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, maximal suppression may be delayed and cumulative, with recovery only after 6-8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, rash, fever, and malaise also are observed. Patients who have received >50 mg/m$^2$ total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of $\geq 70$ mg/m$^2$. There is no effective treatment for the disorder. It must be recognized early, and mitomycin must be discontinued immediately. Mitomycin causes interstitial pulmonary fibrosis; total doses $>30$ mg/m$^2$ have infrequently led to congestive heart failure. Mitomycin may potentiate the cardiotoxicity of doxorubicin.

**Mitotane**

Mitotane $(o,p'$-DDD), a compound chemically similar to the insecticides DDT and DDD, is used in the treatment of neoplasms derived from the adrenal cortex.

The mechanism of action of mitotane has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism.
(Cushing syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.

**ADME.** Approximately 40% of mitotane is absorbed after oral administration. Plasma concentrations of mitotane are still measurable for 6-9 weeks following discontinuation of therapy. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

**Therapeutic Uses.** Mitotane (LYSODREN) is administered in initial daily oral doses of 2-6 g, usually in 3 or 4 divided portions, and increasing to 9-10 g/day if tolerated. The maximal tolerated dose may vary from 2-16 g/day. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spironolactone should not be administered concomitantly, because it interferes with the adrenal suppression produced by mitotane. Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30-50% of such patients.

**Clinical Toxicity.** Although the administration of mitotane produces anorexia and nausea in most patients, somnolence and lethargy in ~34%, and dermatitis in 15-20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary.

**TRABECTEDIN**

Trabectedin (YONDELIS) is the only drug used clinically that is derived from a sea animal, the marine tunicate, *Ecteinascidin turbinate*.

Trabectedin binds to the minor groove of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove. The bulky DNA adduct is recognized by the transcription-coupled nucleotide excision repair complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. Trabectedin has particular cytotoxic effects on cells that lack components of the Fanconi
anemia complex or those that lack the ability to repair double-strand DNA breaks through homologous recombination. Unlike cisplatin and other DNA adduct–forming drugs, its activity requires the presence of intact components of NER, including XPG, which may be important for initiation of single breaks and attempts at adduct removal.

**ADME.** Trabectedin is administered as a 24-h infusion of 1.3 mg/m² every 3 weeks. It is administered with dexamethasone, 4 mg twice daily, starting 24 h before drug infusion to diminish hepatic toxicity. The drug is slowly cleared by CYP3A4, with a plasma $t_{1/2}$ 24-40 h.

**Therapeutic Uses.** Trabectedin is designated as an orphan drug in the U.S. for ovarian cancer, sarcoma, and pancreatic cancer. It is approved outside the U.S. for second-line treatment of soft-tissue sarcomas and for ovarian cancer in combination with a doxorubicin formulation (Doxil). It produces a very high (>50%) disease control rate in myxoid liposarcomas.

**Clinical Toxicity.** Without dexamethasone pretreatment, trabectedin causes significant hepatic enzyme elevations and fatigue in at least one-third of patients. With the steroid, the increases in transaminase are less pronounced and rapidly reversible. Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

**ENZYMES**

**L-ASPARAGINASE**

Malignant lymphoid cells depend on exogenous sources of L-asparagine. Thus, L-asparaginase (L-ASP) has become a standard agent for treating ALL.

**Mechanism of Action.** Most normal tissues synthesize L-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthase and derive the required amino acid from plasma. L-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. L-ASP is used in combination with other agents, including MTX, doxorubicin,
vincristine, and prednisone for the treatment of ALL and for high-grade lymphomas. Resistance arises through induction of asparagine synthetase in tumor cells.

**ADME and Therapeutic Use.** L-ASP (ELSPAR) is given intramuscularly or intravenously. After intravenous administration, *E. coli*–derived L-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a $t_{1/2}$ of 1 day. The enzyme is given in doses of 6000-10,000 IU every third day for 3-4 weeks. Pegasparagase (PEG-L-ASPARAGINASE; ONCASPAN) a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, has much slower clearance from plasma ($t_{1/2}$ of 6-7 days), and it is administered in doses of 2500 IU/m² intramuscularly no more frequently than every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients. Pegasparagase has much reduced immunogenicity (<20% of patients develop antibodies) and has been approved for first-line ALL therapy.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate L-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegasparagase produces more rapid clearance of lymphoblasts from bone marrow than does the *E. coli* preparation and circumvents the rapid antibody-mediated clearance seen with *E. coli* enzyme in relapsed patients. Asparaginase preparations only partially deplete CSF asparagine.

**Clinical Toxicity.** L-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5-20% of patients and may be fatal. In these patients, pegasparagase is a safe and effective alternative. So-called “silent” enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk ALL patients.

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient
clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis also has been observed. The clotting problems may take the form of spontaneous thrombosis, or less frequently, hemorrhagic episodes. Brain magnetic resonance imaging studies should be considered in patients treated with L-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of L-ASP treatment is an infrequent but devastating complication. L-ASP also suppresses immune function. L-ASP terminates the antitumor activity of MTX when given shortly after the antimetabolite. By lowering serum albumin concentrations, L-ASP may decrease protein binding and accelerate plasma clearance of other drugs.

HYDROXYUREA

Hydroxyurea (HU) has unique and diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of fetal hemoglobin in patients with sickle cell disease. It is orally administered, and its toxicity is modest and limited to myelosuppression.

Mechanisms of Action and Resistance. HU inhibits the enzyme ribonucleoside diphosphate reductase, which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU binds the iron molecules that are essential for activation of a tyrosyl radical in the catalytic subunit of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. It causes cells to arrest at or near the G1–S interface through both p53-dependent and independent mechanisms. Because cells are highly sensitive to irradiation at the G1–S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of deoxynucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisomerase II inhibitors and facilitates the incorporation of antimetabolites such as Ara-C, gemcitabine, and fludarabine into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of HDAC (histone deacetylase) inhibitors in vitro.

HU is the primary drug for improving control of sickle cell (HbS) disease in adults and for inducing fetal hemoglobin (HbF) in thalassemia HbC and HbC/S
patients. It reduces vaso-occlusive events, painful cries, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. The mechanism of stimulated HbF production is uncertain. HU stimulates NO production, causing nitrosylation of small-molecular-weight GTPases, a process that stimulates γ-globin production in erythroid precursors. Another property of HU that may be therapeutically relevant is its capacity to reduce L-selectin expression and thereby to reduce adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion. Tumor cells become resistant to HU through increased synthesis of the catalytic subunit of RNR, thereby restoring enzyme activity.

**ADME.** The oral bioavailability of HU is 80-100%; comparable plasma concentrations are seen after oral or intravenous dosing. HU disappears from plasma with a $t_{1/2}$ of 3.5-4.5 h. The drug readily crosses the blood-brain barrier; significant quantities appear in human breast milk. From 40-80% of the drug is recovered in the urine within 12 h after administration. It is advisable to modify initial doses for patients with renal dysfunction.

**Therapeutic Uses.** In cancer treatment, 2 dosage schedules for HU (Hydrea, Droxia, others), alone or in combination with other drugs, are most commonly used in a variety of solid tumors: (1) intermittent therapy with 80 mg/kg administered orally as a single dose every third day or (2) continuous therapy with 20-30 mg/kg administered as a single daily dose. In patients with essential thrombocythemia and in sickle cell disease, HU is given in a daily dose of 15 mg/kg, adjusting that dose upward or downward according to blood counts. The neutrophil count responds within 1-2 weeks to discontinuation of the drug. In treating subjects with sickle cell and related diseases, a neutrophil count of at least 2500 cells/mL should be maintained. Treatment typically is continued for 6 weeks to determine effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, myeloid metaplasia, and essential thrombocytosis, for controlling high platelet or white cell counts. Many of the myeloproliferative syndromes harbor activating
mutations of JAK2, a gene that is downregulated by HU. In essential thrombocythemia, it is the drug of choice for patients with a platelet count >1.5 million cells/mm$^3$ or with a history of arterial or venous thrombosis. In CML, HU has been largely replaced by imatinib. HU is a potent radiosensitizer as a consequence of its inhibition of RNR and has been incorporated into several treatment regimens with concurrent irradiation (i.e., cervical carcinoma, primary brain tumors, head and neck cancer, non–small-cell lung cancer).

**Clinical Toxicity.** Leukopenia, anemia, and occasionally thrombocytopenia are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, and mild dermatological reactions, and, more rarely, stomatitis, alopecia, and neurological manifestations. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in animals and should not be used in women with childbearing potential.

**DIFFERENTIATING AGENTS**

One of the hallmarks of malignant transformation is a block in differentiation. A number of chemical entities (vitamin D and its analogs, retinoids, benzamides and other inhibitors of histone deacetylase, various cytotoxics and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines.

**RETINOIDS**

The biology and pharmacology of retinoids are discussed in Chapter 65. The most important of these for cancer treatment is tretinoin (all-trans retinoic acid [ATRA]), which induces a high rate of complete remission in acute promyelocytic leukemia (APL) as a single agent and, in combination with anthracyclines, cures most patients with this disease.

TRETINOIN (ATRA)
**Mechanism of Action.** Under physiological conditions, the retinoic acid receptor-α (RAR-α) dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the complex and promotes differentiation of cells of multiple lineages. In APL cells, physiological concentrations of retinoid are inadequate to displace the repressor but pharmacological concentrations, are effective in activating the differentiation program and in promoting degradation of the PML–RAR-α fusion gene. The PML gene encodes a transcription factor (promyelocytic leukemia factor) important in inhibiting proliferation and promoting myeloid differentiation. The oncogenic PML–RAR-α gene produces a protein that binds retinoids with much decreased affinity, lacks PML regulatory function, and fails to upregulate transcription factors (C/EBP and PU.1) that promote myeloid differentiation. ATRA also binds and activates RAR-γ and thereby promotes stem-cell renewal, and this action may help restore normal bone marrow renewal. Resistance to ATRA arises by further mutation of the fusion gene, abolishing ATRA binding; by induction of the CYP26A1; or by loss of expression of the PML–RAR-α fusion gene.

**Clinical Pharmacology.** The dosing regimen of orally administered ATRA (VESANOID, others) is 45 mg/m²/day until 30 days after remission is achieved (maximum course of therapy is 90 days). ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. ATRA in combination with an anthracycline induces remission with ≥80% relapse-free long-term survival.

ATRA is cleared by a CYP3A4-mediated elimination with a $t_{1/2}$ of <1 h. Treatment with inducers of CYP3A4 leads to more rapid drug disappearance and resistance to ATRA. Inhibitors of CYPs, such as antifungal imidazoles, block ATRA degradation and may lead to hypercalcemia and renal failure, which responds to diuresis, bisphosphonates, and ATRA discontinuation. Corticosteroids and chemotherapy sharply decrease the occurrence of “retinoic acid syndrome,” which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. When used as a single agent for remission induction, especially in patients with >5000 leukemic cells/mm³ in the peripheral blood, ATRA induces an outpouring of cytokines and mature-appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface and
clog small vessels in the pulmonary circulation, leading to significant morbidity in 15-20% of patients. The syndrome of respiratory distress, pleural and pericardial effusions, and mental status changes may have a fatal outcome. Retinoids also cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, pseudotumor cerebri, hypercalcemia, and hyperlipidemia.

**ARSENIC TRIOXIDE (ATO)**

ATO is a highly effective treatment for relapsed APL, producing complete responses in >85% of such patients. The chemistry and toxicity of arsenic are considered in Chapter 67.

**Mechanism of Action.** The basis for ATO’s antitumor activity remains uncertain. APL cells have high levels of reactive oxygen species (ROS) and are quite sensitive to further ROS induction. ATO inhibits thioredoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate anti-apoptotic proteins such as bcl-2. ATO’s cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the PI3 kinase cell survival pathway, including Akt kinase, S6 kinase, and mammalian target of rapamycin (mTOR). ATO also induces differentiation of leukemic cell lines and in experimental and human leukemias.

**Clinical Pharmacology.** ATO (TRISENOX) is well absorbed orally but in cancer treatment is administered as a 2-h intravenous infusion in dosages of 0.15 mg/kg/day for up to 60 days, until remission is documented. The drug enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Multiple methylated metabolites form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

**Toxicity.** Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects, including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and light-headedness. Fewer than 10% of
patients experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO lead to full reversal of this syndrome. Lengthening of the QT interval on the electrocardiogram occurs in 40% of patients, but rarely do patients develop torsade de pointes. Simultaneous treatment with other QT-prolonging drugs should be avoided. Monitoring of serum electrolytes and repletion of serum K+ in patients with hypokalemia are precautionary measures in patients receiving ATO therapy. In patients exhibiting a significantly prolonged QT (>470 msec), treatment should be suspended, K+ supplemented, and therapy resumed only if the QT returns to normal.

**HISTONE DEACETYLASE INHIBITORS**

**VORINOSTAT**

Vorinostat (ZOLINZA), also known as *suberoylanilide hydroxamic acid* (SAHA), is unique as an epigenetic modifier that directly affects histone function.

*Mechanism of Action.* Acetylation of lysine residues on histones increases the spatial distance between DNA strands and the protein core, allowing access for transcription factor complexes, and enhancing transcriptional activity. Acetyl groups are added by histone acetyltransferases (HACs) and removed by histone deacetylases (HDACs). HDAC inhibitors such as vorinostat increase histone acetylation and thus enhance gene transcription. Many nonhistone proteins also are subject to lysine acetylation and thus are affected by treatment with HDAC inhibitors; the role of their acetylation status in the antitumor action of HDAC inhibitors is unclear.

Vorinostat is a hydroxamic acid modeled after hybrid polar compounds that
cause differentiation of malignant cells in vitro, as do other classes of compounds with HDAC-inhibitory activity. These compounds bind to a critical Zn$^{++}$ ion in the active site of HDAC enzymes. An important distinction between vorinostat and other HDAC inhibitors is that vorinostat and the hydroxymates are pan-HDAC inhibitors, whereas other compounds have selectivity for HDAC isoenzyme subsets. HDAC inhibitors induce cell-cycle arrest, differentiation, and apoptosis of cancer cells; nonmalignant cells are relatively resistant to these effects. These agents increase transcription of cell-cycle regulators, affect levels of nuclear transcription factors, and induce pro-apoptotic genes. HDAC inhibition directly blocks function of the chaperone HSP90 and stabilizes the tumor suppressor p53.

**ADME.** Vorinostat is administered as a once-daily oral dose of 400 mg. It is inactivated by glucuronidation of the hydroxyl amine group, followed by hydrolysis of the terminal carboxamide bond and further oxidation of the aliphatic side chain. The metabolites are pharmacologically inactive. The terminal $t_{1/2}$ in plasma is 2 h. Histones remain hyperacetylated up to 10 h after an oral dose of vorinostat, suggesting that its effects persist beyond its measurable presence in the plasma.

**Therapeutic Uses.** In patients with refractory cutaneous T-cell lymphoma (CTCL), vorinostat produces an overall response rate of 30%, with a median time to progression of 5 months. Vorinostat and other HDAC inhibitors, including romidepsin (depsipeptide; FK228) and MGCD 0103, have shown activity in CTCL, other B- and T-cell lymphomas, and myeloid leukemia.

**Toxicity.** The most common side effects include fatigue, nausea, diarrhea, and thrombocytopenia. Deep venous thrombosis and pulmonary embolism are infrequent but serious adverse events. Caution is advised in patients with underlying cardiac abnormalities, and careful monitoring of the QTc interval and electrolytes (K$^+$, Mg$^{++}$) is necessary.
Many new agents are available to block the fundamental mutations that cause specific cancers: aberrant growth factor receptors, dysregulated intracellular signaling pathways, defective DNA repair and apoptosis, and tumor angiogenesis. The primary tools for inhibiting these targets are monoclonal antibodies that attack cell surface receptors and antigens, and synthetic small molecules that enter cells and engage critical enzymes. These 2 classes of drugs have very different pharmacological properties.

Monoclonal antibodies kill tumor cells by blocking cell surface receptor function and by recruiting immune cells and complement to the antigen–antibody complex. They may be armed to carry toxins or radionuclides to the cells of interest, thereby enhancing their cytotoxic effects. They generally are specific for a single receptor, have a long plasma $t_{1/2}$, and require only intermittent administration. Small molecules may attack the same targets and pathways as the monoclonals, but may also exert their effect by entering cells and inhibiting enzymatic functions (usually tyrosine kinase reactions). The small molecules often inhibit multiple enzymatic sites, have a broad spectrum of target kinases, and tend to be substrates of hepatic CYPs with a $t_{1/2}$ of 12-24 h, and thus require daily oral administration.

These 2 drug classes, when targeted against the same pathway, may have significantly different spectra of antitumor activity. Thus, monoclonal antibodies to the epidermal growth factor receptor (EGFR) are effective in the treatment of head and neck and colon cancers, while small molecules, such as erlotinib and gefitinib, attack the intracellular tyrosine kinase function of the same receptor and have a different spectrum of antitumor activity (non–small cell lung cancer). The specific drug target is of central importance in cancer chemotherapy and forms the organizational basis for the discussion below.
PROTEIN TYROSINE KINASE INHIBITORS

There are 3 basic types of protein kinases (see Chapter 3):

- Kinases that specifically phosphorylate tyrosine residues
- Kinases that phosphorylate serine and threonine residues
- Kinases with activity toward all 3 residues

Tyrosine kinases can be further subdivided into those with an extracellular ligand-binding domain (receptor tyrosine kinases, associated with growth factor receptors, Figure 62–1) and intracellular enzymes (nonreceptor tyrosine kinases, e.g., src, abl, jak, fak, srm). In a number of human malignancies, mutations that constitutively activate protein tyrosine kinases are implicated in malignant transformation.

![Figure 62–1 Growth factor signaling. Binding of agonist ligands to growth factor receptors (monospanning membrane proteins) causes receptor dimerization and activation of cytosolic protein kinase domains, leading to activation of multiple signaling pathways. Shown here are the RAS/MAPK/ERK, PI3K, and SMAD pathways, each of which is activated by receptors or cross-talk from adjacent pathways. Their signals regulate](image-url)

**INHIBITORS OF THE BCR-ABL KINASE: IMATINIB, DASATINIB, AND NILOTINIB**

Imatinib mesylate (STI 571, GLEEVEC, GLIVEC) targets the BCR-ABL tyrosine kinase, which underlies chronic myelogenous leukemia (CML). A single molecular event, in this case the 9:22 translocation, leads to expression of the Abelson proto-oncogene kinase ABL fused to BCR (breakpoint cluster region), yielding a constitutively activated protein kinase, BCR-ABL, and then the malignant phenotype.

Imatinib and the related compounds dasatinib and nilotinib induce clinical and molecular remissions in >90% of CML patients in the chronic phase of disease. Imatinib treats other tumors that carry related tyrosine kinase mutations, including GI stromal tumors (driven by c-KIT mutation), and hypereosinophilia syndrome, chronic myelomonocytic leukemia, and dermatofibrosarcoma protuberans (all driven by mutations that activate the PDGF receptor [PDGFR]).

**CHARACTERISTICS AND MECHANISM OF ACTION.** Imatinib was identified through high-throughput screening against the BCR-ABL kinase. Dasatinib (BMS-354825, SPRYCEL), a second-generation BCR-ABL inhibitor, inhibits the Src kinase, and unlike imatinib, it binds both the open and closed configurations of the BCR-ABL kinase. Nilotinib (AMN107, TASIGNA) was designed to have increased potency and specificity compared to imatinib. Its structure overcomes mutations that cause imatinib resistance. Imatinib and nilotinib bind to a segment of the kinase domain that fixes the enzyme in a closed or nonfunctional state, in which the protein is unable to bind its substrate/phosphate donor, ATP. The 3 BCR-ABL kinase inhibitors differ in their potency of inhibition, their binding specificities, and their susceptibility to resistance mutations in the target enzyme. Dasatinib [(IC\textsubscript{50})=<1 nM] and nilotinib [(IC\textsubscript{50})=<20 nM] inhibit BCR-ABL kinase more potently than does imatinib [(IC\textsubscript{50})=100 nM].

**MECHANISMS OF RESISTANCE.** Resistance to the tyrosine kinase inhibitors arises from point mutations in 3 separate segments of the kinase
domain (see Figure 62–1 in the 12th edition of the parent text). The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate and is enzymatically active. Nilotinib retains inhibitory activity in the presence of most point mutations that confer resistance to imatinib. Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as at amino acids 351 and 355, confer low levels of resistance to imatinib, possibly explaining the clinical response of some resistant patients to dose escalation of imatinib.

Molecular studies have detected resistance-mediating kinase mutations prior to initiation of therapy, particularly in patients with Ph+ acute lymphoblastic leukemia (ALL) or CML in blastic crisis. This finding supports the hypothesis that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mechanisms other than BCR-ABL kinase mutation play a minor role in resistance to imatinib. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment. The multidrug resistant (MDR) gene confers resistance experimentally but has not been implicated in clinical resistance. Philadelphia chromosome-negative clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML and may progress to myelodysplasia (MDS) and to acute myelocytic leukemia (AML). Their origin is unclear.

**ADME**

**Imatinib.** Imatinib is well absorbed after oral administration and reaches maximal plasma concentrations within 2-4 h. The elimination $t_{1/2}$ of imatinib and its major active metabolite, the N-desmethyl derivative, are ~18 and 40 h, respectively. Food does not change the pharmacokinetic profile. Doses >300 mg/day achieve trough levels of 1 <M, which correspond to in vitro levels
required to kill BCR-ABL–expressing cells. In the treatment of GI stromal cell tumors (GISTs), higher doses (600 mg/day) may improve response rates. CYP3A4 is the major metabolizer of imatinib; thus, drugs that induce or interact with CYP3A4 can alter the pharmacokinetics of imatinib. Coadministration of imatinib and rifampin, an inducer of CYP3A4, lowers the plasma imatinib AUC by 70%. Imatinib, as a competitive CYP3A4 substrate, inhibits the metabolism of simvastatin and increases its plasma AUC by 3.5-fold.

**Dasatinib.** Oral dasatinib is well absorbed; its bioavailability is significantly reduced at neutral gastric pH (i.e., after antacids and H2 blockers) but is unaffected by food. The plasma \( t_{1/2} \) of dasatinib is 3-5 h. Dasatinib exhibits dose proportional increases in AUC, and its clearance is constant over the dose range of 15-240 mg/day. Dasatinib doses of 70 mg twice a day, 100 mg daily, and 140 mg daily are equally effective in patients with CML, although the 100-mg daily dose improves progression-free survival. Dasatinib is metabolized primarily by CYP3A4, with minor contributions by FMO3 and UGT. Plasma concentrations of dasatinib are affected by inducers and inhibitors of CYP3A4 in a similar fashion to imatinib.

**Nilotinib.** Approximately 30% of an oral dose of nilotinib (400 mg 2 times daily) is absorbed after administration, with peak concentrations in plasma 3 h after dosing. Unlike the other BCR-ABL inhibitors, nilotinib’s bioavailability increases significantly in the presence of food. The drug has a plasma \( t_{1/2} \) 17 h, and plasma concentrations reach a steady state only after 8 days of daily dosing. Nilotinib is metabolized by CYP3A4, with predictable alteration by inducers, inhibitors, and competitors of CYP3A4. Nilotinib is a substrate and inhibitor of P-glycoprotein.

**THERAPEUTIC USES.** These protein tyrosine kinase inhibitors have efficacy in diseases in which the ABL, kit, or PDGFR have dominant roles in driving the proliferation of the tumor, reflecting the presence of a mutation that results in constitutive activation of the kinase. Imatinib shows remarkable therapeutic benefits in patients with chronic-phase CML (BCR-ABL), GIST (kit mutation positive), chronic myelomonocytic leukemia (EVT6-PDGFR translocation), hypereosinophilia syndrome (FIP1L1-PDGFR), and dermatofibrosarcoma
protuberans (constitutive production of the ligand for PDGFR). It is the agent of choice for GIST patients with metastatic disease and as adjuvant therapy of *c-kit*-positive GIST. The currently recommended dose of imatinib is 400-600 mg/day. Dasatinib is approved for patients with CML resistant or intolerant to imatinib in both chronic (100 mg/day) and advanced phases of disease (70 mg twice daily), and for use combined with cytotoxic chemotherapy in patients with Ph+ ALL who are resistant or intolerant to prior therapies. Nilotinib is approved for patients with CML resistant to or intolerant of prior imatinib therapy.

**TOXICITY.** Imatinib, dasatinib, and nilotinib cause GI symptoms (diarrhea, nausea, and vomiting) that are usually readily controlled. All 3 drugs promote fluid retention, edema, and peri-orbital swelling. Dasatinib may cause pleural effusions. Nilotinib may prolong the QT interval. Myelosuppression occurs infrequently but may require transfusion support, dose reduction, or discontinuation of the drug. These drugs can be associated with hepatotoxicity. Most nonhematological adverse reactions are self-limited and respond to dose adjustments. After the adverse reactions have resolved, the drug may be reinitiated and titrated back to effective doses.

**EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS**

The EGFR belongs to the ErbB family of transmembrane receptor tyrosine kinases. EGFR, also known as ErbB1 or HER1, is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues in the C-terminal domain. Recognition of the phosphotyrosines by other proteins initiates protein-protein interactions that result in stimulation of signaling pathways including MAPK, PI3K/Akt, and STAT pathways (see Figure 62–1). In epithelial cancers, overexpression and mutational activation of the EGFR are a common finding and create a dependence on EGFR signaling in these tumors.
Two separate classes of drugs that target the EGFR pathway are important agents in the therapy of solid tumors. The EGFR tyrosine kinase inhibitors erlotinib and gefitinib bind to the kinase domain and block the enzymatic function of EGFR. The monoclonal antibodies cetuximab and panitumumab bind specifically to the extracellular domain of EGFR and inhibit EGFR-dependent signaling.

**GEFITINIB**

*Mechanism of Action.* Gefitinib inhibits the EGFR tyrosine kinase by competitive blockade of ATP binding. Gefitinib has an IC$_{50}$ of 20-80 nM for the EGFR tyrosine kinase but is significantly less potent against HER2 (ErbB2/neu). Gefitinib has antitumor activity in human xenograft tumors that exhibit high levels of EGFR expression.

**ADME.** Oral bioavailability is ~60%; peak plasma concentrations are achieved within 3-7 h. Absorption of gefitinib is not significantly altered by food but is reduced by drugs that cause elevations in gastric pH. Metabolism of gefitinib is predominantly via CYP3A4, with a terminal $t_{1/2}$ of 41 h. Inducers of CYP3A4 activity decrease gefitinib plasma concentrations and efficacy; conversely, CYP3A4 inhibitors increase plasma concentrations.

**Therapeutic Uses.** Gefitinib initially was approved for the third-line treatment of patients with non–small cell lung cancer. However, a large clinical trial failed to show an effect on survival, leading the FDA to restrict its use to patients who have previously received clinical benefit from the drug. Two large trials have failed to demonstrate a benefit of gefitinib in combination with chemotherapy: patients who were nonsmokers, Asians, or women were most likely to respond to gefitinib. Tumors from these patients frequently have characteristic activating mutations in *EGFR*. The standard dose is 250 mg/day.

**Adverse Effects and Drug Interactions.** Diarrhea and pustular/papular rash occur in ~50% of patients. Other side effects include dry skin, nausea, vomiting, pruritus, anorexia, and fatigue. Most adverse effects occur within the first month of therapy and are manageable with medications and dose reductions. Asymptomatic
increases in liver transaminases may necessitate dose reduction or discontinuation of therapy. Interstitial lung disease occurs in <2% of patients and may have a fatal outcome. Inducers and inhibitors of CYP3A4 will alter plasma concentrations. Patients using warfarin should be monitored closely for elevation of the international normalized ratio (INR) while taking gefitinib.

**ERLOTINIB**

*Mechanism of Action.* Erlotinib (TARCEVA) is a potent inhibitor of the EGFR tyrosine kinase, competitively inhibiting ATP binding at the active site of the kinase. Erlotinib has an IC$_{50}$ of 2 nM for the EGFR kinase. Tumors harboring $k$-$ras$ mutations and *EML4-ALK* translocations do not respond to EGFR kinase inhibitors.

*ADME.* Erlotinib is ~60% absorbed after oral administration but should not be taken with food, which increases its bioavailability to ~100%. Peak plasma levels occur after 4 h. Erlotinib has a $t_{1/2}$ of 36 h and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1. The standard daily dose of erlotinib results in a plasma AUC ~10-fold greater than the AUC of gefitinib.

*Therapeutic Uses.* Erlotinib is approved for second-line treatment of patients with locally advanced or metastatic non–small cell lung cancer. Erlotinib also is approved for first-line treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer in combination with gemcitabine. The recommended dose of erlotinib in non–small cell lung cancer is a 150-mg tablet daily. In pancreatic cancer, the dose is a 100-mg tablet daily, taken at least 1 h before or 2 h after a meal.

*Adverse Effects and Drug Interactions.* The most common adverse reactions are diarrhea, an acneform rash, anorexia, and fatigue. Serious or fatal interstitial lung disease occurs with a frequency of 0.7-2.5%. Serious or fatal hepatic failure due to erlotinib has been reported, particularly in patients with baseline hepatic dysfunction. Other rare but serious toxicities include GI perforation, renal failure, arterial thrombosis, microangiopathic hemolytic anemia, hand-foot skin reaction, and corneal perforation or ulceration. Erlotinib therapy may cause rare
cases of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Concurrent use of proton-pump inhibitors decreases the bioavailability of erlotinib by 50%. Plasma levels can vary due to drug interactions with inducers or inhibitors of CYP3A4. Patients using warfarin may experience elevations of the INR while taking erlotinib. Smoking accelerates metabolic clearance of erlotinib and may decrease its antitumor effects.

**RESISTANCE TO GEFITINIB AND ERLOTINIB**

Patients with non–small cell lung cancer who initially respond to erlotinib or gefitinib have tumors that are dependent on the EGFR signaling pathway. Tumors containing mutations in *EGFR* initially respond to erlotinib and gefitinib but eventually progress. A secondary mutation in the *EGFR* gatekeeper residue, T790M, prevents binding of drug to the kinase domain and confers resistance. Other potential mechanisms of resistance include activation of downstream mediators, efflux of drug, and altered receptor trafficking. Therapy directed at the EGFR may delay disease progression in patients with non–small cell lung cancers that lack activating *EGFR* mutations, although response rates approach zero in these patients.

**CETUXIMAB**

Cetuximab (ERBITUX) is a recombinant chimeric human/mouse immunoglobulin G1 (IgG1) antibody that binds to the extracellular domain of EGFR. Such antibodies, although sharing the same target with erlotinib and gefitinib and having a similar side effect profile, have a different spectrum of antitumor activity.

**Mechanism of Action.** Cetuximab binds specifically to the extracellular domain of EGFR and prevents ligand-dependent signaling and receptor dimerization, thereby blocking cell growth and survival signals. Cetuximab also may mediate antibody-dependent cellular cytotoxicity against tumor cells.

**ADME.** Cetuximab exhibits nonlinear pharmacokinetics. Following intravenous
administration, steady-state levels are achieved by the third weekly infusion. Therapeutic doses that saturate total body receptor pools of EGFR follow zero-order kinetics for elimination. Clearance occurs via EGFR binding and internalization and by degradation in the reticuloendothelial system.

**Therapeutic Uses**

**Head and Neck Cancer.** Cetuximab is used in combination with radiation therapy for locally or regionally advanced squamous cell carcinoma of the head and neck (HNSCC). It also is indicated in monotherapy for patients with metastatic or recurrent HNSCC who fail platinum-based chemotherapy. It is a useful agent in combination with cisplatin-based chemotherapy.

**Metastatic Colon Cancer.** Cetuximab is approved as a single agent for the treatment of EGFR-positive metastatic colorectal cancer; cetuximab is used in patients who cannot tolerate irinotecan-based therapy and in combination with irinotecan for patients refractory to oxaliplatin, irinotecan, and 5-fluorouracil (5-FU). In the first-line setting, cetuximab may improve survival in combination with 5-FU/leucovorin and irinotecan or oxaliplatin. About 40-50% of colorectal tumors carry mutations in the k-ras oncogene and are resistant to the effects of cetuximab. Cetuximab enhances the effectiveness of chemotherapy in patients with k-ras mutant tumors but not k-ras wild-type tumors. The standard dose of cetuximab is a single loading dose of 400 mg/m² intravenously, followed by weekly doses of 250 mg/m² intravenously for the duration of treatment.

**Adverse Effects.** Side effects include an acneform rash (in the majority of patients), pruritus, nail changes, headache, and diarrhea. Rare but serious adverse effects include cardiopulmonary arrest, interstitial lung disease, and hypomagnesemia. In addition, patients can develop anaphylactoid reactions during infusion, which may be related to preexisting IgE antibodies that are more prevalent in patients from the southern U.S.

**PANITUMUMAB**

Panitumumab (Vectibix) is a recombinant, fully humanized IgG_{2k} antibody that binds specifically to the extracellular domain of EGFR. Unlike cetuximab, it does not mediate antibody-dependent cell-mediated cytotoxicity.
Panitumumab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third infusion. The mean $t_{1/2}$ is 7.5 days. Panitumumab improves progression-free survival in patients with metastatic colorectal carcinoma. The dose of panitumumab is 6 mg/kg intravenously given once every 2 weeks. The adverse effects with panitumumab are similar to cetuximab and include rash and dermatological toxicity, severe infusion reactions, pulmonary fibrosis, and electrolyte abnormalities.

**HER2/NEU INHIBITORS**

Both antibodies (trastuzumab, pertuzumab) and small molecules (lapatinib et al.) have striking antitumor effects in patients with HER2-positive breast cancer, and have become essential therapeutic agents in combination with cytotoxic chemotherapy for this aggressive malignancy.

**TRASTUZUMAB.** Trastuzumab (HERCEPTIN) is a humanized monoclonal antibody that binds to the external domain of HER2/neu (ErbB2).

Thirty percent of breast cancers overexpress this receptor due to gene amplification on chromosome 17. Amplification of the receptor is associated with lower response rates to hormonal therapies and to most cytotoxic drugs, with the exception of anthracyclines. Patients with HER2/neu-amplified tumors have higher recurrence rates after standard adjuvant therapy and poorer overall survival. The internal domain of the HER2/neu glycoprotein encodes a tyrosine kinase that activates downstream signal, enhances metastatic potential, and inhibits apoptosis. Trastuzumab exerts its antitumor effects through: inhibition of homo- or heterodimerization of receptor, thereby preventing receptor kinase activation and downstream signaling; initiation of Fcγ-receptor-mediated antibody-dependent cellular cytotoxicity; and blockade of the angiogenetic effects of HER2 signaling.

**Therapeutic Uses.** Trastuzumab is approved for HER2/neu-overexpressing metastatic breast cancer, in combination with paclitaxel as initial treatment or as monotherapy following chemotherapy relapse. Trastuzumab synergizes with
other cytotoxic agents in HER2/neu-overexpressing cancers.

**Pharmacokinetics and Toxicity.** Trastuzumab has dose-dependent pharmacokinetics with a mean $t_{1/2}$ of 5.8 days on the 2-mg/kg maintenance dose. Steady-state levels are achieved between 16 and 32 weeks. The infusional effects of trastuzumab are typical for monoclonal antibodies and include fever, chills, nausea, dyspnea, and rashes. Premedication with diphenhydramine and acetaminophen is indicated. The most serious toxicity of trastuzumab is cardiac failure; reasons for cardiotoxicity are poorly understood. Before initializing therapy, baseline electrocardiogram and cardiac ejection fraction measurement should be obtained to rule out underlying heart disease, and patients deserve careful clinical follow-up thereafter for signs or symptoms of congestive heart failure. When trastuzumab is used as a single agent, $<5\%$ of patients will experience a decrease in left-ventricular ejection fraction, and $1\%$ will have clinical signs of congestive failure. Left-ventricular dysfunction occurs in up to $20\%$ of patients who receive the antibody in combination with doxorubicin and cyclophosphamide. The risk of cardiac toxicity is greatly reduced with taxane–trastuzumab combinations.

**LAPATINIB.** Lapatinib and other pan-HER inhibitors block both ErbB1 and ErbB2 and bind to an internal site on the receptor (usually the ATP-binding pocket), compared to the external binding site of trastuzumab. Lapatinib also inhibits a truncated form of the HER2 receptor that lacks a trastuzumab-binding domain, differences that may account for the activity of lapatinib in trastuzumab-resistant patients.

**Therapeutic Uses.** Lapatinib (TYKERB) is approved for HER2-amplified, trastuzumab-refractory breast cancer, in combination with the fluoropyrimidine analog, capecitabine. As a small molecule, lapatinib crosses the blood-brain barrier more readily than inhibitor antibodies and has produced anecdotal responses in patients with brain metastases in phase III trial.

**Pharmacokinetics and Toxicity.** The drug is administered orally, 1250 mg/day. It is metabolized by CYP3A4 to inactive products and oxidized to an intermediate that has activity against ErbB1 but not ErbB2. The plasma $t_{1/2}$ is 14 h. Concurrent administration of inducers and inhibitors of CYP3A4 may necessitate adjustment of the dose. Lapatinib toxicities include mild diarrhea, cramping, and exacerbation of gastro-esophageal reflux. When lapatinib is
combined with capecitabine, diarrhea becomes a significant side effect (33%). Lapatinib causes an acneform rash in one-third of patients that may be controlled with topical benzoyl peroxide gel. Lapatinib has no clear signal of cardiac toxicity; nonetheless, because it targets ErbB2, lapatinib should be used with caution in combination with other cardiotoxic drugs and with careful surveillance in patients with heart disease.

**INHIBITORS OF ANGIOGENESIS**

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells. Angiogenic factors secreted by tumors include VEGF (*vascular endothelial growth factor*), FGF (*fibroblast growth factor*), TGF-β (*transforming growth factor β*), and PDGF (*platelet-derived growth factor*). Multiple tumor types overexpress these angiogenic factors. Tumor secretion of pro-angiogenic factors turns on an “angiogenic switch,” a process essential to tumor growth and metastasis. In multiple experimental models, blockade of these pro-angiogenic molecules halts tumor growth, and in human cancers, anti-angiogenic drugs also have inhibitory effects.

Leaky capillaries within tumors have increased permeability and cause an increase in tumor interstitial pressure that inhibits blood flow, decreases oxygenation, and prevents drug delivery within the tumor. Antibodies directed at the primary angiogenic factor, VEGF, “normalize” interstitial pressure, improve blood flow, and enhance the ability of chemotherapeutic agents to reach the tumor. Hence, an additional benefit of anti-angiogenic molecules may be their ability to increase the delivery of chemotherapy to the tumor. This hypothesis seems to be validated in the synergy observed when cytotoxic chemotherapy is combined with anti-VEGF antibodies.

VEGF initiates endothelial cell proliferation when it binds to a member of the VEGF receptor (VEGFR) family, a group of highly homologous receptors with intracellular tyrosine kinase domains that includes VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4). The binding of VEGF to its receptor activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and anti-
apoptotic signaling pathways. Antibodies targeting VEGF, such as bevacizumab, sterically hinder the interaction of VEGF with its receptor. Aflibercept (ZALITRAP), acts as a VEGF Trap; it is a recombinant molecule that uses the VEGFR1-binding domain to sequester VEGF and acts as a “soluble decoy receptor” for VEGF. Three small molecules (pazopanib, sorafenib, and sunitinib) that inhibit the kinase function of VEGFR-2 have been approved for clinical use. Although bevacizumab and the small molecules share a similar spectrum of toxicities, they have different spectra of clinical activity and pharmacokinetics.

BEVACIZUMAB

Bevacizumab (AVASTIN), a humanized antibody directed against VEGF-A, delays progression of renal-cell cancer, and, in combination with cytotoxic chemotherapy, effectively treats lung, colorectal, and breast cancers.

ADME. Bevacizumab is administered intravenously as a 30- to 90-min infusion. In metastatic colon cancer, in conjunction with combination chemotherapy, the dose of bevacizumab is 5 mg/kg every 2 weeks. In metastatic non–small cell lung cancer, doses of 15 mg/kg are given every 3 weeks with chemotherapy. For metastatic breast cancer, patients receive 10 mg/kg of bevacizumab every 2 weeks in combination with paclitaxel or docetaxel. The antibody has a plasma $t_{1/2}$ of 4 weeks.

Therapeutic Uses. In clear-cell renal-cell carcinoma, a cancer notoriously resistant to traditional chemotherapeutic agents, single-agent bevacizumab increases survival by 3 months. Bevacizumab is approved in combination with interferon-α for the treatment of metastatic renal-cell carcinoma. Bevacizumab is approved as a single agent following prior therapy for glioblastoma. In all other cancers, bevacizumab has little apparent single-agent activity but improves survival in epithelial cancers in combination with standard chemotherapeutic agents. Bevacizumab with carboplatin and paclitaxel increases survival in non–small lung cancer by 2 months. Likewise, bevacizumab combined with FOLFOX (5-FU, leucovorin, and oxaliplatin) or FOLFIRI (5-FU, leucovorin, and irinotecan) improves survival by 5 months in metastatic colon cancer. Finally, the combination of bevacizumab with docetaxel increases progression-
free survival in patients with metastatic breast cancer.

A slightly altered version of bevacizumab, ranibizumab (Lucentis), in which the Fc region has been deleted, effectively treats wet macular degeneration. Bevacizumab restores hearing in patients with progressive deafness due to neurofibromatosis type 2–related tumors.

**Toxicity.** Bevacizumab causes a wide range of class-related adverse effects. A prominent concern is the potential for vessel injury and bleeding in patients with squamous-cell lung cancer. Bevacizumab is contraindicated for patients who have a history of hemoptysis, brain metastasis, or a bleeding diathesis, but in appropriately selected patients, the rate of life-threatening pulmonary hemorrhage is <2%. The most dreaded vascular toxicity of anti-angiogenic agents is an arterial thromboembolic event (i.e., stroke or myocardial infarction). The rate of arterial thromboembolic events in patients receiving bevacizumab-containing regimens is 3.8% compared to the control rate of 1.7%. To reduce the risk of arterial thromboembolic events, clinicians should evaluate a patient’s risk factors (age >65 years, a past history of arterial thromboembolic events) before starting the drug.

Other toxicities characteristic of anti-angiogenic drugs include hypertension and proteinuria. A majority of patients receiving the drug require antihypertensive therapy, particularly those receiving higher doses and more prolonged treatment. Bevacizumab is rarely associated with congestive heart failure, probably secondary to hypertension, and with reversible posterior leukoencephalopathy in patients with poorly controlled hypertension. GI perforation, a potentially life-threatening complication, has been observed (up to 11%) in patients with ovarian cancer. In colon cancer patients, colonic perforation occurs infrequently during bevacizumab treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment. The rate of colon perforation is <1% in breast and lung cancer patients. Colon cancer surgery patients on bevacizumab have a higher rate (13% vs. 3.4%) of serious wound healing complications. Because of the long t₁/₂ of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should be not resumed for at least 4 weeks after surgery.
SUNITINIB

Sunitinib (SUTENT) competitively inhibits the binding of ATP to the tyrosine kinase domain on the VEGF receptor-2, a mechanism it shares with sorafenib. Sunitinib also inhibits other protein tyrosine kinases at concentrations of 5-100 nM.

Pharmacokinetics. Sunitinib is administered orally in doses of 50 mg once a day. The typical cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off. The dosage and schedule of sunitinib can be increased or decreased according to toxicity (hypertension, fatigue). Dosages <25 mg/day typically are ineffective. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the $t_1/2$ of which is 80-110 h; steady-state levels of the metabolite are reached after ~2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

Therapeutic Uses. Sunitinib has activity in metastatic renal-cell cancer, producing a higher response rate (31%) and a longer progression-free survival than any other approved anti-angiogenic drug. Sunitinib also is approved for treatment of advanced renal-cell carcinoma, GIST that have developed resistance to imatinib as a consequence of c-KIT mutations, and pancreatic neuroendocrine tumors. Specific c-KIT mutations correlate with degree of response to sunitinib (e.g., patients with c-KIT exon 9 mutations have a response rate of 37%; patients with c-KIT exon 11 mutations have only a 5% response rate).

Toxicity. The main toxicities of sunitinib are shared by all anti-angiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multi-targeted tyrosine kinase inhibitor, it has a broader side-effect profile than bevacizumab. Fatigue affects 50-70% of patients and may be disabling. Hypothyroidism occurs in 40-60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils <1000/mL) develop in 10% of patients. Less common side effects include congestive heart failure (usually in association with hypertension) and hand-foot syndrome. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.
SORAFENIB

Sorafenib (NEXAVAR), like sunitinib, targets multiple protein tyrosine kinases and inhibits their catalytic activities at concentrations of 20-90 nM. Sorafenib is the only drug currently approved for treatment of hepatocellular carcinoma. Sorafenib also is approved in metastatic renal-cell cancer, for which sunitinib generally is the preferred first-line therapy.

ADME. Sorafenib is given orally, beginning with 200 mg once a day and increasing to 400 mg twice a day as tolerated. Sorafenib is given every day without treatment breaks. Sorafenib is metabolized to inactive products by CYP3A4 with a $t_{1/2}$ of 20-27 h; with repeated administration, steady-state concentrations are reached within 1 week.

Adverse Effects. Sorafenib patients can experience the vascular toxicities seen with other anti-angiogenic medications. More common adverse effects include fatigue, nausea, diarrhea, anorexia, and rash; uncommonly, bone marrow suppression and GI perforation.

IMMUNOMODULATORS (IMiDs)

Among agents with anti-angiogenic activity, the immunomodulatory analogs (IMiDs) thalidomide and lenalidomide have a most unusual history and a multiplicity of biological and immunological effects. Thalidomide originally was used for the treatment of pregnancy-associated morning sickness but was withdrawn from the market due to teratogenicity and dysmelia (stunted limb growth). It re-entered clinical practice for treatment of erythema nodosum leprosum (see Chapter 56). Further research revealed its anti-angiogenic and immunomodulatory effects. At least 4 distinct mechanisms have been proposed to explain the antitumor activity of IMiDs as summarized by Figure 62–2 and enumerated in its legend.
**Figure 62–2** Schematic overview of proposed mechanisms of antimyeloma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in blue boxes. The proposed sites of action for thalidomide (letters inside red and green circles) are hypothesized to also be operative for thalidomide derivatives. **A.** Direct anti–multiple myeloma (MM) effect on tumor cells, including $G_1$ growth arrest and/or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the anti-apoptotic effect of BCL-2 family members, blocking NF-κB signaling, and inhibition of the production of interleukin-6 (IL-6). **B.** Inhibition of MM-cell adhesion to bone marrow stromal cells partially due to the reduction of IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and interferon-γ (IFN-γ), that increase the number and cytotoxic functionality of natural killer (NK) cells. VEGF, vascular endothelial growth factor.

Both thalidomide and lenalidomide possess potent activity in newly diagnosed and heavily pretreated relapsed/refractory multiple myeloma (MM) patients.
Lenalidomide also is approved for its activity in the 5q–subset of MDS. A specific gene array profile identifies MDS patients who lack the 5q–abnormality but respond to lenalidomide.

THALIDOMIDE

**ADME.** Thalidomide (Thalomid) exists at physiological pH as a racemic mixture of cell-permeable and rapidly interconverting non-polar S(–) and R(+) isomers. The R-enantiomer is associated with the teratogenic and biological activities, while the S accounts for the sedative properties of thalidomide. Thalidomide is given in dosages of 200-1200 mg/day. In treating MM, doses usually are escalated by 200 mg/day every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) supervene. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. Thalidomide absorption from the GI tract is slow and highly variable. It distributes throughout most tissues and organs, without significant binding to plasma proteins. The enantiomers are eliminated with a $t_{1/2} \approx 6$ h, mainly due to spontaneous hydrolysis in all body fluids; the S-enantiomer is cleared more rapidly than the R-enantiomer. Thalidomide and its metabolites are excreted in the urine, while the non-absorbed portion of the drug is excreted unchanged in feces. The inactive hydrolysis products undergo CYP-mediated metabolism. Longer plasma $t_{1/2}$ is reported at highest doses (1200 mg daily). No dose adjustment is necessary in the presence of renal failure.

Thalidomide enhances the sedative effects of barbiturates and alcohol and the catatonic effects of chlorpromazine and reserpine. Conversely, CNS stimulants (such as methamphetamine and methylphenidate) counteract the depressant effects of thalidomide.

LENALIDOMIDE

Lenalidomide (Revlimid) constitutes the lead compound of immunomodulatory thalidomide derivatives. Pharmacological properties include: direct suppression of the tumor cell growth in culture, T-cell and NK-cell activation, suppression of TNF-α and other cytokines, anti-angiogenesis, and promotion of hematopoietic stem
cell differentiation.

**ADME.** The standard dosage of lenalidomide is 25 mg/day for 21 days of a 28-day cycle. The drug is rapidly absorbed following oral administration, reaching peak plasma levels within 1.5 h. The $t_{1/2}$ of parent drug in plasma is 9 h. Approximately 70% of the orally administered dose of lenalidomide is excreted intact by the kidney. Dose adjustments to 10 mg/day for creatinine clearance of 30-50 mL/h and to the same dose every 2 days for creatinine clearance <30 mL/h are recommended for patients with renal failure.

**Therapeutic Use.** Lenalidomide exhibits potent antitumor activity in MM, MDS, and chronic lymphocytic leukemia (CLL); this agent causes fewer adverse side effects and lacks the teratogenicity of thalidomide.

**ADVERSE EFFECTS OF THALIDOMIDE AND LENALIDOMIDE**

Thalidomide is well tolerated at doses <200 mg daily. Common adverse effects are sedation and constipation; the most serious one is peripheral sensory neuropathy, which occurs in 10-30% of patients with MM or other malignancies in a dose- and time-dependent manner. Thalidomide-related neuropathy is an asymmetrical, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. Although symptoms improve upon drug discontinuation, long-standing sensory loss may not reverse. Particular caution should apply in patients with pre-existing neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, bortezomib).

Adverse effects of lenalidomide are much less severe; it causes little sedation, constipation, or neuropathy. The drug depresses bone marrow function and is associated with significant leukopenia (20% of patients). Hepatotoxicity and renal dysfunction are rare. In some CLL patients, lenalidomide causes dramatic lymph node swelling and tumor lysis (tumor flare reaction). Patients with renal dysfunction are prone to this reaction; thus, CLL patients should be started at lower doses of 10 mg/day, with escalation as tolerated. CLL patients should receive pretreatment hydration and allopurinol to avoid the consequences of
tumor swelling and tumor lysis. A negative interaction with rituximab, an anti-CD20 antibody, may result from lenalidomide’s downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies.

Thromboembolic events occur with increased frequency in patients receiving thalidomide or lenalidomide, but particularly in combination with glucocorticoids and with anthracyclines. Anticoagulation reduces this risk and seems indicated in patients presenting with risk factors for clotting.

**PROTEASOME INHIBITION: BORTEZOMIB**

Bortezomib (VELCADE), an inhibitor of proteasome-mediated protein degradation, has a central role in the treatment of MM. Bortezomib has a unique boron-containing structure:

![Bortezomib Structure](image)

**Mechanism of Action.** Bortezomib binds to the β5 subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity. This event disrupts multiple intracellular signaling cascades, leading to apoptosis. An important consequence of proteasome inhibition is its effect on NF-κB, a transcription factor that promotes cell damage response and cell survival. Most cellular NF-κB is cytosolic and bound to IBB; in this form, NF-κB is restricted to the cytosol and cannot enter to the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, IBB becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF-κB, which enters the nucleus and transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins E-selectin, ICAM-1, and VCAM-1), as proliferation (e.g., cyclin-D1) or anti-apoptosis (e.g., cIAPs, BCL-2). NF-κB is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a
hypoxic environment and during chemotherapy. Bortezomib blocks proteasomal degradation of IkB, thereby preventing the transcriptional activity of NF-κB and downregulating survival responses.

Bortezomib also disrupts the ubiquitin-proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. Bortezomib activates the cell’s stereotypical “unfolded protein response” or UPR, in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis. Bortezomib also sensitizes tumor cells to cytotoxic drugs, including alkylators and anthracyclines, and to IMiDs and inhibitors of histone deacetylase.

**ADME.** The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 h should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced 25%. The drug exhibits a terminal $t_{1/2}$ in plasma of 5.5 h. Peak proteasome inhibition reaches 60% within 1 h and declines thereafter, with a $t_{1/2}$ of ~24 h. Bortezomib clearance results from the deboronation of the parent compound (90%), followed by hydroxylation of the boron-free product by CYPs 3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

**Therapeutic Uses.** Bortezomib is used as initial therapy for MM and as therapy for MM after relapse from other drugs. It also is approved for relapsed or refractory mantle cell lymphoma. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., thalidomide, lenalidomide, liposomal doxorubicin, or dexamethasone).

**Toxicity.** Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), and neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, or weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., thalidomide) or diabetes or
with prolonged use. Dose reductions or discontinuation of bortezomib ameliorates the neuropathic symptoms. Injection of bortezomib may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking antihypertensive medications. Cardiac toxicity is rare, but congestive failure and prolonged QT-interval have been reported.

**mTOR INHIBITORS: RAPAMYCIN ANALOGS**

Rapamycin (sirolimus) is a fungal fermentation product that inhibits serine/threonine protein kinase in mammalian cells eponymously named *mammalian target of rapamycin*, or mTOR. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor, PTEN. Activating mutations and amplification of genes in the receptor-PI3K pathway, and loss of function alterations in PTEN, occur frequently in cancer cells, with the result that PI3K signaling is exaggerated and cells exhibit enhanced survival.

Rapamycin and its congeners, temsirolimus and everolimus, are first-line drugs in post-transplant immunosuppression (see Figure 35–1). The mTOR inhibitors have important applications in oncology for treatment of renal and hepatocellular cancer and mantle cell lymphomas. Everolimus was recently FDA-approved for the treatment of advanced pancreatic neuroendocrine tumors.

**Mechanisms of Action and Resistance.** The rapamycins inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3 kinase pathway (Figure 62–3). mTOR forms the mTORC1 complex with a member of the FK506-binding protein family, FKBP12. Among other actions, mTORC1 phosphorylates S6 kinase and also relieves the inhibitory effect of 4EBP on initiation factor eIF-4E, thereby promoting protein synthesis and metabolism. The antitumor actions of the rapamycins result from their binding to FKBP12 and inhibition of mTORC1. Rapamycin and its congeners have immunosuppressant effects, inhibit cell-cycle progression and angiogenesis, and promote apoptosis. Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which
is unaffected by rapamycins and which regulates Akt.

**Figure 62–3 Effect of rapamycin on growth factor signaling.** A key pathway is regulated by phosphatidylinositol-3 kinase (PI3K) and its downstream partner, the mammalian target of rapamycin (mTOR). Rapamycins complex with FKBPP12 to inhibit the mTORC1 complex. mTORC2 remains unaffected and responds by upregulating Akt, driving signals through the inhibited mTORC1. The various downstream outputs of the 2 complexes are shown. Phosphorylation of 4EBP by mTOR inhibits the capacity of 4EBP to inhibit eif-4E and slow metabolism. 4EBP, eukaryotic initiation factor 4e (eif-4E) binding protein; FKB12, immunophilin target (binding protein) for tacrolimus (FK506); IGF1R, insulin-like growth factor 1 receptor; S6K1, S6 kinase 1.

**ADME.** For renal-cell cancer, temsirolimus is given in weekly doses of 25 mg, intravenously; everolimus is administered orally in doses of 10 mg/day. Both
drugs should be administered in the fasting state at least 1 h before a meal. Both parent molecules are metabolized by CYP3A4. Temsirolimus has a plasma $t_{1/2}$ of 30 h; its primary metabolite, sirolimus, has a $t_{1/2}$ of 53 h. Because sirolimus has equivalent activity as an inhibitor of mTORC1, and has a greater AUC, sirolimus is likely the more important contributor to antitumor action in patients. Everolimus has a plasma $t_{1/2}$ of 30 h; on a weekly schedule at doses of 20 mg, it maintains inhibition of mTORC1 for 7 days in white blood cells. Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. The dose of temsirolimus should be doubled in the presence of inducers and reduced by half in the presence of ketoconazole. For everolimus, the dose should be reduced to 5 mg daily for patients with moderate hepatic impairment (Child-Pugh class B); guidelines for dose reduction of temsirolimus in such patients have not been established. The drugs’ pharmacokinetics do not depend on renal function, and hemodialysis does not hasten temsirolimus clearance.

**Therapeutic Uses.** Temsirolimus and everolimus are approved for treatment of renal cancer. Temsirolimus prolongs survival and delays disease progression in patients with advanced and poor- or intermediate-risk renal cancer, as compared to standard interferon-α treatment. Everolimus, as compared to placebo, prolongs survival in patients who had failed initial treatment with anti-angiogenic drugs. mTOR inhibitors also have antitumor activity against mantle cell lymphomas.

**Toxicity.** The rapamycin analogs have very similar patterns of toxicity. Side effects such as a mild maculopapular rash, mucositis, anemia, and fatigue occur in 30-50% of patients. A few patients will develop leukopenia or thrombocytopenia, effects that are reversed if therapy is discontinued. Less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving everolimus and in a smaller percentage of those treated with temsirolimus. If symptoms such as cough or shortness of breath develop or radiological changes progress, the drug should be discontinued. Prednisone may hasten the resolution of radiological changes and symptoms.

**BIOLOGICAL RESPONSE MODIFIERS**

Biological response modifiers include cytokines and monoclonal
antibodies that beneficially affect the patient’s biological response to a neoplasm. Such agents may act indirectly to mediate their antitumor effects (e.g., by enhancing the immunological response to neoplastic cells) or directly, binding to receptors on the tumor cells and delivering toxins or radionuclides. Proteins that currently are in clinical use include the interferons, interleukins, hematopoietic growth factors (e.g., erythropoietin, filgrastim [granulocyte colony-stimulating factor], and sargramostim [granulocyte-macrophage colony-stimulating factor]; see Chapter 37), and monoclonal antibodies.

**MONOCLONAL ANTIBODIES**

Cancer cells express antigens that are attractive targets for monoclonal antibody–based therapy (Table 62–1). Immunization of mice with human tumor cell extracts has led to the isolation of monoclonal Abs reactive against unique or highly expressed target antigens, and a few of these monoclonals possess antitumor activity. Because murine antibodies have a short $t_{1/2}$ in humans, activate human immune effector mechanisms poorly, and induce a human anti-mouse antibody immune response, they usually are chimerized by substituting major portions of the human IgG molecule. The nomenclature adopted for naming therapeutic monoclonal antibodies is to terminate the name in -ximab for chimeric antibodies and -umab for fully humanized antibodies.

| Monoclonal Antibodies Approved For Hematopoietic And Solid Tumors | Table 62–1 |
Presently, monoclonal antibodies are FDA-approved for lymphoid and solid tumor malignancies. Available agents include rituximab and alemtuzumab for lymphoid malignancies, trastuzumab for breast cancer, bevacizumab for colon and lung cancer, and cetuximab and panitumumab for colorectal cancer and head and neck cancer. *Table 62–1* summarizes available monoclonal antibodies and their tumor cell targets; *Table 62–2* summarizes the mechanisms, dose regimens, and toxicities of monoclonal antibody-based agents. Unmodified monoclonal antibodies may kill tumor cells by a variety of mechanisms (e.g., antibody-dependent cellular cytotoxicity [ADCC], complement-dependent cytotoxicity [CDC], and direct induction of apoptosis by antigen binding), but the clinically relevant mechanisms for most antibodies are uncertain. Monoclonal antibodies also may be linked to a toxin (immunotoxins), such as gemtuzumab ozogamicin (MYLOTARG) or denileukin diftitox (ONTAK), or conjugated to a radioactive isotope, as in the case of $^{90}$Yttrium ($^{90}$Y)-ibritumomab tiuxetan (Zevalin) (*see Table 62–1*).

**UNARMED MONOCLONAL ANTIBODIES**
**RITUXIMAB.** Rituximab (RITUXAN) is a chimeric monoclonal antibody that targets the CD20 B-cell antigen (Tables 62–1 and 62–2).

CD20 is found on cells from the pre–B cell stage through its terminal differentiation to plasma cells and is expressed on 90% of B-cell neoplasms. Monoclonal antibody binding to CD20 generates transmembrane signals that produce autophosphorylation and activation of protein serine/tyrosine kinases,
induction of \( c-myC \) oncogene expression, and expression of major histocompatibility complex class II molecules. CD20 also may regulate transmembrane \( Ca^{2+} \) conductance through its function as a \( Ca^{2+} \) channel. It is unclear which of these actions relates to the pharmacological effects of rituximab.

**ADME.** Rituximab has a \( t_{1/2} \) of ~22 days. The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy at a dose of 375 mg/m\(^2\). As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3-6 months. In combination regimens, the drug may be administered every 3-4 weeks, with chemotherapy, for up to 8 doses. As maintenance therapy following 6-8 cycles of combination chemotherapy, rituximab may be given once weekly for 4 doses, at 6-month intervals, for up to 16 doses. The rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Infusions should begin at 50 mg/h, and in the absence of infusion reactions, the rate can increase in 50-mg/h increments every 30 min to a maximum rate of 400 mg/h. Pretreatment with antihistamines, acetaminophen, and glucocorticoids decreases the risk of hypersensitivity reactions. Patients with large numbers of circulating tumor cells (as in CLL) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m\(^2\) on day 1 of treatment, and patients should receive standard tumor lysis prophylaxis. The remainder of the dose can then be given on day 3.

**Therapeutic Uses.** Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with chemotherapy for the initial treatment of diffuse large B-cell lymphoma. Rituximab improves response rates when added to combination chemotherapy for other indolent B-cell non-Hodgkin lymphomas (NHLs), including CLL, mantle cell lymphoma, Waldenström macroglobulinemia, and marginal zone lymphomas. Maintenance of remission with rituximab delays time to progression and improves overall survival in indolent NHL. It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemias, cryoglobulin-induced renal disease, and multiple sclerosis.

**Resistance and Toxicity.** Resistance to rituximab may emerge through
downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels. Polymorphisms in 2 of the receptors for the antibody Fc region responsible for complement activation may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL. Rituximab infusional reactions can be life-threatening, but with pretreatment are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. Rituximab may cause reactivation of hepatitis B virus or rarely, JC virus (with progressive multifocal leukoencephalopathy). Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may supervene 1-5 months after administration (see Table 62–2).

**OFATUMUMAB**

Ofatumumab (ARZERRA) is a second monoclonal antibody that binds to CD20 at sites on the major and minor extracellular loops of CD20, distinct from the site targeted by rituximab. Binding of the drug results in B-cell lysis (both CDC and ADCC). Ofatumumab is approved for treating CLL after failure of fludarabine and alemtuzumab. A complex dosing scheme is used, beginning with small (300 mg) doses on day 1, followed by higher doses (up to 2 g/week) for 7 weeks, followed by 2 g every 4 weeks for 4 additional doses. Ofatumumab’s primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored in hepatitis B carriers.

**ALEMTUZUMAB**

Alemtuzumab (CAMPATH) is a humanized IgG-κ) monoclonal antibody. The drug binds to CD52 antigen present on the surface of a subset of normal neutrophils and on all B and T lymphocytes, on
testicular elements and sperm, and on most B- and T-cell lymphomas. Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a favorable target for unconjugated monoclonal antibodies. Alemtuzumab can induce tumor cell death through ADCC and CDC.

**ADME; Therapeutic Uses.** Alemtuzumab is administered intravenously in dosages of 30 mg/day, 3 times/week. Premedication with diphenhydramine (50 mg) and acetaminophen (650 mg) should precede drug infusion. Dosing should begin with a 3-mg infusion, followed by a 10-mg dose 2 days later and, if well tolerated, a 30-mg dose 2 days later. The drug has an initial mean \( t_{1/2} \) of 1 h, but after multiple doses, the \( t_{1/2} \) extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment, presumably through saturation of CD52-binding sites. Clinical activity has been demonstrated in both B- and T-cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogs. In chemotherapy-refractory CLL, overall response rates are \(~40\%\), with complete responses of 6\% in multiple series. Response rates in patients with untreated CLL are higher (overall response rates of 83\% and complete responses of 24\%).

**Toxicity.** Serious toxicities include acute infusion reactions and depletion of normal neutrophils and T cells (see Table 62–2). Myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or auto-immune responses. Immunosuppression leads to a significant risk of fungal, viral, and other opportunistic infections, particularly in patients who have previously received purine analogs. Patients should receive antibiotic prophylaxis against *Pneumocystis carinii* and herpes virus during treatment and for at least 2 months following therapy with alemtuzumab. Because reactivation of cytomegalovirus (CMV) infections may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. CD4\(^+\) T-cell counts may remain profoundly depleted (<200 cells/µL) for 1 year. Alemtuzumab does not combine well with chemotherapy in standard regimens because of significant infectious complications.

**IPILIMUMAB**
Ipilimumab (YERVOY) is a human monoclonal antibody against CTLA-4, approved for the treatment of late stage inoperable melanoma. The agent potentiates T cell proliferation by removing inhibition by cytotoxic T lymphocyte antigen-4 (CTLA-4). Ipilimumab treatment is associated with severe and fatal immunological adverse effects.

**MONOCLONAL ANTIBODY–CYTOTOXIN CONJUGATES**

**GEMTUZUMAB OZOOGAMICIN**

Gemtuzumab ozogamicin (MYLOTARG) is a humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of calicheamicin, a potent antitumor antibiotic. The CD33 antigen is present on most hematopoietic cells, on >80% of AMLs, and on most myeloid cells in patients with myelodysplasias. However, other normal cell types lack CD33 expression, making this antigen attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, gemtuzumab ozogamicin undergoes endocytosis; cleavage of calicheamicin from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death.

**Clinical Pharmacology.** The antibody conjugate produces a 30% complete response rate in relapsed AML, when administered at a dose of 9 mg/m² for up to 3 doses at 2-week intervals. The $t_{1/2}$ of total and unconjugated calicheamicin are 41 h and 143 h, respectively. Following a second dose, the $t_{1/2}$ of drug-antibody conjugate increases to 64 h. Most patients require 2 to 3 doses to achieve remission. The drug is approved in patients >60 years of age with AML in first relapse. Primary toxicities include myelosuppression in all patients treated and hepatocellular damage in 30-40% of patients, manifested by hyperbilirubinemia and enzyme elevations. It also causes a syndrome that resembles hepatic veno-occlusive disease when patients subsequently undergo
myeloablative therapy or when gemtuzumab ozogamicin follows high-dose chemotherapy. Defibrotide, an orphan drug, may prevent severe or fatal hepatic injury in patients who develop signs of hepatic failure while receiving a stem cell transplant following gemtuzumab ozogamicin. Prolonged myelosuppression may complicate the patient’s course following remission induction with gemtuzumab ozogamicin.

**RADIOIMMUNOCONJUGATES**

Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells (Tables 62–1 and 62–2). $^{131}$Iodine ($^{131}$I) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The $\gamma$ particles emitted by $^{131}$I can be used for both imaging and therapy, but protein-iodine conjugates have the drawback of releasing free $^{131}$I and $^{131}$I-tyrosine into the blood, and thus present a health hazard to people in contact with the patient. The $\beta$-emitter $^{90}$Y has emerged as an alternative to $^{131}$I, based on its higher energy and longer path length. Thus, it may be more effective in tumors with larger diameters. It also has a short $t_{1/2}$ and remains conjugated, even after endocytosis, providing a safer profile for outpatient use.

Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with $^{131}$I (tositumomab [Bexxar]) or $^{90}$Y (ibritumomab tiuxetan [Zevalin]). Both drugs have shown responses rates in relapsed lymphoma of 65-80%. When using Zevalin, an initial dose of unlabeled rituximab is administered, followed by an imaging dose of Indium-111-labeled Zevalin. Biodistribution is determined, allowing calculation of a therapeutic dose of $^{90}$Y Zevalin. A pretreatment dose of rituximab then is administered to saturate nonspecific binding sites, followed by the therapeutic dose of $^{90}$Y Zevalin. The steps in Bexxar administration closely follow those of Zevalin. An imaging dose precedes the therapeutic dose given 1 week later. These agents cause antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias.

**INTERLEUKIN-2**
IL-2 is a 133–amino acid glycoprotein (MW ~ 15 kDa) produced by activated T cells and NK cells; it promotes activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2 receptor. Resting T cells and nearly all types of tumor cells lack receptor expression and are unresponsive to IL-2.

The IL-2 receptor has 3 components: (1) an α chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; (2) a β chain, a 75-kDa protein involved in intracellular signaling; and (3) a γ chain, a 64-kDa protein that is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21) and also is involved in signaling. In the absence of the α chain, IL-2-binding affinity is reduced by a factor of 100.

**Mechanism of Action.** IL-2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells. The mechanism of tumor cell killing has not been precisely defined.

**Pharmacokinetics.** The serum $t_{1/2}$ of IL-2 after intravenous administration has an α phase of about 13 min and a β phase of about 90 min. IL-2 is excreted in the urine as an inactive metabolite.

**Therapeutic Use.** Aldesleukin (PROLEUKIN) possesses the biological activities of human native IL-2. The drug is approved for use in metastatic renal-cell cancer and metastatic melanoma. High-dose IL-2 produces an overall response rate of ~19% in patients with renal-cell cancer, and 8% achieve a complete response. Responses last a median of 8-9 years. High-dose IL-2 induces an overall response rate of ~16% in patients with metastatic melanoma, and 6% achieve a complete response. Responses last a median of ~5 years. Low-dose IL-2 also produces responses, but the duration of the responses may be less than with high-dose IL-2. Aldesleukin may be administered in several ways. High-dose IL-2 is 600,000-720,000 IU/kg administered by intravenous bolus every 8 h until dose-limiting toxicity appears or 14 total doses have been given; the schedule may be repeated after 9 days of rest for a maximum of 28 doses. Low-dose IL-2 is 60,000 or 72,000 IU/kg given by intravenous bolus every 8 h for 15 doses. A third regimen involves delivery of 18 million units/m² daily by continuous
intravenous infusion for 5 days. Chronic administration doses are 250,000 IU/kg subcutaneously daily for 5 days followed by 125,000 IU/kg daily for 6 weeks.

**Toxicity.** IL-2 toxicities are dominated by the capillary leak syndrome in which intravascular fluid leaks into the extravascular space, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems. Symptoms include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, and neutropenia. Most patients develop a pruritic skin rash. Hypothyroidism may occur. Arrhythmias are a rare complication. These toxicities can be life-threatening, yet nearly all are reversible within 24-48 h of discontinuing therapy. Patients should have normal renal and hepatic function before beginning therapy and should be closely supervised during drug administration.

**DENILEUKIN DIFTITOX**

Denileukin diftitox (ONTAK) is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria toxin. The high-affinity IL-2R has limited tissue expression and is an attractive target for an immunotoxin. Introduction of the diphtheria toxin fragment into cells leads to ADP-ribosylation and inactivation of eukaryotic elongation factor EF-2, inhibition of protein synthesis, and thence, cell death.

**Clinical Pharmacology.** Denileukin diftitox is approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. It should be administered at 9 or 18 µg/kg/day by intravenous infusion over 30-60 min for 5 consecutive days every 21 days for 8 cycles. Response rates of 30-37% have been achieved, with a median response duration of 6.9 months. The drug is quickly distributed and has a terminal \( t_{1/2} \) of ~70 min. Denileukin diftitox clearance in later cycles of treatment accelerates by 2- to 3-fold as a result of development of antibodies, but serum levels exceed those required to produce cell death in IL-2R-expressing cell lines (1-10 ng/mL for >90 min). Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities include acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases
toxicity.

COLONY-STIMULATING FACTORS

Many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression can limit the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) has advanced the ability to use combination therapy or high-dose therapy with diminished complications such as febrile neutropenia (see Chapter 37).

NEWLY APPROVED FIRST-IN-CLASS DRUGS

**Vemurafenib** *(ZELBORAF)* is an orally administered selective inhibitor of the BRAF serine-threonine kinase that is FDA-approved for the treatment of metastatic melanoma harboring activating BRAF (V600E) mutations.

**Crizotinib** *(XALKORI)* is an ATP-competitive oral small-molecule inhibitor of the anaplastic lymphoma kinase (ALK) and mesenchymal-epithelial transition factor (c-MET) tyrosine kinase. The FDA granted accelerated approval to crizotinib for the treatment of patients with locally advanced or metastatic non–small cell lung cancer harboring ALK gene rearrangements.

**Omacetaxine mepesuccinate** *(SYNRIBO)* injection is an alkaloid that inhibits protein translation by preventing initial elongation in protein synthesis. It is approved for treatment of adults with chronic myeloid leukemia (CML) and with resistance to two or more tyrosine kinase inhibitors.

**Vismodegib** *(ERIVEDGE)* is a first-in-class hedgehog signaling pathway inhibitor approved for the treatment of adult patients with basal cell carcinoma. It acts as a competitive antagonist of the SMO receptor preventing the activation of the GLI family transcription factors.

For details of other approvals from 2011 to the present, see updates by Dr. Nelda Murri on the G&G webpages at AccessMedicine.com and AccessPharmacy.com.
The growth of a number of cancers is hormone-dependent or regulated by hormones. Glucocorticoids are used for their antiproliferative and lympholytic properties and to ameliorate untoward responses to other treatments. Estrogen, androgen, and GnRH analogs and antagonists are effective in extending survival and delaying or preventing tumor recurrence of both breast and prostate cancer. These molecules interrupt the stimulatory axis created by systemic pools of androgens and estrogens, inhibit hormone production or hormone binding to receptors, and ultimately block expression of genes that promote tumor growth and survival.

GLUCOCORTICOIDS

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 42. Only the applications of these drugs in the treatment of neoplastic disease are considered here.

Glucocorticoids act by binding to a specific physiological receptor that translocates to the nucleus and induces antiproliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults. In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in ≤30% of children. However, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. Thus, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies,
including Hodgkin disease, non-Hodgkin lymphoma, multiple myeloma, and chronic lymphocytic leukemia (CLL). Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

A number of glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 42). Prednisone, e.g., usually is administered orally in doses as high as 60-100 mg, for the first few days and gradually reduced to levels of 20-40 mg/day, using the lowest possible effective dose. Side effects of these agents include glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 42). Dexamethasone is the preferred agent for remission induction in multiple myeloma, usually in combination with melphalan, anthracyclines, vincristine, bortezomib, or thalidomide. Glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Doses of 4-6 mg every 6 h have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. Acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases.

PROGESTINS

Progestational agents (see Chapters 40 and 66) are used as second-line hormonal therapy for metastatic hormone-dependent breast cancer and in the management of endometrial carcinoma previously treated by surgery and radiotherapy. In addition, progestins stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS.

Medroxyprogesterone (Depo-Provera, others) can be administered intramuscularly in doses of 400-1000 mg weekly. An alternative oral agent is megestrol acetate (Megace, others; 40-320 mg daily in divided doses). Hydroxyprogesterone (not available in the U.S.) usually is administered intramuscularly in doses of 1000 mg 1 or more times weekly. Beneficial effects have been observed in one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of
estrogen receptors (ERs) and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose dependent, with some patients demonstrating second responses following escalation of megestrol to 1600 mg/day. Clinical use of progestins in breast cancer has been largely superseded by the advent of tamoxifen and the aromatase inhibitors (AIs).

**ESTROGENS AND ANDROGENS**

The pharmacology of the estrogens and androgens appears in Chapters 40, 41, and 66. These agents are of value in certain neoplastic diseases, notably those of the prostate and mammary gland, because these organs are dependent on hormones for their growth, function, and morphological integrity.

High doses of estrogen have long been recognized as effective treatment of breast cancer. Paradoxically, anti-estrogens also are effective. Thus, because of equivalent efficacy and more favorable side effects, anti-estrogens such as tamoxifen and the AIs have replaced estrogens or androgens for breast cancer. The presence of the ERs and progesterone receptors (PRs) on tumor tissue serves as a biomarker for response to hormonal therapy in breast cancer and identifies the subset of patients with a ≥60% likelihood of responding. The response rate to anti-estrogen treatment is somewhat lower in the subset of patients with tumors that are ER+ or PR+ but also positive for human epidermal growth factor receptors HER1/neu amplification. In contrast, ER-negative and PR-negative carcinomas do not respond to hormonal therapy. Responses to hormonal therapy may not be apparent clinically or by imaging for 8-12 weeks. The medication typically should be continued until the disease progresses or unwanted toxicities develop. The duration of an induced remission in patients with metastatic disease averages 6-12 months but sometimes can last for many years.

**ANTI-ESTROGEN THERAPY**

Anti-estrogen approaches for the therapy of hormone receptor–positive breast cancer include the use of *selective estrogen-receptor modulators* (SERMs), *selective estrogen-receptor downregulators* (SERDs), and AIs (*Table 63–1*).
Clinical Uses for Anti-Estrogen Therapy in ER+ Breast Cancer

*Premen, premenopausal; Postmen, postmenopausal; AI, aromatase inhibitor; PD, progressive disease; TAM, tamoxifen; ER, estrogen receptor.*

**SELECTIVE ESTROGEN-RECEPTOR MODULATORS**

SERMs bind to the ER and exert either estrogenic or anti-estrogenic effects, depending on the specific organ. Tamoxifen citrate is the most widely studied anti-estrogenic treatment in breast cancer. However, tamoxifen also exerts estrogenic agonist effects on non-breast tissues, which influences the overall therapeutic index of the drug. Therefore, several novel anti-estrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen have been developed. These novel anti-estrogens can be divided into tamoxifen analogs (e.g., toremifene [FARESTON], droloxifene, idoxifene), “fixed ring” compounds (e.g., raloxifene [EVISTA], lasofoxifene, arzoxifene, miproxifene, levormeloxifene, EM652), and the SERDs (e.g., fulvestrant [FASLODEX], SR 16234, and ZK 191703, the latter also termed “pure anti-estrogens”).

**TAMOXIFEN**
Tamoxifen was developed as an oral contraceptive but instead was found to induce ovulation and to have antiproliferative effects on estrogen-dependent breast cancer cell lines. Tamoxifen is prescribed for the prevention of breast cancer in high-risk patients, for the adjuvant therapy of early-stage breast cancer, and for the therapy of advanced breast cancer. It also prevents the development of breast cancer in women at high risk based on a strong family history, prior nonmalignant breast pathology, or inheritance of the BRCA1 or BRCA2 genes.

**Mechanism of Action.** Tamoxifen is a competitive inhibitor of estradiol binding to the ER. There are 2 subtypes of ERs: ERα and ERβ, which have different tissue distributions and can either homo- or heterodimerize. Binding of estradiol and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and inhibition of ER dimerization. Dimerization facilitates the binding of the ER to specific DNA estrogen-response elements (EREs) in the vicinity of estrogen-regulated genes. Co-regulator proteins interact with the receptor to act as co-repressors or co-activators of gene expression. Differences in tissue distribution of ER subtypes, the function of co-regulator proteins, and the various transcriptional activating factors likely explain the variability of response to tamoxifen in hormone receptor–positive (ER+) breast cancer and its agonist and antagonist activities in noncancerous tissues. Other organs displaying agonist effects of tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer), the coagulation system (thromboembolism), bone metabolism (increase in bone mineral density [BMD]), and liver (tamoxifen lowers total serum cholesterol, low-density-lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A-I levels).

**ADME.** Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3-7 h and steady-state levels being reached at 4-6 weeks. Metabolism of tamoxifen is complex and principally involves CYPs 3A4/5, and 2D6 in the formation of N-desmethyl tamoxifen, and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite (Figure 63–1). Both
metabolites can be further converted to 4-hydroxy-\(N\)-desmethyltamoxifen, which retains high affinity for the ER. The parent drug has a terminal \(t_{1/2}\) of 7 days; the \(t_{1/2}\) of \(N\)-desmethyltamoxifen and 4-hydroxytamoxifen are significantly longer (14 days). After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal.

![Diagram of Tamoxifen and its metabolites](Image)

**Figure 63–1** Tamoxifen and its metabolites.

*Therapeutic Uses.* The usual oral dose of tamoxifen in the U.S. is 20 mg once a day. Tamoxifen is used for the endocrine treatment of women with ER\(^+\) metastatic breast cancer or following primary tumor excision as adjuvant therapy. For the adjuvant treatment of premenopausal women, tamoxifen is given for 5 years, or in postmenopausal women, for 2 years, followed by an AI.
In patients with high risk of recurrence, tamoxifen may be sequenced after adjuvant chemotherapy. Tamoxifen is used in premenopausal women with ER+ tumors. Alternative or additional anti-estrogen strategies in premenopausal women include oophorectomy or gonadotropin-releasing hormone analogs. The combination of tamoxifen and a GnRH analog in premenopausal women (to reduce high estrogen levels resulting from tamoxifen effects on the gonadal-pituitary axis) yields better response rates and improved overall survival than either drug alone. Tamoxifen also has shown effectiveness (a 40-50% reduction in tumor incidence) in initial trials for preventing breast cancer in women at increased risk. Tamoxifen only reduces ER+ tumors without affecting ER-negative tumors, which contribute disproportionately to breast cancer mortality.

**Toxicity.** The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, hair loss, nausea, and vomiting. Menstrual irregularities, vaginal bleeding and discharge, pruritus vulvae, and dermatitis occur with increasing severity in postmenopausal women. Tamoxifen also increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive 20 mg/day for ≥2 years. Tamoxifen increases the risk of thromboembolic events, which increase with the age of a patient and also in the perioperative period. Hence, it often is recommended to discontinue tamoxifen prior to elective surgery. Tamoxifen causes retinal deposits, decreased visual acuity, and cataracts, although the frequency of these changes is more common in patients on high doses of drug.

**Tamoxifen Resistance.** Initial or acquired resistance to tamoxifen frequently occurs. CYP2D6 is required for the activation of tamoxifen to its active metabolite endoxifen (see Figure 63–1). Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of the potent metabolites 4-OH tamoxifen and endoxifen, and are associated with higher risks of disease relapse and a lower incidence of hot flashes. Crosstalk between the ER and HER2/neu pathway also has been implicated in tamoxifen resistance. The paired box 2 gene product (PAX2) has been identified as a crucial mediator of ER repression of ErbB2 by tamoxifen. Interactions between PAX2 and the ER co-activator AIB-1/SRC-3 determine tamoxifen response in breast cancer cells.

**TOREMIFENE**
Toremifene (FARESTON) is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile. Toremifene is indicated for the treatment of breast cancer in women with tumors that are ER+ or of unknown receptor status.

SELECTIVE ESTROGEN RECEPTOR DOWNREGULATORS

SERDs, also termed “pure anti-estrogens,” include fulvestrant and a host of agents in experimental trials (RU 58668, SR 16234, ZD 164384, and ZK 191703). SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

FULVESTRANT

Fulvestrant (FASLODEX) is approved for postmenopausal women with hormone receptor–positive metastatic breast cancer that has progressed on tamoxifen.

Mechanism of Action. Fulvestrant is a steroidal anti-estrogen that binds to the ER with an affinity >100 times that of tamoxifen. The drug inhibits the binding of estrogen but also alters the receptor structure such that the receptor is targeted for proteasomal degradation; fulvestrant also may inhibit receptor dimerization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells; as a consequence of this ER downregulation, the drug abolishes ER-mediated transcription of estrogen-dependent genes.

ADME and Dosing. Peak plasma concentrations are reached ~7 days after intramuscular administration of fulvestrant and are maintained over 1 month. The plasma t1/2 is ~40 days. Steady-state concentrations are reached after 3-6 monthly injections. There is rapid distribution and extensive protein binding of this highly lipophilic drug. Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), metabolize fulvestrant. CYP3A4 appears to be the only CYP isoenzyme involved in the metabolism of fulvestrant. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of anti-estrogenic activity (~22% that of fulvestrant). Less than 1% of the parent drug is excreted
intact in the urine.

The approved dosing for fulvestrant is 250 mg by intramuscular injection monthly. Because it takes ~3-6 months for fulvestrant to reach steady-state levels with monthly dosing, alternative regimens have been studied. A loading dose regimen of 500 mg on day 0, 250 mg on days 14 and 28, and then 250 mg each month yields maximum fulvestrant concentrations in plasma an average of 12 days after the first dose and maintains those levels thereafter.

**Therapeutic Uses.** Fulvestrant is used in postmenopausal women as anti-estrogen therapy of hormone receptor–positive metastatic breast cancer after progression on first-line anti-estrogen therapy such as tamoxifen. Fulvestrant is at least as effective in this setting as the third-generation AI anastrozole.

**Toxicity and Adverse Effects.** Fulvestrant generally is well tolerated, the most common adverse effects being nausea, asthenia, pain, vasodilation (hot flashes), and headache. The risk of injection site reactions, seen in ~7% of patients, is reduced by giving the injection slowly. In tamoxifen-resistant patients, anastrozole and fulvestrant produce equivalent quality-of-life outcome measures.

**AROMATASE INHIBITORS**

Aromatase converts androgens to estrogens (e.g., androstenedione to estrone). Aromatase inhibitors (AIs; Figure 63–2) block this enzymatic activity, reducing estrogen production. AIs now are considered the standard of care for adjuvant treatment of postmenopausal women with hormone receptor–positive breast cancer, either as initial therapy or sequenced after tamoxifen.
Aromatase (CYP19A1) is responsible for the conversion of adrenal androgens and gonadal androstenedione and testosterone to the estrogens, estrone (E1) and estradiol (E2), respectively (Figures 63–2 and 63–3). In postmenopausal women, this conversion is the primary source of circulating estrogens, while estrogen production in premenopausal women primarily is from the ovaries. In postmenopausal women, AIs can suppress most peripheral aromatase activity, leading to profound estrogen deprivation. AIs are classified as first, second, or third generation. In addition, they are further classified as type 1 (steroidal) or type 2 (nonsteroidal) AIs according to their structure and mechanism of action. Type 1 inhibitors are steroidal analogs of androstenedione (see Figure 63–2) that
bind covalently and irreversibly to the same site on the aromatase molecule. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.

![Figure 63–3 Steroid synthesis pathways.](image)

The shaded area contains the pathways used by the adrenal glands and gonads. Enzymes are labeled in green, inhibitors in red. A, aromatase; 3β, 3β-hydroxysteroid dehydrogenase; 5α-R, 5α-reductase; 11β, 11β-hydroxylase; 17, 20, C-17, 20-lyase (also CYP17); 17α, 17α-hydroxylase (CYP17); 17βR, 17β-reductase; 18, aldosterone synthase; 21, 21-hydroxylase.

THIRD-GENERATION AROMATASE INHIBITORS

The third-generation inhibitors include the type 1 steroidal agent *exemestane* and the type 2 nonsteroidal imidazoles *anastrozole* and *letrozole*. Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women.

ANASTROZOLE

Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole,
binds competitively and specifically to the heme of the CYP19. Anastrozole, 1 mg, administered once daily for 28 days, reduces total body androgen aromatization by 96.7% Anastrozole also reduces aromatization in large ER+ breast tumors.

**ADME.** Anastrozole is absorbed rapidly after oral administration. Steady-state is attained after 7 days of repeated dosing. Anastrozole is metabolized by N-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is via the liver and biliary tract. The elimination $t_{1/2}$ is ~50 h. The pharmacokinetics of anastrozole, which can be affected by drug interactions via the CYP system, are not altered by coadministration of tamoxifen or cimetidine.

**Therapeutic Uses.** Anastrozole (ARIMIDEX), 1 mg administered orally once daily, is approved for upfront adjuvant hormonal therapy in postmenopausal women with early-stage breast cancer and as treatment for advanced breast cancer. In early-stage breast cancer, anastrozole is significantly more effective than tamoxifen in delaying time to tumor recurrence and decreasing the odds of a primary contralateral tumor. In advanced breast cancer, postmenopausal women with disease progression while taking tamoxifen showed a statistically significant survival advantage with anastrozole 1 mg/day versus megestrol acetate 40 mg 4 times daily. Women with ER+ or PR+ metastatic breast cancer, anastrozole showed a statistically significant advantage over tamoxifen in median time to disease progression.

**Adverse Effects and Toxicity.** Compared to tamoxifen, anastrozole has been associated with a significantly lower incidence of vaginal bleeding, vaginal discharge, hot flashes, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep venous thrombosis, including pulmonary embolism. Anastrozole is associated with a higher incidence of musculoskeletal disorders and fracture than tamoxifen. In advanced disease, anastrozole is as well tolerated as megestrol and causes less weight gain. The estrogen depletion caused by anastrozole and other AIs raises the concern of bone loss. Compared with tamoxifen, treatment with anastrozole results in significantly lower BMD in the lumbar spine and total hip. Bisphosphonates prevent AI-induced bone loss in postmenopausal women.
LETRAZOLE

Letrozole is approved for upfront adjuvant hormonal therapy in postmenopausal women with early-stage breast cancer and as treatment for advanced breast cancer. In postmenopausal women with primary breast cancer, letrozole inhibits estrogen aromatization by 99% and reduces local aromatization within the tumors. The drug has no significant effect on the synthesis of adrenal steroids or thyroid hormone and does not alter levels of a range of other hormones. Letrozole also reduces cellular markers of proliferation more than tamoxifen in human estrogen-dependent tumors that overexpress HER1 and HER2/neu.

**ADME.** Letrozole is rapidly absorbed after oral administration, with a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2-6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive metabolite mainly via the kidneys with a $t_{1/2} \sim 41$ h.

**Therapeutic Uses.** The usual dose of letrozole (Femara) is 2.5 mg administered orally once daily. In early-stage breast cancer, extending adjuvant endocrine therapy with letrozole (beyond the standard 5-year period of tamoxifen) improves disease-free survival compared with placebo and improves overall survival in the subset of patients with positive axillary nodes. Furthermore, upfront letrozole is significantly more effective than upfront tamoxifen in terms of time to tumor recurrence and odds of a primary contralateral tumor. In advanced breast cancer, letrozole is superior to tamoxifen as first-line treatment; time to disease progression is significantly longer and objective response rate is significantly greater with letrozole, but median overall survival is similar between groups. As second-line therapy of advanced breast cancer that has progressed on tamoxifen or after oophorectomy, letrozole has efficacy equal to that of anastrozole and similar to or better than that of megestrol.

**Adverse Effects and Toxicity.** Letrozole is well tolerated; the most common treatment-related adverse events are hot flashes, nausea, and hair thinning. In the trial of extended adjuvant therapy, adverse events were hot flashes, arthralgia, myalgia, and arthritis. Letrozole has a low overall incidence of cardiovascular
side effects. Compared with tamoxifen, the use of upfront letrozole results in significantly more clinical fractures. Bisphosphonates prevent letrozole-induced bone loss in postmenopausal women.

**EXEMESTANE**

Exemestane is a more potent, orally administered analog of the natural aromatase substrate, androstenedione, and lowers estrogen levels more effectively than does its predecessor, formestane. Exemestane irreversibly inactivates aromatase and is a “suicide substrate.” Doses of 25 mg/day inhibit aromatase activity by 98% and lower plasma estrone and estradiol levels by ~90% in postmenopausal women.

**ADME.** Orally administered exemestane is rapidly absorbed from the GI tract; its absorption is increased by 40% after a high-fat meal. Exemestane has a terminal $t_{1/2}$ of ~24 h. It is extensively metabolized in the liver, ultimately to inactive metabolites. One metabolite, 17-hydroxyexemestane, has weak androgenic activity that could contribute to antitumor activity. Although active metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.

**Therapeutic Uses.** Exemestane (AROMASIN), 25 mg administered orally once daily, is approved for disease progression in postmenopausal women who complete 2-3 years of adjuvant tamoxifen (based on a clinical trial in women with ER$^+$ breast cancer). In advanced breast cancer, exemestane improves time to disease progression compared with tamoxifen as first-line treatment. In a phase III trial against megestrol in women with disease progressing on prior anti-estrogen therapy, patients receiving exemestane had a similar response rate but improved time to disease progression and time to treatment failure and a longer duration of survival compared with those taking megestrol acetate.

**Clinical Toxicity.** Exemestane generally is well tolerated. Discontinuations due to toxicity are uncommon (2.8%). Hot flashes, nausea, fatigue, increased sweating, peripheral edema, and increased appetite have been reported. Compared to tamoxifen in early-stage breast cancer, exemestane caused more frequent arthralgia and diarrhea but less frequent vaginal bleeding and muscle cramps. Visual disturbances and clinical fractures were more common with
Androgens stimulate the growth of normal and cancerous prostate cells. Androgen deprivation therapy (ADT) is the mainstay of treatment for patients with advanced prostate cancer.

Localized prostate cancer frequently is curable with surgery or radiation therapy. However, when distant metastases are present, hormone therapy is the primary treatment. ADT is the standard first-line treatment. ADT is accomplished via surgical castration (bilateral orchiectomy) or medical castration (using gonadotropin-releasing hormone [GnRH] agonists or antagonists). Other hormone therapy approaches are used in second-line treatment and include anti-androgens, estrogens, and inhibitors of steroidogenesis. ADT is not a curative treatment. ADT can alleviate cancer-related symptoms and normalize serum prostate-specific antigen (PSA) in >90% of patients. ADT provides important quality-of-life benefits, including reduction of bone pain and reduction of rates of pathological fracture, spinal cord compression, and ureteral obstruction. It also prolongs survival.

The duration of response to ADT for patients with metastatic disease is variable but typically lasts 14-20 months. Disease progression despite ADT signifies a castration-resistant state. Despite castrate levels of testosterone, low-level androgen (DHEA) synthesis from the adrenal glands may permit the continued androgen-driven growth of prostate cancer cells. Therefore, anti-androgens (which competitively bind the androgen receptor [AR]), inhibitors of steroidogenesis (such as ketoconazole), and estrogens frequently are employed as secondary hormone therapies. Unlike the response to ADT, only the minority of patients experience symptomatic relief or tumor regression when treated with secondary hormone therapies. When patients become refractory to further hormonal therapies, their disease is considered androgen independent. In these patients, the next treatment option usually is cytotoxic chemotherapy; docetaxel has a proven survival benefit, with average overall survival of 18 months.

Common side effects of androgen deprivation include vasomotor flushing, loss of libido, impotence, gynecomastia, fatigue, anemia, weight gain, decreased
insulin sensitivity, altered lipid profiles, osteoporosis and fractures, and loss of muscle mass. ADT is associated with an increased risk of diabetes and coronary heart disease. However, retrospective analyses have not revealed a compelling increase in cardiovascular mortality due to GnRH agonists. Skeletal-related events due to ADT may be mitigated by bisphosphonate therapy, such as zoledronic acid (ZOMETA) or inhibitors of osteoclast activation, such as denosumab. Anti-androgens, when compared with GnRH agonists, cause more gynecomastia, mastodynia, and hepatotoxicity but less vasomotor flushing, and loss of BMD. Estrogens cause a hypercoagulable state and increase cardiovascular mortality in prostate cancer patients and are no longer standard treatment options.

GONADOTROPIN-RELEASING HORMONE AGONISTS AND ANTAGONISTS

The most common form of ADT involves chemical suppression of the pituitary gland with GnRH agonists. Synthetic GnRH analogs (Table 63–2) have greater receptor affinity and reduced susceptibility to enzymatic degradation than the naturally occurring GnRH molecule and are 100-fold more potent. Several long-acting preparations are available in doses that are approved for 3-, 4-, and 6-month administrations.

GnRH agonists bind to GnRH receptors on pituitary gonadotropin-producing...
cells, causing an initial release of both LH and FSH and a subsequent increase in testosterone production from testicular Leydig cells. After ~1 week of therapy, GnRH receptors are downregulated on the gonadotropin-producing cells, causing a decline in the pituitary response. The fall in serum LH leads to a decrease in testosterone production to castrate levels within 3-4 weeks of the first treatment. Subsequent treatments maintain testosterone at castrate levels.

During the transient rise in LH, the resultant testosterone surge may induce an acute stimulation of prostate cancer growth and a “flare” of symptoms from metastatic deposits. Patients may experience an increase in bone pain or obstructive bladder symptoms lasting for 2-3 weeks. The flare phenomenon can be effectively counteracted with concurrent administration of 2-4 weeks of oral anti-androgen therapy, which may inhibit the action of the increased serum testosterone levels. Besides avoidance of the initial flare, GnRH antagonist therapy offers no apparent advantage compared with GnRH agonists. The GnRH antagonist, degarelix, is not associated with systemic allergic reactions and is approved for prostate cancer in the U.S.

Combined androgen blockade (CAB) requires administration of ADT with an anti-androgen. The theoretical advantage is that the GnRH agonist will deplete testicular androgens, while the anti-androgen component competes at the receptor with residual androgens made by the adrenal glands. CAB provides maximal relief of androgen stimulation. Several trials suggest a benefit for CAB in 5-year survival but not at earlier time points. Toxicity and costs associated with CAB are higher than with ADT alone.

ANTI-ANDROGENS

Anti-androgens bind to ARs and competitively inhibit the binding of testosterone and dihydrotestosterone. Unlike castration, anti-androgen therapy by itself does not decrease LH production; therefore, testosterone levels are normal or increased. Men treated with anti-androgen monotherapy maintain some degree of potency and libido and do not have the same spectrum of side effects seen with castration. Currently, anti-androgen monotherapy is not indicated as first-line treatment for patients with advanced prostate cancer. Anti-androgens most commonly are used in clinical practice as secondary
hormone therapy or in CAB.

**MECHANISM OF ACTION OF NONSTEROIDAL ANTI-ANDROGENS.** The nonsteroidal anti-androgens are taken orally and inhibit ligand binding and consequent AR translocation from the cytoplasm to the nucleus.

**AVAILABLE ANTI-ANDROGENS.** Anti-androgens are classified as steroidal, including cyproterone and megestrol, or nonsteroidal, including flutamide, bicalutamide (CASODEX, others), and nilutamide (NILANDRON). Cyproterone is associated with liver toxicity and has inferior efficacy compared with other forms of ADT. Cyproterone is not available in the U.S. Neither bicalutamide nor flutamide is approved as monotherapy at any dose for treatment of prostate cancer in the U.S.

*Flutamide.* Flutamide is given as a 250-mg dose every 8 h. It has a $t_{1/2}$ of 5 h; its major metabolite, hydroxyflutamide, is biologically active. Common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur.

*Bicalutamide.* Bicalutamide (CASODEX, others) is taken once daily at a dosage of 50 mg/day when given with a GnRH agonist; it has a $t_{1/2}$ of 5-6 days. Both enantiomers of bicalutamide undergo glucuronidation to inactive metabolites, and the parent compounds and metabolites are eliminated in bile and urine. The elimination $t_{1/2}$ of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. Bicalutamide is well tolerated at higher doses. Daily bicalutamide is significantly inferior compared with surgical or medical castration.

*Nilutamide.* Nilutamide (NILANDRON) is a second-generation anti-androgen that is taken once-daily administration at 150 mg/day. It has an elimination $t_{1/2}$ of 45 h and is metabolized to 5 products that are all excreted in the urine. Common side effects include mild nausea, alcohol intolerance (5-20%), and diminished ocular adaptation to darkness (25-40%); rarely, interstitial pneumonitis occurs. Nilutamide appears to offer no benefit over the first-generation drugs above and has the least favorable toxicity profile.

**ESTROGENS**
High estrogen levels can reduce testosterone to castrate levels in 1-2 weeks via negative feedback on the hypothalamic–pituitary axis. Estrogen also may compete with androgens for steroid hormone receptors and may thereby exert a cytotoxic effect on prostate cancer cells. Estrogens are associated with increased myocardial infarctions, strokes, and pulmonary emboli and increased mortality, as well as impotence, and lethargy. One benefit is that estrogens prevent bone loss.

**INHIBITORS OF STEROIDOGENESIS**

In the castrate state, AR signaling, despite low steroid levels, supports continued prostate cancer growth. AR signaling may occur due to androgens produced from nongonadal sources, AR gene mutations, or AR gene amplification. Nongonadal sources of androgens include the adrenal glands and the prostate cancer cells themselves (see Figure 63–3). Androstenedione, produced by the adrenal glands, is converted to testosterone in peripheral tissues and tumors. Intratumoral de novo androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation. Thus, inhibitors of androgen synthesis may be useful secondary therapy in reducing AR signaling.

**Ketoconazole.** Ketoconazole is an antifungal agent that also inhibits both testicular and adrenal steroidogenesis by blocking CYPs, primarily CYP17 (17α-hydroxylase). Ketoconazole is administered off label as secondary hormone therapy to reduce adrenal androgen synthesis in castration-resistant prostate cancer. Diarrhea and hepatic enzyme elevations limit its use as initial hormone therapy; consequent poor patient compliance reduces its efficacy. Ketoconazole is given in doses of 200 mg or 400 mg 3 times daily. Hydrocortisone (400-mg dose) is coadministered to compensate for inhibition of adrenal steroidogenesis. A related compound, itraconazole, inhibits the activation of Smoothened (SMO), a component of the Hedgehog (Hh) signaling pathway, which is overly active in certain cancers. Thus, this class of antifungal agents may act by several distinct mechanisms and prove useful in treating other cancers.

**Abiraterone.** Abiraterone is an irreversible inhibitor of 17α-hydroxylase and C-17,20-lyase (CYP17) activity, with greater potency and selectivity than ketoconazole. The prodrug abiraterone acetate (ZYTIGA) is approved for use with prednisone in metastatic castration-resistant prostate cancer. With continuous
administration, abiraterone increases ACTH levels, resulting in mineralocorticoid excess. Recommended oral dose of abiraterone acetate is 1000 mg administered once daily (on an empty stomach) with 5 mg prednisone administered twice daily. Side effects include joint swelling, hypokalemia, hot flush, diarrhea, cough, hypertension, arrhythmia, urinary frequency, dyspepsia, and upper respiratory tract infection.
Section IX
Special Systems Pharmacology
The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties.

EXTRAOCULAR STRUCTURES

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 64–1). In the orbit, connective (i.e., Tenon’s capsule) and adipose tissues and 6 extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or globe). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon’s, and retrobulbar injections.

Figure 64–1 Anatomy of the globe in relationship to the orbit and eyelids.
Various routes of administration of anesthesia are demonstrated by the blue needle pathways.

The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the fornix, located superiorly and inferiorly behind the upper and lower lids, respectively. Topical medications usually are placed in the inferior fornix, also known as the inferior cul-de-sac.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 64–2). The secretory system is composed of the main lacrimal gland, which is located in the temporal outer portion of the orbit, and accessory glands located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 64–1 and Chapter 8). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (see Chapter 15), antihistamines (see Chapter 32), and drugs used in the management of Parkinson disease (see Chapter 22).

Figure 64–2 Anatomy of the lacrimal system.

Table 64–1
Tears constitute a trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior layer is composed primarily of lipids; the middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands, constitutes ~98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea. The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (see Figure 64–2). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

**OCULAR STRUCTURES**

The eye is divided into anterior and posterior segments (Figure 64–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm’s canal), iris, lens, zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

ANTERIOR SEGMENT

Cornea and Drug Access. The cornea is a transparent and avascular tissue organized into 5 layers (Figure 64–3B). Representing an important barrier to
foreign matter, including drugs, the hydrophobic epithelial layer comprises 5 to 6 cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman’s membrane, a layer of collagen fibers. Constituting ~90% of the corneal thickness, the stroma, a hydrophilic layer, is organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet’s membrane, the basement membrane of the corneal endothelium. Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal integrity by active transport processes and serve as a hydrophobic barrier. Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophobic–hydrophilic–hydrophobic domains of the various anatomical layers.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1-2 mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the corneal epithelial stem cells, Tenon’s capsule, episclera, corneoscleral stroma, canal of Schlemm, and trabecular meshwork (see Figure 64–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds ~250 µL of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, which holds ~50 µL of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

Aqueous Humor Dynamics and Regulation of Intraocular Pressure (IOP).
Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber and leaves the eye primarily by the trabecular meshwork and canal of Schlemm, thence to an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80-95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see “Glaucoma” and Chapter 33).

The peripheral anterior chamber angle is an important anatomical structure for differentiating 2 forms of glaucoma: open-angle glaucoma, which is by far the most common form of glaucoma in the U.S., and angle-closure glaucoma.
Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production and/or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, by either laser or incision, but short-term medical management may be necessary to reduce the acute IOP elevation and to clear the cornea prior to surgery. Long-term IOP reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork.

In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing through the pupil from the posterior chamber to the anterior chamber. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing the iris base to be pushed against the angle wall, thereby covering the trabecular meshwork and closing the filtration angle and markedly elevating the IOP. The result is known as an acute attack of pupillary-block angle-closure glaucoma.

Iris and Pupil. The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see “Distribution”). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 64–4), which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes miosis (constriction). The use of pharmacological agents to dilate normal pupils and to evaluate the pharmacological response of the pupil is summarized in Table 64–2. Pharmacological agents are also used for the diagnostic evaluation of anisocoria (see Figure 64–5 in the 12th edition of the parent text).
Figure 64–4 Autonomic innervation of the eye by the sympathetic (a) and parasympathetic (b) nervous systems. (Adapted with permission from Wybar KC, Kerr-Muir M. Bailliere’s Concise Medical Textbooks, Ophthalmology, 3rd ed. New York: Bailliere Tindall; 1984. Copyright © Elsevier.)

Solid black arrows represent the corneal route; dashed blue arrows represent the conjunctival/scleral route; the black dashed arrow represents the nasolacrimal absorption pathway. (Adapted with permission from Chien D-S, et al. *Curr Eye Res*, 1990;9(11):1051–1059. Copyright © 1990 Informa Healthcare.)

**Ciliary Body.** The ciliary body serves 2 very specialized roles:
• Secretion of aqueous humor by the epithelial bilayer
• Accommodation by the ciliary muscle

The anterior portion of the ciliary body (pars plicata) comprises 70-80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonule suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as accommodation, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists, through the process called cycloplegia. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This latter effect accounts for at least some of the IOP-lowering effect of both directly acting and indirectly acting parasympathomimetic drugs.

**Lens.** The lens is suspended by zonules, specialized fibers emanating from the ciliary body. The lens is ~10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a cataract.

**POSTERIOR SEGMENT**

Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye’s posterior pole is particularly challenging.

**Sclera.** The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, by Tenon’s capsule, and by the conjunctiva. The tendons of the 6 extraocular muscles insert collagen fibers into the superficial scleral. Numerous blood vessels pierce the sclera through emissaria to both supply and drain the choroid, ciliary body, optic nerve, and iris. Inside the scleral shell, a capillary network (vascular choroid) nourishes the outer retina. Between the outer retina
and the capillary network lie Bruch’s membrane and the retinal pigment epithelium, whose tight junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

Retina. The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels; it contains the photoreceptors and the rhodopsin-based G-protein signaling system.

Vitreous. Approximately 80% of the eye’s volume is the vitreous, a clear medium containing collagen type II, hyaluronic acid, proteoglycans, glucose, ascorbic acid, amino acids, and a number of inorganic salts. Glutamate in the vitreous may have a relationship to glaucoma: ganglion cells appear to die in glaucoma via apoptosis, a process that glutamate, acting on NMDA receptors, can stimulate. Memantine, a noncompetitive NMDA receptor antagonist, is currently being investigated clinically as a treatment for glaucoma.

Optic Nerve. The optic nerve is a myelinated nerve conducting the retinal output to the CNS. It comprises:

• An intraocular portion, which is visible as the optic disk in the retina
• An intraorbital portion
• An intracanalicular portion
• An intracranial portion

The nerve is ensheathed in meninges continuous with the brain. At present, pharmacological treatment of optic neuropathies usually is based on management of the underlying disease. For example, nonarteritic ischemic optic neuropathy is best treated with intravitreal glucocorticoids, and optic neuritis with intravenous glucocorticoids. Glaucomatous optic neuropathy is medically managed by decreasing IOP.

PHARMACOKINETICS AND TOXICOLOGY OF OCULAR THERAPEUTIC AGENTS
Drug-Delivery Strategies. Properties of varying ocular routes of administration are outlined in Figure 64–1 and Table 64–3.

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. *Prolonging the time in the cul-de-sac beneath the eye lid facilitates drug absorption.* Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a zero-order rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a prolonged period of time rather than as a bolus.

PHARMACOKINETICS. The pharmacokinetic principles of absorption, distribution, metabolism, and excretion determine the time
course of drug action in the eye, however, the routes of ocular drug administration, the flow of ocular fluids, and the architecture of the eye introduce other variables specific to the eye. Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon’s, and retrobulbar routes.

**ABSORPTION.** After topical instillation of a drug, the rate and extent of absorption are determined by the time the drug remains in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva. A drug’s residence time may be prolonged by changing its formulation. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver; thus, topical ophthalmic medications can cause significant systemic side effects, especially when used chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 64–5.

Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug’s diffusion capacity are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is a differential solubility process; the cornea resembles a trilaminar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, a drug with both hydrophilic and lipophilic properties is best suited for transcorneal absorption. Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal epithelial defects and corneal ulcers, may alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed.

**DISTRIBUTION.** Topically administered drugs may undergo systemic
distribution primarily by nasal mucosal absorption and possibly by local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures and potentially to the systemic circulation via the trabecular meshwork pathway (see Figure 64–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of α adrenergic–receptor agonists is slower in onset in human volunteers with darkly pigmented irides compared to those with lightly pigmented irides: drug-melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see Chapter 49) causes a toxic retinal lesion known as a “bull’s-eye” maculopathy, which is associated with a decrease in visual acuity.

METABOLISM. Biotransformation of ocular drugs may be significant; a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, GSH-conjugating enzymes, COMT, MAO, and 11 β-hydroxysteroid dehydrogenase are found in the eye. The esterases have been of particular interest, permitting development of ester prodrugs for enhanced corneal permeability (e.g., dipivefrin hydrochloride is a prodrug for epinephrine, and latanoprost is a prodrug for PGF\(_2\alpha\); both drugs are used for glaucoma management).

TOXICOLOGY. Most local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periorcular skin, and nasal mucosa. Eyedrops and contact lens solutions commonly contain antimicrobial preservatives such as benzalkonium chloride, chlorobutanol, chelating agents, and, rarely, thimerosal. In particular, benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy. All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 64–5), so systemic side effects may occur.

*For specific information on dosing, formulation, and trade names, refer to the Physicians’ Desk Reference for Ophthalmic Medicines, which is published annually.

*Polymyxin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gentamicin, oxytetracycline, or trimethoprim. See Chapters 52–55 for further discussion of these antibiotic agents.

THERAPEUTIC USES OF OCULAR ANTIMICROBIALS. Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (i.e., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral...
antibiotics are administered.

**Dacryoadenitis**, an infection of the lacrimal gland, is most common in children and young adults; it may be bacterial (typically *Staphylococcus aureus*, *Streptococcus* spp.) or viral (seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

**Dacryocystitis** is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicular infections may be caused by *S. aureus*, *Streptococcus* spp., diphtheroids, *Candida* spp., and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the lids include *hordeolum* and *blepharitis*. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands at the eyelid margins. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic (gel, drops, or ointment). Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, usually associated with a *Staphylococcus* sp. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used. Systemic tetracycline, doxycycline, minocycline, and erythromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

**Conjunctivitis** is an inflammatory process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. The less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. The more commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus, vaccinia variola virus) and bacterial sources (e.g., *Neisseria* spp., *Streptococcus pneumoniae*, *Haemophilus* spp., *S. aureus*, *Moraxella lacunata*, and chlamydial spp.). *Rickettsia*, fungi, and parasites, in both cyst and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an
appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

*Keratitis*, or corneal inflammation, can occur at any level of the cornea. Numerous microbial agents have been identified as causes of infectious keratitis, including bacteria, viruses, fungi, spirochetes, and cysts and trophozoites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates). Mild, small, more peripheral infections usually are not cultured, and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for cultures and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture and sensitivity results.

*Endophthalmitis* is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis usually is caused by bacteria or fungi, or rarely by spirochetes. The typical case occurs during the early postoperative course (e.g., after cataract, glaucoma, cornea, or retinal surgery), following trauma, or by endogenous seeding in an immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics. Immediate vitrectomy (i.e., specialized surgical removal of the vitreous) is beneficial for patients who have light perception–only vision. Vitrectomy for other causes of endophthalmitis (e.g., glaucoma bleb related, posttraumatic, or endogenous) may be beneficial. In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source, but the efficacy of systemic antibiotics with trauma is not well established.

**ANTIVIRAL AGENTS.** Antiviral drugs used in ophthalmology are summarized in Table 64–5 (see Chapter 58 for details of these agents).

* PK, punctate keratopathy; H, hypersensitivity. *Off-label use. For additional details, see Chapter 58.

THERAPEUTIC USES. The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus, and retinitis. There currently are no antiviral agents for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated by symptomatic relief of irritation.

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and CMV. Topical antiviral agents are indicated for the treatment of epithelial disease due to herpes simplex infection. When treating viral keratitis topically, there is a very narrow margin between the therapeutic topical antiviral activity and the toxic effect on the cornea; hence, patients must be followed very closely. Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis (predominantly a cell-mediated immune reaction), topical glucocorticoids accelerate recovery. For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral acyclovir in reducing the risk of recurrence.
**Herpes zoster ophthalmicus** is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus. Currently, there are no ophthalmic preparations of acyclovir approved by the FDA, although an ophthalmic ointment is available for investigational use.

**Viral retinitis** may be caused by herpes simplex virus, CMV, adenovirus, and varicella zoster virus. With highly active antiretroviral therapy (HAART; see Chapter 59), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis. Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal ganciclovir has been found to be an effective alternative to systemic use. Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by various combinations of oral, intravenous, intravitreal injection of, and intravitreal implantation of antiviral medications.

**ANTIFUNGAL AGENTS**

The only currently available topical ophthalmic antifungal preparation is a polyene, natamycin (NATACYN). Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, or intravitreal routes of administration (Table 64–6; see also Chapter 57).

<thead>
<tr>
<th>Table 64–6</th>
</tr>
</thead>
</table>

**Antifungal Agents for Ophthalmic Use**
THERAPEUTIC USES. As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Ophthalmic indications for antifungal medications include fungal keratitis, scleritis, endophthalmitis, mucormycosis, and canaliculitis. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

ANTIPROTOZOAL AGENTS

Parasitic infections involving the eye usually manifest themselves as a form of uveitis, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis.

THERAPEUTIC USES. In the U.S., the most commonly encountered protozoal infections include Acanthamoeba and Toxoplasma gondii. In contact lens wearers who develop keratitis, physicians should be highly suspicious of the
presence of Acanthamoeba. Risk factors for Acanthamoeba keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The aromatic diamidines (i.e., propamidine isethionate in both topical aqueous and ointment forms [BROLENE, NOT AVAILABLE IN U.S.]) have been used successfully to treat this relatively resistant infectious keratitis. The cationic antiseptic agent polyhexamethylene biguanide (PHMB) also is used in drop form for Acanthamoeba keratitis. Topical chlorhexidine can be used as an alternative to PHMB. Oral imidazoles (e.g., itraconazole, fluconazole, ketoconazole, voriconazole) often are used in addition to the topical medications. Resolution of Acanthamoeba keratitis often requires many months of treatment.

Treatment of toxoplasmosis is indicated when inflammatory lesions encroach upon the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids: (1) pyrimethamine, sulfadiazine, and folinic acid (leucovorin); (2) pyrimethamine, sulfadiazine, clindamycin, and folinic acid; (3) sulfadiazine and clindamycin; (4) clindamycin; (5) trimethoprim-sulfamethoxazole ± clindamycin. Other protozoal infections (e.g., giardiasis, leishmaniasis, malaria) and helminths are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections.

AUTONOMIC AGENTS

THERAPEUTIC USES. Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus. The autonomic agents used in ophthalmology and the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 64–7.

*Same as for atropine*
Glaucoma. Glaucoma is characterized by progressive optic nerve cupping and visual field loss. Risk factors include increased IOP, positive family history of glaucoma, African American heritage, and possibly myopia and hypertension. Reducing IOP can delay glaucomatous nerve or field damage. Although markedly elevated IOPs (e.g., >30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients (ocular hypertensives) apparently can tolerate IOPs in the mid- to high 20s. Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range, and this form of the disease sometimes is called normal- or low-tension glaucoma. A reduction of IOP by 30% reduces disease progression from ~35-10%, even for normal-tension glaucoma patients. At present the pathophysiological processes
involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood. Current pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique for glaucoma therapy.

A stepped medical approach depends on the patient’s health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. A stepped medical approach may begin with a **topical prostaglandin (PG)** analog. Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogs have largely replaced β adrenergic–receptor antagonists as first-line medical therapy for glaucoma. The PG analogs consist of latanoprost (XALATAN), travoprost (TRAVATAN, TRAVATAN Z), bimatoprost (LUMIGAN, LATISSE), and tafluprost (ZIOPTAN). PGF$_{2α}$ reduces IOP but has intolerable local side effects. Modifications to the chemical structure of PGF$_{2α}$ have produced analogs with a more acceptable side-effect profile. The mechanism by which this occurs is unclear. PGF$_{2α}$ and its analogs (prodrugs that are hydrolyzed to PGF$_{2α}$) bind to FP receptors that link to G$_{q11}$ and then to the PLC–IP$_3$–Ca$_{2+}$ pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by PGF$_{2α}$ range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts.

The **β receptor antagonists** now are the next most common topical medical treatment. Nonselective β blockers bind to both β$_1$ and β$_2$ receptors and include timolol, levobunolol, metipranolol, and carteolol. The β$_1$-selective antagonist, betaxolol, is available for ophthalmic use but is less efficacious than the nonselective β blockers because the β receptors of the eye are largely of the β$_2$ subtype. However, betaxolol is less likely to cause breathing difficulty due to blockade of pulmonary β$_2$ receptors. In the eye, the targeted tissues are the
ciliary body epithelium and blood vessels, where β₂ receptors account for 75-90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β receptor–mediated cyclic AMP–PKA pathway; β blockade blunts adrenergic activation of this pathway. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production.

When there are medical contraindications to the use of PG analogs or β receptor antagonists, other agents, such as an α₂ adrenergic receptor agonist or topical carbonic anhydrase inhibitor (CAI), may be used as first-line therapy. The α₂ adrenergic agonists appear to decrease IOP by reducing aqueous humor production and by enhancing both conventional (via an α₂ receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. Although effective, epinephrine is poorly tolerated, principally due to localized irritation and hyperemia. Dipivefrin is an epinephrine prodrug that is converted into epinephrine by esterases in the cornea; it is much better tolerated but is still prone to cause epinephrine-like side effects. The α₂ adrenergic agonist and clonidine derivative, apraclonidine (IOPIDINE), is a relatively selective α₂ adrenergic agonist that is highly ionized at physiological pH and does not cross the blood-brain barrier, and is thus relatively free of the CNS effects of clonidine. Brimonidine (ALPHAGAN, others) also is a selective α₂ adrenergic agonist but is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α₂ receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α₂ receptors, these drugs stimulate the G₁ pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production.

The development of a topical CAI was prompted by the poor side-effect profile of oral CAIs. Dorzolamide (TRUSOPT, others) and brinzolamide (AZOPT) both work by inhibiting carbonic anhydrase (isoform II), which is found in the ciliary body epithelium. This reduces the formation of bicarbonate ions, which reduces fluid transport and, thus, IOP.

Any of these 4 drug classes can be used as additive second- or third-line therapy.
In fact, the β receptor antagonist timolol has been combined with the CAI dorzolamide in a single medication (COSOPT, others) and with the α2 adrenergic agonist brimonidine (COMBigan). Such combinations reduce the number of drops needed and may improve compliance.

**Topical miotic agents** are less commonly used today because of their numerous side effects and inconvenient dosing. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors. Echothiophate (PHOSPHOLINE IODIDE) is an organophosphate inhibitor of acetylcholinesterase; it is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then **systemic therapy with CAI** is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 25), followed by methazolamide. The least well tolerated are acetazolamide tablets.

**TOXICITY OF ANTI-GLAUCOMA AGENTS.** Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. α2 Agonists, effective in IOP reduction, can cause a vasoconstriction–vasodilation rebound phenomenon leading to a red eye. Ocular and skin allergies from topical epinephrine, related prodrug formulations, apraclonidine, and brimonidine are common. Brimonidine is less likely to cause ocular allergy and therefore is more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children <2 years of age. Systemic absorption of α2 agonists and β adrenergic antagonists can induce all the side effects of systemic administration. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects.

_Uveitis._ Inflammation of the uvea, or uveitis, has both infectious and non-infectious causes, and medical treatment of the underlying cause (if known), in
addition to the use of topical therapy, is essential. Cyclopentolate (Cyclogyl, others), tropicamide (Mydriacyl), or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine (Isopto Hyoscine), and homatropine frequently are used to prevent posterior synechia formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution of scopolamine 0.3% in combination with 10% phenylephrine (Murowcoll-2) is available for this purpose. Two others, 1% hydroxyamphetamine hydrobromide combined with 0.25% tropicamide (Paremyd) and 1% phenylephrine in combination with 0.2% cyclopentolate (Cyclomydrol), are indicated only for induction of mydriasis. Topical steroids usually are adequate to decrease inflammation, but sometimes they must be supplemented with systemic steroids.

Strabismus. Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing diplopia (double vision), strabismus in children may lead to amblyopia (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with hyperopia, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest esotropia (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by ~7 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. This is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye. Echothiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echothiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.
**Surgery and Diagnostic Purposes.** For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose (see Table 64–7). Intraoperatively, there are circumstances in which miosis is preferred, and 2 cholinergic agonists are available for intraocular use, acetylcholine (Miochol-E) and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or lid droop (ptosis); the edrophonium test is helpful in diagnosing these patients (see Chapter 10). For surgical visualization of the lens, trypan blue (VisionBlue) is marketed to facilitate visualization of the lens and for staining during surgical vitrectomy procedures to guide the excision of tissue (MembraneBlue).

**ANTI-INFLAMMATORY, IMMUNOMODULATORY, AND ANTIMITOTIC DRUGS**

**GLUCOCORTICOIDS.** Glucocorticoids have an important role in managing ocular inflammatory diseases; their chemistry and pharmacology are described in Chapter 42.

**Therapeutic Uses.** The glucocorticoids formulated for topical administration to the eye are dexamethasone (Dexasol, others), prednisolone (Pred Forte, others), fluorometholone (FML, others), loteprednol (Alrex, Lotemax), rimexolone (Vexol), and difluprednate (Durezol). Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, anterior uveitis, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site. Steroids commonly are given systemically and by sub-Tenon’s capsule injection to manage posterior uveitis. Intravitreal injection of steroids is used to treat age-related macular degeneration (ARMD), diabetic retinopathy, and cystoid macular edema. Two intravitreal triamcinolone formulations, Trivaris and Triensure, are approved for ocular inflammatory conditions unresponsive to topical corticosteroids and visualization during vitrectomy,
respectively. Parenteral steroids followed by tapering oral doses is the preferred treatment for optic neuritis. An ophthalmic implant of fluocinolone (RETISERT) is marketed for the treatment of chronic, non-infectious uveitis.

**Toxicity of Steroids.** Ocular complications include the development of posterior subcapsular cataracts, secondary infections, and secondary open-angle glaucoma. There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only ~5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however, moderate to marked steroid-induced IOP elevations may occur in up to 90% of patients. Newer topical steroids, so-called “soft steroids” (e.g., loteprednol), have been developed that reduce, but do not eliminate, the risk of elevated IOP.

**Nonsteroidal Anti-Inflammatory Agents.** Pharmacological properties of nonsteroidal anti-inflammatory drugs (NSAIDs) are presented in Chapter 34.

**Therapeutic Uses.** Five topical NSAIDs approved for ocular use: flurbiprofen (OCUFEN, others), ketorolac (ACULAR, others), diclofenac (VOLTAREN, others), bromfenac (XIBROM), and nepafenac (NEVANAC). Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. Diclofenac is used for postoperative inflammation. Both ketorolac and diclofenac are effective in treating cystoid macular edema occurring after cataract surgery and in controlling pain after corneal refractive surgery. Bromfenac and nepafenac are indicated for treating postoperative pain and inflammation after cataract surgery. Topical and systemic NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

**ANTIＨＩＳＴＡＭＩＮＥＳ ＡＮＤ ＭＡＳＴ-ＣＥＬＬ ＳＴＡＢＩＬＩＺＥＲＳ**

Pheniramine (see Chapter 32) and antazoline, both H1 receptor antagonists, are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis; emedastine
difumarate (EMADINE) also is used. Cromolyn sodium (CROLOM, others) has found limited use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. Lodoxamide tromethamine (ALOMIDE) and pemirolast (ALAMAST), mast-cell stabilizers, also are available for ophthalmic use. Nedocromil (ALOCRIL) also is primarily a mast-cell stabilizer with some antihistamine properties. Olopatadine hydrochloride (PATANOL, PATADAY), ketotifen fumarate (ZADITOR, ALAWAY), bepotastine (BEPREVE), and azelastine (OPTIVAR) are H₁ antagonists with mast cell–stabilizing properties. Epinastine (ELESTAT) antagonizes H₁ and H₂ receptors and exhibits mast cell–stabilizing activity.

**IMMUNOSUPPRESSANTS**

Topical cyclosporine (cyclosporin A; RESTASIS) is approved for the treatment of chronic dry eye associated with inflammation. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort. Interferon α-2b is used in the treatment of conjunctival papilloma and certain conjunctival tumors.

**ANTIMITOTIC AGENTS.** In glaucoma surgery, the anti-neoplastic agents fluorouracil and mitomycin (MUTAMYCIN) (see Chapter 61) improve the success of filtration surgery by limiting the postoperative wound-healing process.

*Therapeutic Uses.* Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. Fluorouracil may be used intraoperatively at the trabeculectomy site and/or subconjunctivally during the postoperative course. Both agents work by limiting the healing process; sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection. In corneal surgery, mitomycin has been used topically. Mitomycin can be used to reduce the risk of scarring after procedures to remove corneal opacities and prophylactically to prevent corneal scarring after
photorefractive and phototherapeutic keratectomy. Mitomycin also is used to treat certain conjunctival and corneal tumors. Caution is advocated when using mitomycin in light of the potentially serious delayed ocular complications.

Intraocular methotrexate (see Chapter 61) is used to treat uveitis and uveitic cystoid macular edema. It also has been used to treat the uncommon complication of lymphoma in the vitreous, an inaccessible compartment for most anti-neoplastic drugs.

**AGENTS USED IN OPHTHALMIC SURGERY**

*Presurgical Antiseptics.* Povidone iodine (BETADINE) is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prep periocular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. Hypersensitivity to iodine is a contraindication.

*Viscoelastic Substances.* Such agents assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate (HEALON, others), chondroitin sulfate (VISCOAT), or hydroxypropylmethylcellulose and share the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Complications associated with viscoelastic substances are related to transient elevation of IOP after surgery.

*Ophthalmic Glue.* Cyanoacrylate tissue adhesive (ISODONT, DERMABOND, HISTOACRYL), while not FDA-approved for the eye, is widely used in the management of corneal ulcerations and perforations. Fibrinogen glue (TISSEEL, EVICEL) is increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts.

*Anterior Segment Gases.* Sulfur hexafluoride (SF₆) and perfluoropropane gases are used as vitreous substitutes during retinal surgery. They are used in non-expansile concentrations to treat Descemet’s detachments, typically after cataract surgery. These detachments can cause mild to severe corneal edema. The gas is injected into the anterior chamber to push Descemet’s membrane up against the stroma, where ideally it reattaches and clears the corneal edema.
Vitreous Substitutes (*Table 64–8*). Several compounds, including gases, perfluorocarbon liquids, and silicone oils are available. Their primary use is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. The use of expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons (specific gravity, 1.76-1.94) are denser than vitreous and are helpful in flattening the retina when vitreous is present. Silicone oil (polydimethylsiloxanes; AdatoSil 5000) is used for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

**Surgical Hemostasis and Thrombolytic Agents.** Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially
significant inflammatory response may occur that can be minimized by thorough irrigation after hemostasis is achieved.

*Recombinant tissue plasminogen activator* (t-PA; alteplase) (see Chapter 30) has been used during intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage. Alteplase also has been administered subconjunctivally and intracamerally (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of t-PA is bleeding.

**Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders.** Botulinum toxin type A is FDA-approved for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), axillary hyperhidrosis, and spasmodic torticollis (cervical dystonia). Two botulinum toxin type A preparations are marketed in the U.S.: onabotulinumtoxin A (*BOTOX, BOTOX COSMETIC*) and abobotulinumtoxinA (*DYSPORT*). By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. Complications related to this toxin include double vision (diplopia) and lid droop (ptosis) and, rarely, potentially life-threatening distant spread of toxin effect from the injection site (hours to weeks after administration).

**Agents Used to Treat Blind and Painful Eye.** Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

**Ocular Side Effects of Systemic Agents**

Certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening. Examples are listed in the following sections.
Glaucoma. The anti-seizure drug topiramate (TOPAMAX, others) reportedly causes choroidal effusions leading to angle-closure glaucoma.

Retina. Numerous drugs have toxic side effects on the retina. The anti-arthritis and antimalarial medicines hydroxychloroquine (PLAQUENIL, others) and chloroquine can cause a central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until ~6 years after the drug is started. Stopping the drug will not reverse the damage but will prevent further toxicity. Tamoxifen can cause a crystalline maculopathy. The antiseizure drug vigabatrin (SABRIL) causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

Optic Nerve. The PDE5 inhibitors, sildenafil (VIAGRA, REVATIO), vardenafil (LEVITRA), and tadalafil (CIALIS, ADCIRCA), inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection. The drugs also mildly inhibit PDE6, which controls the levels of cyclic GMP in the retina, causing a bluish haze or light sensitivity. Multiple medications can cause a toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss, including ethambutol, chloramphenicol, and rifampin. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

Anterior Segment. Steroids have been implicated in cataract formation. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of Mycobacterium avium complex (MAC) opportunistic infections in human immunodeficiency virus (HIV)-positive persons, is associated with an iridocyclitis and even hypopyon. This will resolve with steroids or by stopping the medication.

Ocular Surface. Isotretinoin (ACCUPLAN, others) has a drying effect on mucous membranes and is associated with dry eye and meibomian gland dysfunction.

Cornea Coryanghiva and Eyelids. The cornea, conjunctiva, and eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed cornea verticillata, appearing as fine tan or brown pigment in the epithelium. The deposits seldom affect vision and are rarely a cause to discontinue the medication. The deposits
disappear slowly when the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern. The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmented deposits in the cornea, conjunctiva, and eyelids. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone.

**AGENTS USED TO ASSIST IN OCULAR DIAGNOSIS**

A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity), to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics), and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed earlier. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed below.

**Anterior Segment and External Diagnostic Uses.** Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes fluorescein, rose bengal, and lissamine green are used in evaluating these problems. **Fluorescein** (available as a 2% alkaline solution, 10% and 25% solutions for injection, and an impregnated paper strip) reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to determine the patency of the nasolacrimal system. In addition, this dye is used in **applanation tonometry** (IOP measurement) and to assist in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. **Fluorexon (FLUORESOFT)**, a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place). **Rose bengal** and **lissamine green** (available as saturated paper strips) stain devitalized tissue on the cornea and conjunctiva.
**Posterior Segment Diagnostic Uses.** The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either **fluorescein sodium** or **indocyanine green**. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

**TREATMENT OF RETINAL NEOVASCULARIZATION AND MACULAR DEGENERATION**

**Verteporfin** (**Visudyne**) is approved for photodynamic therapy of the exudative form of ARMD with predominantly classic choroidal neovascular membranes. Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. Verteporfin is administered intravenously; once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Activation of the drug in the presence of oxygen generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The $t_{1/2}$ of the drug is 5-6 h; it is eliminated predominantly in the feces. Potential side effects include headache, injection-site reactions, and visual disturbances. The drug causes temporary photosensitization; patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving it.

**Pegaptanib** (**Macugen**), a selective vascular endothelial growth factor (VEGF) antagonist, is approved for neovascular (wet) ARMD. VEGF$_{165}$ induces angiogenesis and increases vascular permeability and inflammation, which actions likely contribute to the progression of the neovascular (wet) form of ARMD, a leading cause of blindness. Pegaptanib inhibits VEGF$_{165}$ binding to VEGF receptors. Pegaptanib (0.3 mg) is administered once every 6 weeks by intravitreous injection into the eye to be treated. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported.

**Eylea** (**Aflibercept**) is a recombinant fusion protein, consisting of portions of human VEGF receptors 1 and 2, that acts as a soluble decoy receptor for VEGF-
A. It is approved for neovascular (wet) form of ARMD. Aflibercept (2 mg) is administered once every 4 weeks by intravitreous injection into the eye for 12 weeks followed by 2 mg once every 8 weeks. Serious side effect may include eye pain or redness, swelling, vision problems, photosensitivity, headaches, sudden numbness on one side of the body, confusion, and problems with speech and balance. The drug is contraindicated in patients who have an active eye inflection active ocular inflammation.

**Bevacizumab** (AVASTIN) is a monoclonal murine antibody that targets VEGF-A and thereby inhibits vascular proliferation and tumor growth (see Chapter 62).

**Ranibizumab** (LUCENTIS) is a variant of bevacizumab that has had the Fab domain affinity matured. Both drugs are delivered by intravitreal injection and often are used on a weekly or monthly basis for maintenance therapy. Both have been associated with the risk of cerebral vascular accidents.

**ANESTHETICS IN OPHTHALMIC PROCEDURES**

Topical anesthetic agents used clinically in ophthalmology include proparacaine and tetracaine drops, lidocaine gel (see Chapter 20), and intranasal cocaine.

Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system. Lidocaine and bupivacaine are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is ketamine, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extraocular muscles, which may result in expulsion of intraocular contents.

**VITAMIN A**
Vitamin deficiencies can alter eye function, especially a deficiency of vitamin A (Table 64–9). In vision, the functional form of vitamin A is *retinal*; its deficiency interferes with vision in dim light, contributing to a condition known as *night blindness* (nyctalopia).

**Chemistry and Terminology.** *Retinoid* refers to the chemical entity *retinol* and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogs that need not have retinol-like (vitamin A) activity. The purified plant pigment carotene (provitamin A) is a protean source of vitamin A. β-Carotene is the most active carotenoid found in plants. The structural formulas for β-carotene and the vitamin A family of retinoids are shown in Figure 64–6. Retinoic acid analogs used clinically are discussed in detail in Chapter 65.
Photoreception is accomplished by 2 types of specialized retinal cells, termed rods and cones. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The chromophore of both rods and cones is 11-cis-retinal. The holoreceptor in rods is termed rhodopsin—a combination of the protein opsin and 11-cis-retinal attached as a prosthetic group. The 3 different types of cone cells (red, green, and blue) contain individual, related photoreceptor proteins and respond optimally to light of different wavelengths. Figure 64–7 summarizes the signaling pathway initiated by absorption of a photon by 11-cis-retinal in rods.
Figure 64–7 A pharmacologist’s view of photoreceptor signaling. The system is an example of GPCR signaling. The basal state (DARK) is represented by the shaded area to the left. The signal, a photon, activates the receptor, rhodopsin, resulting in the isomerization of 11-cis-retinal to all-trans-retinal and initiating the LIGHT reactions (on the right side of the figure). The main characteristics of the DARK and LIGHT states are summarized in the boxes at the bottom of each section. The guanylyl cyclase activity is constitutively active and enhanced by Ca$^{2+}$. Mostly Na$^+$ and some Ca$^{2+}$ enter via the CNG channels, contributing to depolarization. The Na$^+$/Ca$^{2+}$ exchanger (NCX), Na$^+/K^+$ ATPase, and K$^+$ currents are active and contribute to hyperpolarization. PDE5 inhibitors such as sildenafil also inhibit PDE6, causing a bluish cast to vision. $\alpha_t$, the $\alpha$ sub-unit of
VITAMIN A DEFICIENCY AND VISION. Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. Upon depletion of retinol from liver and blood, usually at plasma concentrations of retinol of <0.2 mg/L (0.70 µM), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency is overcome, opsin, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs.

Vitamin A and Epithelial Structures. In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells. In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness. Common causes of vitamin A deficiency include malnutrition and bariatric surgery.

Retinoic acid influences gene expression by combining with nuclear receptors (see Figures 3–12 and 6–8). There are 2 families of retinoid receptors: the retinoic acid receptors (RARs), and the retinoid X receptors (RXRs). The endogenous RXR ligand is 9-cis-retinoic acid.

Therapeutic Uses. Nutritional vitamin A deficiency causes xerophthalmia, a progressive disease characterized by nyctalopia (night blindness), xerosis (dryness), and keratomalacia (corneal thinning), which may lead to corneal perforation. Vitamin A therapy can reverse xerophthalmia; however, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have a role in corneal epithelial wound healing. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an
ophthalmologist and to avoid high-dose vitamin E. Clinical studies suggest a reduction in the risk of progression of some types of ARMD by high doses of vitamins C (500 mg), E (400 IU), β-carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg).

**WETTING AGENTS AND TEAR SUBSTITUTES**

The current management of dry eyes usually includes instilling artificial tears and ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film.

Common viscosity agents include cellulose polymers, polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel-like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. **Tyloxapol** (ENUCLENE) is marketed as an over-the-counter ophthalmic preparation used to facilitate the wearing comfort of artificial eyes. The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision, and consequently, they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions. A hydroxypropyl cellulose ophthalmic insert (LACRISERT) that is placed in the inferior cul-de-sac and dissolves during the day is available to treat dry eyes.

**Therapeutic Uses.** Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see “Absorption”), or ophthalmic cyclosporine (see “Immunosuppressants”). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson
syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes, ophthalmic cyclosporine, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic cyclosporine (RESTASIS) can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca.

OSMOTIC AGENTS

The main osmotic drugs for ocular use are glycerin, mannitol, and hypertonic saline. Glycerin and mannitol are used for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol and/or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. Sodium chloride is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical glycerin, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.
The skin is a multifunctional and multicompartment organ. Figure 65–1 outlines general features of skin structure and percutaneous absorption pathways. Drugs can be applied to skin for 2 purposes: to directly treat disorders of the skin and to deliver drugs to other tissues.

**Figure 65–1** Cutaneous drug delivery. Diagrammatic representation of the 3 compartments of the skin as they relate to drug delivery: surface, stratum (Str.), and viable tissues. After application of a drug to the surface, evaporation and structural/compositional alterations occur that determine the drug’s
bioavailability. The stratum corneum limits diffusion of compounds into the viable skin and body. After absorption, compounds either bind targets in viable tissues or diffuse within the viable tissue or into the cutaneous vasculature, and thence to internal cells and organs. (Reproduced with permission from Wolff K, et al., eds. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York: McGraw-Hill; 2008, Figure 215–1. Copyright © 2008 by The McGraw-Hill Companies, Inc. All rights reserved.)

Non-pharmacological therapy for skin diseases includes the entire electromagnetic spectrum applied by many sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and prodrugs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are used to decrease the effect of various wavelengths of ultraviolet (UV) light and ionizing radiation.

**Stratum Corneum.** The stratum corneum (outer 5-600 μm) is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. Many drugs may partition into the stratum corneum and form a reservoir that will diffuse into the rest of skin even after topical application of the drug has ceased. The stratum corneum differs in thickness, with the palm and sole being the thickest (400-600 μm) followed by the general body stratum corneum (10-16 μm), and the scrotum (5 μm). Facial and post-auricular regions have the thinnest stratum corneum.

**Living Epidermis.** The living layers of the epidermis with metabolically active cells comprise a layer ~100 thick (Figure 65–2). Intercalated in the living epidermis are pigment-producing cells (melanocytes), dendritic antigen-presenting cells (Langerhans cells), and other immune cells (γ-δ T-cells); in diseased epidermis, many immunological cells, including lymphocytes and polymorphonuclear leucocytes, may be present and be directly affected by applied drugs.
Figure 65–2 Structure of the epidermis. The epidermis matures progressively from the stratum basale (SB) to the stratum spinosum (SS), stratum granulosum (SG), and stratum corneum (SC). Important structural and metabolic proteins are produced at specific layers of the epidermis. (Reproduced with permission from Wolff K, et al., eds. Fitzpatrick’s Dermatology in General Medicine, 7th ed. New York: McGraw-Hill; 2008, Figure 45–2. Copyright © 2008 by The McGraw-Hill Companies, Inc. All rights reserved.)

Dermis and Its Blood Vessels. The superficial capillary plexus between the epidermis and dermis is the site of the majority of the systemic absorption of cutaneous drugs (see Figure 65–1). There are large numbers of lymphatics as well. Beneath the 1.2-mm-thick dermis with its collagen and proteoglycans that may bind drugs there, targets for drugs include mast cells (permanent residents and producers of many inflammatory mediators) and infiltrating immune cells producing cytokines. Hair follicles form a lipid-rich pathway for drug
absorption. Sweat glands are not known as a pathway for the absorption of drugs. Some drugs (e.g., griseofulvin, ketoconazole) are excreted to the skin by this route.

**MECHANISMS OF PERCUTANEOUS ABSORPTION.** Passage through the outermost layer is the rate-limiting step for percutaneous absorption. Preferable characteristics of topical drugs include low molecular mass (<600 Da), adequate solubility in both oil and water, and a high partition coefficient so the drug will selectively partition from the vehicle to the stratum corneum. Except for very small particles, water-soluble ions and polar molecules do not penetrate significantly through intact stratum corneum. The exact amount of drug entering or leaving the skin in clinical situations usually is not measured; rather, the clinical endpoint (e.g., reduction in inflammation) usually is the desired effect.

A hydrated stratum corneum allows more percutaneous absorption and often is achieved through the selection of drugs formulated in occlusion vehicles such as ointments and the use of plastic films, wraps, or bags for the hands and feet and shower or bathing caps for the scalp, or through the use of medications that are impregnated on patches or tapes. Occlusion may be associated with increased growth of bacteria with resultant infection (folliculitis) or maceration and breakdown of the epidermis. Transport of most drugs is a passive thermodynamic process, and heat generally increases penetration. Ultrasonic energy or laser-induced vibration also can be used to increase percutaneous absorption. The latter may function by the production of lacunae in the stratum corneum.

The epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment. A specific CYP isoform, CYP26A1, metabolizes retinoic acid and may control its level in the skin. In addition, transporter proteins that influence influx (OATP) or efflux (MDR, P-glycoprotein) of certain xenobiotics are present in human keratinocytes. Genetic variants of enzymes that regulate the cellular influx and efflux of methotrexate have been associated with toxicity and effectiveness in patients with psoriasis.

**PHARMACOLOGIC IMPLICATIONS OF EPIDERMAL STRUCTURE.** The healthcare provider, when proposing topical application of drugs (Table 65–1), must consider proper dosage and frequency of application, extent and condition of the permeability barrier, patient age and weight, physical form of the
preparation to be applied, and whether intralesional or systemic administration should be used. Various drug vehicles have specific advantages and disadvantages (Table 65–2). Newer vehicles include liposomes and microgel formulations that can enhance solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy. *Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in a greater systemic exposure.*

**Vehicles for Topically Applied Drugs**
GLUCOCORTICOIDS

Glucocorticoids have immunosuppressive and anti-inflammatory properties. They are administered locally, through topical and intralesional routes, and systemically, through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are discussed in Chapter 42.

TOPICAL GLUCOCORTICOIDS. Topical glucocorticoids have been grouped into 7 classes in order of decreasing potency (Table 65–3).
Therapeutic Uses. Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies among body areas; the steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Twice-daily application of topical glucocorticoids is sufficient, and more frequent application does not improve response. In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin. Intralesional preparations
of glucocorticoids include insoluble preparations of triamcinolone acetonide (KENALOG-10) and triamcinolone hexacetonide (ARISTOSPAN), which solubilize gradually and therefore have a prolonged duration of action.

Toxicity. Chronic use of class 1 topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used on this site. Occlusion increases the risk of HPA suppression.

SYSTEMIC GLUCOCORTICOIDS. Systemic glucocorticoid therapy is used for severe dermatological illnesses and generally reserved for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 42).

Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects are seen with alternate-day dosing; if chronic therapy is required, prednisone usually is tapered to every other day as soon as practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate (SOLU-MEDROL, others) is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multi-system disease, and dermatomyositis. The dose usually is 0.5-1 g given over 2-3 h. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

Toxicity and Monitoring. Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 42. Most side effects are dose-dependent.

RETINOIDS

Retinoids comprise natural and synthetic compounds that exhibit vitamin A–like biological activity or bind to nuclear receptors for retinoids (see Figures 3–12 and 6–8). Characteristics of topical and
systemic retinoids are summarized in Tables 65–4 and 65–5. Systemic retinoids are used to treat acne and disorders of keratinization.

*First-generation retinoids* include retinol (vitamin A), tretinoin (all-trans-retinoic acid; vitamin A acid), isotretinoin (13-cis-retinoic acid), and alitretinoin (9-cis-retinoic acid). *Second-generation retinoids*, also known as aromatic retinoids, include acitretin and methoxsalen (also known as etretinate; not marketed in the U.S.). *Third-generation retinoids* were designed to optimize receptor-selective binding and include tazarotene, bexarotene, and adapalene.

**Mechanism of Action.** Retinoids exert their effects on gene expression by activating 2 families of receptors—*retinoic acid receptors* (RARs) and *retinoid X receptors* (RXRs)—that are members of the steroid receptor superfamily. Upon
binding to a retinoid, RARs and RXRs form heterodimers (RAR-RXR), which subsequently bind specific DNA sequences called *retinoic acid–responsive elements* (RAREs) that activate transcription of genes whose products produce the desirable pharmacological effects of these drugs and their unwanted side effects (see Table 6–5 and Figures 3–12 and 6–8).

**Targeted Therapeutic Actions.** Retinoids that target RARs predominantly affect cellular differentiation and proliferation; retinoids that target RXRs predominantly induce apoptosis. Hence, tretinoin, adapalene, and tazarotene, which target RARs, are used in acne, psoriasis, and photoaging (disorders of differentiation and proliferation), whereas bexarotene and alitretinoin, which target RXRs, are used in mycosis fungoides and Kaposi sarcoma (to induce apoptosis of malignant cells).

**Retinoid Toxicity.** Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. RAR-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas RXR-selective retinoids induce more physiochemical changes. Because all oral retinoids are potent teratogens, they should be used carefully in females of childbearing potential and not in pregnant patients. Suicide or suicide attempts have been associated with the use of isotretinoin.

**TOPICAL RETINOIDS**

Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce *P. acnes* counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for non-inflammatory (comedonal) acne and often are combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, 2 important features of photoaging, also are improved with topical retinoids. Within the dermis, this is believed to result from inhibition of activator protein-1 (AP-1) that normally activates synthesis of
matrix metalloproteinases in response to UV irradiation. In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia.

**Toxicity and Monitoring.** Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging (see relative irritancy in Table 65–4). These effects often decrease with time and are lessened by concomitant use of emollients. Patients also may experience photosensitivity reactions (enhanced reactivity to UV radiation) and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, it is recommended use of topical retinoids should be avoided during pregnancy.

**TRETINOIN**

Topical tretinoin (all-trans-retinoic acid) is photolabile and should be applied once nightly for acne and photoaging. Benzoyl peroxide also inactivates tretinoin and should not be applied simultaneously. Formulations with copolymer microspheres (RETIN-A MICRO) or prepolyolprepolymer-2 (AVITA) that gradually release tretinoin to decrease irritancy are available.

**ADAPALENE**

Adapalene (DIFFERIN) has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight, stable in the presence of benzoyl peroxide, and tends to be less irritating at the 0.1% concentration.

**TAZAROTENE**

Tazarotene (TAZORAC, AVAGE) is approved for the treatment of psoriasis, photoaging, and acne vulgaris. Tazarotene gel, applied once daily, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with tazarotene.

**ALITRETINOIN**

Alitretinoin (PANRETIN) is a retinoid that binds all types of retinoid receptors and is applied 2 to 4 times daily to cutaneous lesions of Kaposi sarcoma. Alitretinoin should not be applied concurrently with insect repellants containing diethyltoluamide (DEET, N, N-diethyl-m-toluamide) because it may increase DEET absorption.
**BEXAROTENE**

Topical bexarotene (TARGRETIN) is approved for early-stage (IA and IB) cutaneous T-cell lymphoma. Its application is titrated up from every other day to 2-4 times daily over several weeks to improve patient tolerance. Patients using bexarotene should avoid products containing DEET due to an increased risk for DEET toxicity.

**SYSTEMIC RETINOIDS**

Systemic retinoids (Table 65–5) are approved for the treatment of acne, psoriasis, and cutaneous T-cell lymphoma.

*Therapeutic Use; Contraindications.* Off-label uses include ichthyosis, Darier disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosus, subacute lupus erythematosus, and discoid lupus erythematosus. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

*Toxicity and Monitoring.* Acute toxicities may include mucocutaneous or laboratory abnormalities; bony changes may occur after chronic use at high doses. Mucocutaneous side effects may include cheilitis, xerosis, blepharoconjunctivitis, cutaneous photosensitivity, photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a “retinoid dermatitis” characterized by erythema, pruritus, and scaling. Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines. There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis (DISH) syndrome, premature epiphyseal closure, and other skeletal abnormalities.

Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Although the risk appears to be minimal, men should avoid retinoid therapy when actively trying to father children. Prescribing of isotretinoin in the U.S. is restricted via the risk-mitigation iPLEDGE system. Serum lipid elevation is the most common laboratory abnormality. Less common laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. A baseline evaluation of serum lipids, serum transaminases, and
complete blood count (CBC) and a pregnancy test should be obtained prior to starting any systemic retinoids. Laboratory values should be checked monthly for the first 3-6 months and once every 3 months thereafter.

**ISOTRETINOIN**
Isotretinoin (Accutane, others) is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. Clinical effects generally are noted within 1-3 months of starting therapy. Approximately one-third of patients will relapse, usually within 3 years of stopping therapy. Although most relapses are mild and respond to conventional management with topical and systemic anti-acne agents, some may require a second course of isotretinoin. There are several reports of patients developing signs of depression while on isotretinoin. Current guidelines recommend monthly monitoring of all patients on isotretinoin for signs of depression.

**ACITRETIN**
Acitretin (Soriatane, SoriataneCK) is approved for use in the cutaneous manifestations of psoriasis. Full clinical benefit occurs at 3-4 months. Acitretin has a $t_{1/2}$ of $\sim 50$ h, however, when combined with alcohol, acitretin is esterified in vivo to produce etretinate, which has a $t_{1/2}$ of $> 3$ months. Thus, female patients of childbearing age should avoid pregnancy for 3 years after receiving acitretin to avoid retinoid-induced embryopathy.

**BEXAROTENE**
Bexarotene (Targretin) is a retinoid that selectively binds RXRs. Oral and topical formulations of bexarotene are approved for use in patients with cutaneous T-cell lymphoma. Studies suggest that bexarotene induces apoptosis of malignant cells. Because it is metabolized by CYP3A4, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase and inducers of CYP3A4 (e.g., rifamycins, carbamazepine, dexamethasone, efavirenz, phenobarbital) will decrease plasma levels of bexarotene. Side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of $TSH$ gene expression, pancreatitis, leukopenia, and GI symptoms. Thyroid function should be measured before initiating therapy and periodically thereafter.

**VITAMIN ANALOGS**
CALCIPOTRIENE. Calcipotriene (DOVONEX, others) is a topical vitamin D analog that is used in the treatment of psoriasis.

**Mechanism of Action.** Calcipotriene exerts its effects through the vitamin D receptor (VDR) (see Chapter 44). Upon binding the VDR, the drug-receptor complex associates with the RXR-α and binds to vitamin D response elements on DNA, increasing expression of genes that modulate epidermal differentiation and inflammation lead to improvement in psoriatic plaques.

**Therapeutic Use.** Calcipotriene is applied twice daily to plaque psoriasis on the body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the recommended 100 g/week limit and resolves within days of discontinuation of calcipotriene. Calcipotriene also causes perilesional irritation and mild photosensitivity.

β-Carotene. **β-Carotene** (see Figure 64–6) is a precursor of vitamin A that is in green and yellow vegetables. No β-carotene products are currently FDA-approved. Dietary supplementation with β-carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen. However, a recent meta-analysis concluded that β-carotene, vitamin A, and vitamin E given singly or combined with other antioxidant supplements actually increase mortality. FDA’s Maximum Recommended Therapeutic Dose (MRTD) for β-carotene is 0.05 mg/kg/day.

PHOTOCHEMOTHERAPY

Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone (phototherapy) or in the presence of an exogenous photosensitizing drug (photochemotherapy), such as a psoralen (furocoumarin) derivative that absorbs UV energy and becomes
reactive (Table 65–6). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications, such as phenothiazines, thiazides, sulfonamides, NSAIDs, sulfonylureas, tetracyclines, and benzodiazepines.

*D*Controversial. See Table 66–3 for pregnancy category.

Dermatologists subdivide the UV region into UVB (290-320 nm), UVA2 (320-340 nm), UVA1 (340-400 nm), and UVC (100-290 nm) radiation. UVC radiation is almost completely absorbed by stratospheric ozone. UVB is the most
erythrogenic and melanogenic type of radiation. It is the major action spectrum for sunburn, tanning, skin cancer, and photoaging. UVA radiation is only a thousandth as erythrogenic as UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases.

**PUVA: PSORALENS AND UVA.** Orally administered methoxsalen followed by UVA (PUVA) is FDA-approved for the treatment of vitiligo and psoriasis.

**Pharmacokinetics.** Dissolved psoralens (e.g., Oxsoralen Ultra) are absorbed rapidly after oral administration, whereas crystallized forms (e.g., 8-MOP) are absorbed slowly and incompletely. Fatty foods also reduce absorption. There is a significant, but saturable, first-pass elimination in the liver. For these reasons, peak photosensitivity varies significantly between individuals but typically is maximal 1-2 h after ingestion. Methoxsalen has a serum t½ of~1 h, but the skin remains sensitive to light for 8-12 h.

**Mechanism of Action.** The action spectrum for oral PUVA is between 320 and 340 nm. Two distinct photoreactions take place. Type I reactions involve the oxygen-independent photoaddition of psoralens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce antiproliferative, immunosuppressive, and anti-inflammatory effects.

**Therapeutic Uses.** Methoxsalen is supplied in soft gelatin capsules (Oxsoralen-Ultra) and hard gelatin capsules (8-MOP) for oral use. The dose is 10-70 mg, depending on weight (0.4-0.6 mg/kg), taken ~2 h before UVA exposure. A lotion containing 1% methoxsalen (Oxsoralen) is available for topical application for vitiligo and can be diluted for use in bath water to minimize systemic absorption. An extracorporeal solution (Uvadex) is available for cutaneous T-cell lymphoma (see “Photopheresis”).

Approximately 90% of psoriatic patients have clearing or virtual clearing of skin disease within 30 treatments with methoxsalen. Remission typically lasts 3-6 months; thus, patients often require maintenance therapy with intermittent PUVA or other agents. Vitiligo typically requires between 150 and 300 treatments.
Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed off label in the treatment of atopic dermatitis, alopecia areata, lichen planus, and urticaria pigmentosa.

**Toxicity and Monitoring.** The major side effects of PUVA are listed in Table 65–6. Ocular toxicity can be prevented by wearing UVA-blocking glasses the day of treatment.

**Photopheresis.** Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are exposed to UVA radiation in the presence of methoxsalen. Methoxsalen (UVADEX) is injected directly into the extracorporeal plasma before radiation and reinfusion. The treated lymphocytes are returned to the patient, undergoing apoptosis over 48-72 h. ECP is used for cutaneous T-cell lymphoma and off label for various other T-cell medicated diseases, including graft-versus-host disease, transplantation rejection, scleroderma, and type I diabetes mellitus. Initially, patients receive therapy every 1-4 weeks, and intervals are increased as the patient improves. ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

**Photodynamic Therapy (PDT).** PDT combines the use of photosensitizing drugs and visible light for the treatment of dermatological disorders. Two drugs are approved for topical PDT: aminolevulinic acid (ALA; Levulan Kerastick) and methylaminolevulinate (MAL; Metvixia). Both are prodrugs that are converted into protoporphyrin IX within living cells (Figure 65–3). In the presence of specific wavelengths of light (see Table 65–6) and oxygen, protoporphyrin produces singlet oxygen, which oxidizes cell membranes, proteins, and mitochondrial structures, leading to apoptosis. PDT is approved for use on precancerous actinic keratoses and also is commonly used on thin, nonmelanoma skin cancers; acne; and for photorejuvenation. Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin (see Table 65–6) and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Because the $t_{1/2}$ of the accumulated porphyrins is $\sim 30$ h, patients should protect their skin from sunlight.
and intense light for at least 48 h after treatment to prevent phototoxic reactions.

**Figure 65–3** *Heme biosynthesis pathway.* **A.** Under physiological conditions, heme inhibits the enzyme δ aminolevulinic acid (ALA) synthetase by negative feedback. However, δ when ALA is provided exogenously, this control point is bypassed, leading to excessive accumulation of heme. **B.** Heme.

**ANTIHISTAMINES**

*Histamine* (see Chapter 32) is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch receptors. Additional chemical itch mediators can act as pruritogens on C fibers, including *neuropeptides*, *prostaglandins*, *serotonin*, *acetylcholine*, and *bradykinin*. Furthermore, receptor systems (e.g., vanilloid, opioid, and cannabinoid receptors) on cutaneous sensory nerve fibers may modulate itch and offer novel future targets for anti-pruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express H₁, H₂, and H₄ receptors. Both H₁ and H₂ receptors are involved in wheal formation and erythema; only H₁ receptor agonists cause pruritus (see Chapter 32). However, blockade of H₁ receptors does not totally relieve itching, and combination therapy with H₁ antagonists (see Table 32–2) and H₂ blockers (see Chapter 45) may be superior to the use of H₁ blockers alone.
Oral antihistamines, particularly H₁ receptor antagonists, have anticholinergic activity and are sedating (see Chapter 32), making them useful for the control of pruritus. First-generation sedating H₁ receptor antagonists include hydroxyzine, diphenhydramine (Benadryl, others), promethazine, and cyproheptadine. Doxepin is a good alternative to traditional oral antihistamines for severe pruritus. A 5% topical cream formulation of doxepin (Prudoxin, Zonalon), which can be used in conjunction with low- to moderate-potency topical glucocorticoids, also is available. Allergic contact dermatitis to doxepin has been reported. The anti-pruritic effect from topical doxepin is comparable to that of low-dose oral doxepin therapy.

Second-generation H₁ receptor antagonists lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood-brain barrier. They include cetirizine (Zyrtec, others), levocetirizine dichloride (Xyzal), loratadine (Claritin, others), desloratadine (Clarinex), and fexofenadine hydrochloride (Allegra, others). While second-generation “nonsedating” H₁ receptor blockers are as effective as the first-generation H₁ blockers, they are metabolized by CYP3A4 and, to a lesser extent, by CYP2D6 and should not be coadministered with medications that inhibit these enzymes (e.g., imidazole antifungals, macrolide antibiotics).

ANTIMICROBIAL AGENTS

ANTIBIOTICS

Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris. Systemic antibiotics also are prescribed commonly for acne and deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VII, Chemotherapy of Microbial Diseases (Chapters 53-56). Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne. Acne vulgaris is the most common dermatological disorder treated with either topical or systemic antibiotics. The anaerobe P. acnes is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the
pilosebaceous unit, where O$_2$ tension is low. *P. acnes* generates free fatty acids that are irritants and may lead to microcomedo formation and resulting inflammatory lesions. Suppression of cutaneous *P. acnes* with antibiotic therapy is correlated with clinical improvement. Commonly used topical antimicrobials in acne include clindamycin (CLEOCIN T, others), erythromycin (ERYDERM, others), benzoyl peroxide, and antibiotic–benzoyl peroxide combinations (BENZACLIN, DUAC, others). Other antimicrobials used in treating acne include sulfacetamide (KLARON, others), sulfacetamide/sulfur combinations (SULFACET-R, others), metronidazole (METROCREAM, METROGEL, NORITATE), and azelaic acid (AZELEX, others). *Systemic therapy* is prescribed for patients with more extensive disease and acne that is resistant to topical therapy. Effective agents include tetracycline (SUMycin, others), doxycycline (MONODOX, others), minocycline (MINOCIN, others), and trimethoprim–sulfamethoxazole (BACTRIM, others). Antibiotics usually are administered twice daily, and doses are tapered after control is achieved.

The tetracyclines are the most commonly employed antibiotics because they are inexpensive, safe, and effective. The initial daily dose usually is 1 g in divided doses. Although tetracyclines are antimicrobial agents, efficacy in acne may be more dependent on anti-inflammatory activity. Minocycline has better GI absorption than tetracycline and may be less photosensitizing than either tetracycline or doxycycline. Side effects of minocycline include dizziness and hyperpigmentation of the skin and mucosa, serum sickness–like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with local administration of antifungal drugs.

**Cutaneous Infections.** Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of pyoderma. Skin infections with gram-negative bacilli are rare, although they can occur in diabetics and patients who are immunosuppressed; appropriate parenteral antibiotic therapy is required for their treatment.

*Topical therapy* frequently is adequate for impetigo, the most superficial bacterial infection of the skin caused by *S. aureus* and *S. pyogenes*. Mupirocin (pseudomonic acid, BACTROBAN, others) is effective for such localized infections. It inhibits protein synthesis by binding to bacterial isoleucyl-tRNA
Mupirocin is inactive against normal skin flora. Mupirocin is available as a 2% ointment or cream, applied 3 times daily. A nasal formulation is indicated to eradicate methicillin-resistant S. aureus (MRSA) nasal colonization. Retapamulin ointment 1% (ALTABAX) also is FDA-approved for the topical treatment of impetigo caused by susceptible strains of S. aureus or S. pyogenes in patients >9 months of age. Retapamulin selectively inhibits bacterial protein synthesis by interacting at a site on the 50S subunit of bacterial ribosomes.

Neomycin is active against staphylococci and most gram-negative bacilli, however, it may cause allergic contact dermatitis, especially on disrupted skin. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Polymyxin B is active against aerobic gram-negative bacilli. Neomycin, bacitracin, and polymyxin B (NEOSPORIN ORIGINAL OINTMENT, DOUBLE ANTIBIOTIC OINTMENT, others) are sold alone or in various combinations with other ingredients (e.g., hydrocortisone, lidocaine, or pramoxine) in a number of over-the-counter formulations.

Deep Skin Infections. Because streptococcal and staphylococcal species also are the most common causes of deep cutaneous infections, penicillins (especially β-lactamase–resistant β-lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment (see Chapter 53). A growing concern is the increased incidence of skin and soft-tissue infections with hospital- and community-acquired MRSA and drug-resistant pneumococci. Infection with community-acquired MRSA often is susceptible to trimethoprim–sulfamethoxazole. In addition to various traditional systemic antibiotics (such as erythromycin), novel antibacterial agents such as linezolid, quinupristin–dalfopristin, and daptomycin also have been approved for the treatment of complicated skin and skin-structure infections (see Chapter 53).

ANTIFUNGAL AGENTS

Fungal infections are among the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. Griseofulvin, topical and oral imidazoles, triazoles, and allylamines are the most effective antifungal agents available. The pharmacology, uses, and toxicities of antifungal drugs
are discussed in Chapter 57. Recommendations for cutaneous antifungal therapy are summarized in Table 65–7.

**Table 65–7**

The azoles miconazole (Micatin, others) and econazole (Spectazole, others) and the allylamines naftifine (Naftin) and terbinaine (Lamisil, others) are effective topical agents for the treatment of localized tinea corporis and uncomplicated tinea pedis. Topical therapy with the azoles is preferred for localized cutaneous candidiasis and tinea versicolor. Systemic therapy is necessary for the treatment of tinea capitis or follicular-based fungal infections. Oral griseofulvin has been the traditional medication for treatment of tinea capitis. Oral terbinaine is a safe and effective alternative to griseofulvin in treating tinea capitis in children.

**ANTIVIRAL AGENTS**

Viral infections of the skin are very common and include human papillomavirus (HPV), herpes simplex virus (HSV), condyloma acuminatum (HPV), molluscum contagiosum (poxvirus), and chicken pox (varicellazoster virus [VZV]). Acyclovir (Zovirax), famciclovir (Famvir, others), and valacyclovir (Valtrex) frequently are used systemically to treat HSV and VZV infections (see Chapter 58). Cidofovir (Vistide) may be useful in treating acyclovir-resistant HSV or VZV and other cutaneous viral infections. Topically, acyclovir, docosanol (Abreva), and penciclovir (Denavir) are available for treating mucocutaneous HSV. Podophyllin (25% solution) and podophlox (Condylox, others) 0.5% solution are used to treat condylomata. The immune response modifier
imiquimod (Aldara) is discussed below. Interferons α-2b (Intron A), α-n1 (not commercially available in the U.S.), and α-n3 (Alferon N) may be useful for treating refractory or recurrent warts.

**AGENTS USED TO TREAT INFESTATIONS**

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations.

**Permethrin** is a synthetic pyrethroid that interferes with insect sodium transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported in Cimex (bed bugs) and other insects. A 5% cream is available for the treatment of scabies, and a 1% cream, a cream rinse, and topical solutions are available OTC for the treatment of lice. Permethrin is approved for use in infants >2 months of age. Other agents used in the treatment of lice are pyrethrins + piperonyl butoxide (lotion, gel, shampoo, and mousse) and Klout shampoo (acetic acid + isopropanol).

**Lindane** has been used as a commercial insecticide as well as a topical medication. Due to several cases of neurotoxicity in humans, the FDA has labeled lindane as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing <110 pounds. Lindane is contraindicated in premature infants and patients with seizure disorders.

**Malathion** (Ovide) is an organophosphate that binds acetylcholinesterase in lice, causing paralysis and death. It is approved for treatment of head lice in children >6 years of age.

**Benzyl alcohol** (Ulesfia) 5% lotion is approved for the treatment of lice. Benzyl alcohol inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate.
Ivermectin (STROMECTOL) is an oral anthelmintic drug (see Chapter 51) approved to treat onchocerciasis and strongyloidiasis. Recently, ivermectin lotion (SKLICE) was approved to treat lice. It also is effective in the off-label treatment of scabies. Minor CNS side effects include dizziness, somnolence, vertigo, and tremor. For both scabies and lice, ivermectin typically is given at a dose of 200 μg/kg, which may be repeated in 1 week. It should not be used in children weighing <15 kg.

Less effective topical treatments for scabies and lice include 10% crotamiton cream and lotion (EURAX) and extemporaneously compounded 5% precipitated sulfur in petrolatum. Crotamiton and sulfur may be considered for use in patients in whom lindane or permethrin is contraindicated.

ANTIMALARIAL AGENTS

Antimalarials used in dermatology include chloroquine (ARALEN, others), hydroxychloroquine (PLAQUENIL, others), and quinacrine (ATABRINE) (see Chapter 49). Common dermatoses treated with antimalarials include cutaneous lupus erythematosus, cutaneous dermatomyositis, polymorphous light eruption, porphyria cutanea tarda, and sarcoidosis. The mechanism by which antimalarial agents exert their anti-inflammatory therapeutic effects is unknown. The usual dosages of antimalarials are 200 mg twice a day (maximum of 6.5 mg/kg/day) of hydroxychloroquine, 250-500 mg/day (maximum of 3 mg/kg/day) of chloroquine, and 100-200 mg/day of quinacrine. Clinical improvement may be delayed for several months. Hydroxychloroquine is the most common antimalarial used in dermatology. Patients with porphyria cutanea tarda require lower doses of antimalarials to avoid severe hepatotoxicity.

CYTOTOXIC AND IMMUNOSUPPRESSANT DRUGS

Cytotoxic and immunosuppressant drugs are used in dermatology for immunologically mediated diseases such as psoriasis, autoimmune blistering diseases, and leukocytoclastic vasculitis. See Table 65–8 for their mechanisms of action.

Table 65–8

Mechanisms of Action of Selected Cytotoxic and Immunosuppressant
Methotrexate (RHEUMATREX, others) is used for moderate to severe psoriasis. It suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen (CLA)–positive T-cells and endothelial cell E-selectin, which may account for its efficacy. Methotrexate is useful in treating a number of other dermatological conditions, including pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and cutaneous T-cell lymphoma.

Methotrexate should never be coadministered with probenecid, trimethoprim–sulfamethoxazole, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in
bone marrow suppression. Fatalities have occurred because of concurrent treatment with methotrexate and nonsteroidal anti-inflammatory agents. Methotrexate exerts significant antiproliferative effects on the bone marrow; therefore, CBCs should be monitored serially. Physicians administering methotrexate should be familiar with the use of folinic acid (leucovorin) to rescue patients with hematological crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary. Methotrexate-induced hepatic fibrosis may occur more commonly in patients with psoriasis than in those with rheumatoid arthritis. Consequently, liver biopsy is recommended when the cumulative dose reaches 1-1.5 g. Patients with abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Many clinicians routinely administer folic acid along with methotrexate to ameliorate side effects. Methotrexate is contraindicated during pregnancy and lactation.

AZATHIOPRINE. Azathioprine (IMURAN, others) is discussed in Chapter 35. In dermatological practice, the drug is used off label as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet disease.

Starting dosage is 1-2 mg/kg/day. Because it takes 6-8 weeks to achieve therapeutic effect, azathioprine often is started early in the course of disease management. Careful laboratory monitoring is important. The enzyme thiopurine S-methyltransferase (TPMT) activity should be measured before initiating azathioprine therapy (see Chapter 35).

FLUOROURACIL. Topical formulations of fluorouracil (5-FU) (CARAC, others) are used in multiple actinic keratoses, actinic cheilitis, Bowen disease, and superficial basal cell carcinomas not amenable to other treatments. Fluorouracil is applied once or twice daily for 2-8 weeks, depending on the indication. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of
5-FU has been used for keratoacanthomas, warts, and porokeratoses.

**INGENOL MEBUTATE.** Ingenol mebutate (PICATO) gel, an extract from the plant *Euphorbia peplus*, is FDA approved for actinic keratoses.

In experimental studies, it was reported to rapidly cause mitochondrial swelling and apoptosis of dysplastic keratinocytes. The gel is applied once daily for 2-3 consecutive days. Adverse effects may include local skin irritation, pain, pruritus, and infection at application site, periorbital edema, nasopharyngitis, and headache.

**ALKYLATING AGENTS**

*Cyclophosphamide* is an effective cytotoxic and immunosuppressive agent. Both oral and intravenous preparations of cyclophosphamide are used in dermatology. Cyclophosphamide is FDA-approved for treatment of advanced cutaneous T-cell lymphoma.

Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener granulomatosis, polyarteritis nodosa, Churg-Strauss angiitis, Behçet disease, scleromyxedema, and cytophagic histiocytic panniculitis. The usual oral dosage is 2-3 mg/kg/day in divided doses, and there often is a 4- to 6-week delay in onset of action. Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer. Cyclophosphamide has many adverse effects, including the risk of secondary malignancy and myelosuppression, and is used only in the most severe, recalcitrant dermatological diseases.

**Mechlorethamine hydrochloride** (MUSTARGEN) and **carmustine** (BICNU) are used topically to treat cutaneous T-cell lymphoma.

Both can be applied topically as a solution or in an extemporaneously compounded ointment form. It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and
hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and post-treatment telangiectases.

**CALCINEURIN INHIBITORS**

Chapter 35 describes the mechanisms of action and clinical pharmacology of these agents. Figure 35–1 shows their main molecular effects as immunosuppressants.

*Cyclosporine.* Cyclosporine (Neoral, Gengraf, others) is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum.* Cyclosporine is FDA-approved for the treatment of psoriasis. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual initial oral dosage is 2.5 mg/kg/day given in 2 divided doses.

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise $>$30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of $<$5 mg/kg, and regularly monitoring blood pressure. Alternation with other therapeutic modalities may diminish cyclosporine toxicity. Patients with psoriasis who are treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies. The risk of cutaneous malignancies is compounded if patients have received phototherapy with PUVA.

*Tacrolimus.* Tacrolimus (FK506, Protopic) is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations (Prograf). Systemic tacrolimus has shown some efficacy in the treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet disease. When administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia.

Topical formulations (0.03% and 0.1%) of tacrolimus ointment are approved for
the treatment of atopic dermatitis in adults and children >2 years of age. Other uses in include intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea. Ointment is applied to the affected area 2 times daily and generally is well tolerated. An advantage of topical tacrolimus over topical glucocorticoids is that tacrolimus does not cause skin atrophy and therefore can be used safely in locations such as the face and intertriginous areas. Common side effects at the site of application are transient erythema, burning, and pruritus. Other adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia. Systemic absorption generally is very low and decreases with resolution of the dermatitis. Topical tacrolimus should be used with extreme caution in patients with Netherton syndrome because these patients have been shown to develop elevated blood levels of the drug after topical application.

**Pimecrolimus.** Pimecrolimus 1% cream (ELIDEL) is a macrolide approved for the treatment of atopic dermatitis in patients >2 years of age. Its mechanism of action and side-effect profile are similar to those of tacrolimus. Pimecrolimus has less systemic absorption. Similar precautions with regard to UV exposure should be taken during treatment with pimecrolimus. Tacrolimus and pimecrolimus should only be used as second-line agents for short-term and intermittent treatment of atopic dermatitis (eczema) in patients unresponsive to, or intolerant of, other treatments. These drugs should be avoided in children <2 years of age.

**OTHER IMMUNOSUPPRESSANT AND ANTI-INFLAMMATORY AGENTS**

**MYCOPHENOLEATE MOFETIL.** Mycophenolate mofetil (CELLCEPT), a prodrug, and mycophenolate sodium (MYFORTIC) are immunosuppressants approved for prophylaxis of organ rejection in patients with renal, cardiac, and hepatic transplants (see Chapter 35).

Mycophenolic acid functions as a specific inhibitor of T and B lymphocyte activation and proliferation. The drug also may enhance apoptosis. Mycophenolate mofetil is used increasingly to treat inflammatory and
autoimmune diseases in dermatology in dosages ranging from 1-2 g/day orally; this agent is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders, and has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum. Isolated cases of progressive multifocal leukoencephalopathy (PML) and pure red cell aplasia have been reported in solid organ transplant patients receiving mycophenolate mofetil.

**IMIQUIMOD.** Imiquimod (ALDARA) exerts immunomodulatory effects by acting as a ligand at toll-like receptors in the innate immune system and inducing the cytokines interferon-α (IFN-α), tumor necrosis factor-α (TNF-α), and IL-1, IL-6, IL-8, IL-10, and IL-12. Approved for the treatment of genital warts, imiquimod is applied to genital or perianal lesions 2 times a week usually for a 16-week period (and repeated as necessary). Imiquimod also is approved for the treatment of actinic keratoses. No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. The drug is FDA-approved for the treatment of nodular and superficial basal cell carcinomas at a dosage of 5 applications per week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget disease, and Bowen disease. Irritant reactions occur in virtually all patients; the degree of inflammation parallels therapeutic efficacy.

**VINBLASTINE** Systemic vinblastine (VELBAN, others) is approved for use in Kaposi sarcoma and advanced cutaneous T-cell lymphoma. Intrallesional vinblastine also is used to treat Kaposi sarcoma. Intrallesional bleomycin (BLENOXANE, others) is used for palliative treatment of squamous cell carcinoma and recalcitrant warts and has cytotoxic and pro-inflammatory effects. Intrallesional injection of bleomycin into the digits has been associated with a vasospastic response that mimics Raynaud phenomenon, local skin necrosis, and flagellate hyperpigmentation. Systemic bleomycin has been used for Kaposi sarcoma (see Chapter 61). Liposomal anthracyclines (specifically doxorubicin [DOXIL, CAELYX]) may provide first-line monotherapy for advanced Kaposi sarcoma.

**DAPSONE** Dapsone is used in dermatology for its anti-inflammatory properties, particularly
in sterile (non-infectious) pustular diseases of the skin. Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects. See also Figure 56–5 and accompanying text in Chapter 56.

Dapsone is approved for use in dermatitis herpetiformis and leprosy. It is particularly useful in the treatment of linear immunoglobulin A (IgA) dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey–Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet syndrome, granuloma faciale, relapsing polychondritis, Behçet disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare.

An initial dosage of 50 mg/day is prescribed, followed by increases of 25 mg/day at weekly intervals, titrated to the minimal dosage necessary for effect. Potential side effects of dapsone include methemoglobinemia and hemolysis. The glucose-6-phosphate dehydrogenase (G6PD) level should be checked in all patients. The H₂ blocker cimetidine, at a dose of 400 mg 3 times daily, alters the degree of methemoglobinemia by competing with dapsone for CYPs. Toxicities include agranulocytosis, peripheral neuropathy, and psychosis.

**THALIDOMIDE.** Thalidomide (THALOMID) is an anti-inflammatory, immunomodulating, anti-angiogenic agent experiencing resurgence in the treatment of dermatological diseases. For details of its actions, see Chapter 35 under “Immunostimulants” and Figure 62–2 and associated text.

Thalidomide is FDA-approved for the treatment of erythema nodosum leprosum. There are reports suggesting its efficacy in actinic prurigo, aphthous stomatitis, Behçet disease, Kaposi sarcoma, and the cutaneous manifestations of lupus erythematosus, as well as prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. In utero exposure can cause limb abnormalities (phocomelia), as well
as other congenital anomalies. It also may cause an irreversible neuropathy. 

Because of its teratogenic effects, thalidomide use is restricted to specially licensed physicians who fully understand the risks. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.

**BIOLOGICAL AGENTS**

Biological agents (see Chapters 35 and 62) include recombinant cytokines, interleukins, growth factors, antibodies, and fusion proteins.

Five biological agents are approved for the treatment of psoriasis (Table 65–9). Psoriasis is a disorder of Th1 cell-mediated immunity (Figure 65–4), with the epidermal changes being secondary to the effect of released cytokines. Biological therapies modify the immune response in psoriasis through (1) reduction of pathogenic T-cells, (2) inhibition of T-cell activation, (3) immune deviation (from a Th1 to a Th2 immune response), and (4) blockade of the activity of inflammatory cytokines. The appeal of biological agents in the treatment of psoriasis is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation versus traditional systemic therapies that are broadly immunosuppressive or cytotoxic.

*Lf*, lymphocyte function-associated antigen; IgG, immunoglobulin G; TNF, tumor necrosis factor; SC, subcutaneous; IV, intravenous; Adalimumab, TNF inhibitor.

Figure 65–4 Immunopathogenesis of psoriasis. Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as-yet undefined antigen(s) presented by antigen-presenting cells (APCs). The T-cells release pro-inflammatory cytokines, such as tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ), that induce keratinocyte and endothelial cell proliferation. CLA, cutaneous lymphocyte-associated antigen.

INHIBITORS OF T-CELL ACTIVATION

ALEFACEPT. Alefacept (AMEVIVE) is an immunobiological agent approved for the treatment of moderate to severe psoriasis.

Alefacept consists of a recombinant fully human fusion protein composed of the binding site of the leukocyte function–associated antigen 3 (LFA-3) protein and a human IgG1 Fc domain. The LFA-3 portion of the alefacept molecule binds to CD2 on the surface of T-cells, thus blocking a necessary co-stimulation step in T-cell activation (Figure 65–5). Importantly, because CD2 is expressed preferentially on memory-effector T-cells, naive T-cells are largely unaffected by alefacept. A second important action of alefacept is its ability to induce apoptosis of memory-effector T-cells through simultaneous binding of its IgG1 portion to immunoglobulin receptors on cytotoxic cells and its LFA-3 portion to CD2 on T-cells, thus inducing granzyme-mediated apoptosis of memory-effector T-cells. This may lead to a reduction in CD4+ lymphocyte counts, requiring a baseline CD4+ lymphocyte count before initiating alefacept and then biweekly during therapy.
EFALIZUMAB. Efalizumab (RAPTIVA) is a humanized monoclonal antibody against the CD11a molecule of LFA-1.

By binding to CD11a on T-cells, efalizumab prevents binding of LFA-1 to intercellular adhesion molecule (ICAM)-1 on the surface of antigen-presenting cells, vascular endothelial cells, and cells in the dermis and epidermis (see Figure 65–5), thereby interfering with T-cell activation and migration and cytotoxic T-cell function. A transient peripheral leukocytosis occurs in some patients taking efalizumab, which may be due to the inhibition of T-cell trafficking. Other side effects include thrombocytopenia, exacerbation of psoriasis. Therefore, CBCs should be obtained at baseline and periodically...
thereafter. Caution should be exercised in patients who develop neurological signs while on efalizumab.

**TUMOR NECROSIS FACTOR INHIBITORS**

TNF-α is central to the T\textsubscript{H}1 response in active psoriasis, inducing inflammatory cytokines, upregulating intracellular adhesion molecules, inhibiting apoptosis of keratinocytes and inducing their proliferation. Blockade of TNF-α reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions.

Because TNF-α inhibitors alter immune responses, patients on all anti-TNF-α agents are at increased risk for serious infection and for malignancies. Other adverse events include exacerbation of congestive heart failure and demyelinating disease in predisposed patients. All patients should be screened for tuberculosis, history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to therapy.

**ETANERCEPT.** Etanercept (ENBREL) is a soluble, recombinant, fully human TNF receptor fusion protein consisting of 2 molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG\textsubscript{1}. Etanercept binds soluble and membrane-bound TNF, thereby inhibiting the action of TNF. Etanercept used at 0.4 mg/kg twice weekly in pediatric psoriasis is safe and efficacious. Etanercept use is associated with an increased risk of infections (bacterial sepsis, tuberculosis), including leading to hospitalization or death.

**INFILIXIMAB.** Infliximab (REMICADE) is a mouse-human chimeric IgG\textsubscript{1} monoclonal Ab that binds to soluble and membrane-bound TNF-α. Infliximab is a complement-fixing Ab that induces complement-dependent and cell-mediated lysis when bound to cell-surface-bound TNF-α. Neutralizing antibodies to infliximab may develop. Concomitant administration of methotrexate or glucocorticoids may suppress this Ab formation.
ADALIMUMAB. Adalimumab (HUMIRA) is a human IgG₁ monoclonal Ab that binds soluble and membrane-bound TNF-α. Like infliximab, it can mediate complement-induced cytolysis on cells expressing TNF. Unlike infliximab, adalimumab is fully human, which reduces the risk for development of neutralizing antibodies.

A FUSION PROTEIN TARGETING CUTANEOUS T-CELL LYMPHOMA

DENILEUKIN DIFTITOX. Denileukin diftitox or DAB389–IL-2 (ONTAK) is a fusion protein composed of diphtheria toxin fragments A and B and the receptor-binding portion of IL-2. DAB389–IL-2 is indicated for advanced cutaneous T-cell lymphoma in patients with >20% of T-cells expressing the surface marker CD25.

The IL-2 receptor (IL-2R) is present on malignant and activated T-cells but not resting B and T-cells. Following binding to the IL-2R, DAB389–IL-2 is internalized by endocytosis. The active fragment of diphtheria toxin then is released into the cytosol, where it inhibits protein synthesis via ADP ribosylation of elongation factor-2 (EF-2), leading to cell death. Response rate is 30%. Adverse effects include pain, fevers, chills, nausea, vomiting, and diarrhea; immediate hypersensitivity reaction in 60% of patients; and capillary leak syndrome in 20-30% of patients.

INTRAVENOUS IMMUNOGLOBULIN

Intravenous immunoglobulin (IVIG) is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 35). Preparations of IVIG are composed of >90% IgG, with minimal amounts of IgA, soluble CD4, CD8, HLA molecules, and cytokines. In dermatology, IVIG is used off label as an adjuvant or rescue therapy for autoimmune bullous diseases, toxic epidermal necrolysis, connective tissue diseases, vasculitis, urticaria, atopic dermatitis, and graft-versus-host disease.
Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include suppression of IgG production, accelerated catabolism of IgG, neutralization of complement-mediated reactions, neutralization of pathogenic antibodies, downregulation of inflammatory cytokines, inhibition of autoreactive T lymphocytes, inhibition of immune cell trafficking, and blockage of Fas-ligand/Fas-receptor interactions. IVIG is contraindicated in patients with severe selective IgA deficiency (IgA <0.05 g/L). These patients may possess anti-IgA antibodies that place them at risk for severe anaphylactic reactions. Other relative contraindications include congestive heart failure and renal failure.

**SUNSCREENS**

Photoprotection from the acute and chronic effects of sun exposure is readily available with sunscreens. The major active ingredients of available sunscreens include chemical agents that absorb incident solar radiation in the UVB and/or UVA ranges and physical agents that contain particulate materials that can block or reflect incident energy and reduce its transmission to the skin. The FDA has recently issued new rules for standardizing sunscreen efficacy, reviewed in an update (May 12, 2012) to the online version of Goodman & Gilman.

There is evidence that the regular use of sunscreens can reduce the risk of actinic keratoses and squamous cell carcinomas of the skin. Except for total sun avoidance, sunscreens are the best single method of protection from UV-induced damage to the skin. However, there is a need for more definitive answers to questions related to the efficacy of sunscreens in reducing skin cancer risk.

**UVA Sunscreen Agents.** Currently available UVA filters in the U.S. include (1) avobenzone, also known as Parsol 1789; (2) oxybenzone; (3) titanium dioxide; (4) zinc oxide; and (5) ecamsule (Mexoryl SX). Additional UVA sunscreens, including bemotrizinol (Tinosorb S) and bisoctrizole (Tinosorb M), are not available in the U.S.

**UVB Sunscreen Agents.** There are numerous UVB filters, including p-aminobenzoic acid (PABA) esters (e.g., padimate O), cinnamates (e.g., octinoxate), octocrylene, and salicylates (e.g., octisalate).
TREATMENT OF PRURITUS

Pruritus (itching) occurs in a multitude of dermatological disorders, including dry skin or xerosis, atopic eczema, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. In addition to treating the underlying disorder, a general approach to the treatment of pruritus can be made by classifying pruritus into 1 of 4 clinical categories (Table 65–10). Long experience shows that gold works well for treatment of the itching palm.

Neuropathic Pruritus: Itch due to disease of afferent nerves

| Carbamazepine: Blockade of synaptic transmission and use-depandan Na⁺ channels |
| Gabapentin: Suppresses neuronal hyperexcitability by inhibiting voltage-depandan Ca²⁺ channels |
| Topical anesthetics (EMLA, benzocaine, pramoxine): ↓ nerve conduction via Na⁺ channel blockade |

Neurogenic Pruritus: Itch that arises from the nervous system without evidence of neural pathology

| Thalidomide: Central depressant |
| Opioid-receptor antagonists (naloxone, naltrexone): ↓ opioidergic tone |
| Tricyclic antidepressants: ↓ pruritus signaling via altered [neurotransmitter] |
| Selective serotonin reuptake inhibitors (SSRIs): ↓ pruritus signaling via altered [neurotransmitter] |

Psychogenic Pruritus: Itch due to psychological illness

| Anxiolytics (alprazolam, clonazepam, benzodiazepines): Relieve stress-reactive pruritus |
| Antipsychotic agents (chlorpromazine, thioridazine, thiothixene, olanzapine): Relieve pruritus with impulsive qualities |
| Tricyclic antidepressants: Relieve depression and insomnia related to pruritus |
| SSRIs: Relieve pruritus with compulsive qualities |

DRUGS FOR HYPERKERATOTIC DISORDERS

Keratolytic agents reduce hyperkeratosis through myriad mechanisms (e.g., breaking of intercellular junctions, increasing stratum corneum
water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verrucae.

**α-Hydroxy acids** can reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydrolytic enzymes, and drawing water into the stratum corneum, allowing cell separation to occur. They also appear to increase glycosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photoaging. The FDA requires that cosmetics containing α-hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun. α-Hydroxy acids used include glycolic, lactic, malic, citric, hydroxycaprylic, hydroxycapric, and mandelic.

**Salicylic acid** functions through solubilization of intercellular cement, reducing corneocyte adhesion, and softening the stratum corneum. Salicylism may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment, and use should be limited to <2 g to the skin surface in a 24-h period. Salicylic acid, while chemically not a true a β-hydroxy acid, often is listed as such on cosmetic labels. Other β-hydroxy acids ingredients in cosmetics include β-hydroxybutanoic acid, δ-tropic acid, and trethocanic acid. Sun protection should accompany the topical application of these agents.

**Urea**, at low concentrations, increases skin absorption and retention of water, leading to increased flexibility and softness of the skin. At concentrations >40%, urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

**Sulfur** is keratolytic, anti-septic, anti-parasitic, and anti-seborrheic. It exerts its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide (H₂S). H₂S breaks down keratin, causing dissolution of the stratum corneum.

**Propylene glycol** (as 60-100% solutions in water) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis.
DRUGS FOR ANDROGENETIC ALOPECIA

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults >40 years of age. It is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone binds to the androgen receptor; the hormone-receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic alopecia is aimed at reducing hair loss and maintaining existing hair.

Minoxidil. Minoxidil (ROGAINE, others), developed as an antihypertensive agent (see Chapter 27), was noted to be associated with hypertrichosis in some patients. Topical minoxidil is available as a 2% or 5% solution. Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hairs. Treatment must be continued or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil.

Finasteride. Finasteride (PROPECIA, other) inhibits the type II isozyme of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (see Chapter 41) and that is found in hair follicles. Balding areas of the scalp are associated with increased dihydrotestosterone levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/day) has been shown to variably increase hair growth in men over a 2-year period. Finasteride is approved for use only in men. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. As with minoxidil, treatment with finasteride must be continued, or any new hair growth will be lost.

TREATMENT OF HYPERPIGMENTATION
These agents are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on post-inflammatory pigmentation within the dermis.

**Hydroquinone.** Hydroquinone (1,4-dihydrobenzene; TRI-LUMA) decreases melanocyte pigment production by inhibiting the conversion of dopa to melanin through inhibition of the enzyme tyrosinase. Other mechanisms include inhibition of DNA and RNA synthesis, degradation of melanosomes, and destruction of melanocytes. There are multiple formulations, to which penetration enhancers, microsponges, and sunscreen ingredients are added. Adverse effects may include dermatitis and ochronosis.

**Monobenzone.** Monobenzone (BENOQUIN), causes permanent hypopigmentation and should not be used for routine hormonally induced or post-inflammatory hyper-pigmentation.

**Azelaic.** Azelaic acid (AZELEX, FINACEA) inhibits tyrosinase activity but is less effective than hydroquinone. Because it has mild comedolytic, antimicrobial, and anti-inflammatory properties, it also is often used in acne and papulopustular rosacea.

**Mequinol.** Mequinol (4-hydroxyanisole, methoxyphenol, hydroquinone monomethyl ether, or p-hydroxyanisole) is a competitive inhibitor of tyrosinase. It is available as a 2% prescription product (SOLAGE) in combination with 0.01% tretinoin and vitamin C for skin lightening.

**MISCELLANEOUS AGENTS**

**Capsaicin** is an alkaloid derived from plants of the Solanaceae family (i.e., hot chili peppers). Capsaicin interacts with the transient receptor potential vanilloid (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli. Chronic exposure to capsaicin first stimulates and then desensitizes this channel to capsaicin and diverse other noxious stimuli. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin is available at various concentrations as a cream (ZOSTRIX, others), lotion (CAPSIN),
gel, roll-on, and transdermal patch. Capsaicin is FDA-approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis, and is used for off-label treatment of postherpetic neuralgia and painful diabetic neuropathy.

**Podophyllin**, podophyllum resin, a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple), contains podophyllotoxin (podofilox), which binds to microtubules and causes mitotic arrest in metaphase. Podophyllum resin (10-40%) is applied by a physician and left in place for no longer than 2-6 h weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. Podofilox is available as a 0.5% solution for home application 2 times daily for 3 consecutive days, repeated weekly as needed up to 4 cycles.
Drugs to control fertility and treat disorders of the female reproductive organs collectively are among the most frequently prescribed agents in clinical practice. This chapter discusses a number of common clinical issues and their drug therapies that are central to women’s health. The focus is on reproductive disorders and aspects of therapy rather than comprehensive coverage of the drugs themselves, which are described in more detail elsewhere (e.g., see Chapter 33 for prostaglandins; Chapter 38 for the gonadotropins, gonadotropin-releasing hormone [GnRH] agonists and antagonists, and oxytocin; Chapter 40 for estrogens and progestins; Section VII for antibiotics).

**CONTRACEPTION**

Contraception can be administered as planned prophylaxis or postcoitally for emergency contraception (i.e., high-dose estrogen-containing oral contraceptive pills, high-dose progestin pills, a progesterone antagonist, intrauterine devices). A progesterone antagonist also can be used to terminate an established pregnancy.

**PLANNED CONTRACEPTION**

**COMBINATION ORAL CONTRACEPTIVES.** Pills containing an estrogen and progestin are the most widely used (Table 66–1); they act primarily by suppressing the luteinizing hormone (LH) surge and thereby preventing ovulation. A wide variety of preparations are available for oral, transdermal, and vaginal administration (see Table 66–2 in the 12th edition of the parent text for a list of branded formulations, many of which are available as generics). Almost all contain ethinyl estradiol as the estrogen and a 17α-alkyl-19-
**nortestosterone** derivative as the progestin, and are administered for the first 21-24 days of a 28-day cycle.

### Table 66–1

**One-Year Failure Rate with Various Forms of Contraception**

<table>
<thead>
<tr>
<th>BIRTH CONTROL METHOD</th>

### Table 66–2

**Sexually Transmitted Gynecological Infections and Recommended Therapie**
MECHANISMS OF ACTION. Estrogen sensitizes the hypothalamus and pituitary gonadotropes to the feedback inhibitory effects of the progestin and minimizes breakthrough bleeding. The progestin exerts negative feedback, which suppresses the LH surge and thereby prevents ovulation, and protects against uterine cancer by opposing the proliferative effects of the estrogen on the uterine endometrium.

FORMULATIONS. Newer formulations offer effective contraception with improved activity profiles. They contain lower amounts of hormones to minimize adverse effects; some incorporate progestins with less androgenic activity (e.g., gestodene, desogestrel) or that antagonize the mineralocorticoid
receptor and thereby reduce the tendency toward edema (e.g., drospirenone). Traditionally, combination oral contraceptives were packaged with 21 pills containing active hormone and 7 placebo tablets; each active pill contained a constant amount of the estrogen and progestin (i.e., a monophasic formulation). In an effort to maximize the antiovulatory effects and prevent breakthrough bleeding while minimizing total exposure to the hormones, some formulations provide active pills with 2 (biphasic) or 3 (triphasic) different amounts of 1 or both hormones to be used sequentially during each cycle.

“Extended-cycle” contraceptives extend the number of active pills per cycle and thus decrease the duration of menstrual bleeding. Two products contain 24 active pills with only 4 placebo tablets (e.g., YAZ [which contains drospirenone as the progestin] and LOESTRIN 24). Two products are packaged as 91-day packets, with 84 estrogen/progestin tablets and 7 placebo tablets (SEASONALE) or 7 tablets containing a lower dose of ethinyl estradiol alone (SEASONIQUE). Finally, LYBREL is provided in 28-day packets that contain only hormone pills and no placebo. All of these extended-cycle formulations appear to be comparable to the traditional products as contraceptives; aside from an increased frequency of breakthrough bleeding initially, no unexpected adverse effects have been observed.

A weekly transdermal contraceptive patch (Ortho Evra) releases ethinyl estradiol (20 μg/day) and norelgestromin (which is metabolized to norgestimate; 150 μg/day). In response to pharmacokinetic data suggesting that this patch provides higher estrogen exposure (AUC) than the low-dose oral contraceptive pills, the FDA added a black box advisory that notes this pharmacokinetic difference and warns of a potential increased risk of venous thromboembolism. Local reactions to the patch occur in ~5-15% of users and may be decreased by pre-application of a topical glucocorticoid. A vaginal ring (NuvaRing) also is available that releases ethinyl estradiol (15 μg daily) and etonogestrel (an active metabolite of desogestrel; 120 μg daily). Each ring is used for 3 weeks, followed by a 1-week interval without the ring.

The combination estrogen/progestin formulations provide highly effective (~99%) contraception and also have a number of noncontraceptive benefits, including protection against certain cancers (e.g., ovarian, endometrial, colorectal), decreased iron-deficiency anemia secondary to menstrual blood loss, and decreased risk of fractures due to osteoporosis. Combination oral
contraceptives also are widely used for conditions such as endometriosis, dysmenorrhea, menorrhagia, irregular menstrual cycles, premenstrual dysphoric disorder, acne, and hirsutism.

**ADVERSE EFFECTS.** Serious adverse effects of the combination estrogen/progestin contraceptive agents are relatively rare. Thromboembolic disease, largely due to the estrogenic component, is the most common serious side effect. Estrogen concentration, the patient’s age, smoking, and inherited thrombophilias all influence the risk of developing thromboembolic disease. The impact of combination oral contraceptives on breast cancer has been highly debated; although a meta-analysis of epidemiological studies concluded that the combination oral contraceptives did increase the risk of breast cancer, studies conducted with the lower doses of hormones in current formulations suggest that the risk of breast cancer is not increased.

Other adverse effects include hypertension, edema, gallbladder disease, and elevations in serum triglycerides (see Chapter 40). With pills containing drospirenone, which antagonizes the mineralocorticoid receptor, serum K⁺ should be monitored in women at risk for hyperkalemia (e.g., those on K⁺-sparing diuretics or drugs that inhibit the renin–angiotensin system). The combination oral contraceptives are contraindicated in women with a history of thromboembolic disease, cerebrovascular disease, migraine headaches with aura, estrogen-dependent cancer, impaired hepatic function or active liver disease, undiagnosed uterine bleeding, and suspected pregnancy. Patients with a history of gestational diabetes should be monitored closely, and drug cessation should be strongly considered in anticipation of events associated with an increased risk of venous thromboembolism (e.g., elective surgery).

**PROGESTIN-ONLY CONTRACEPTIVES.** Progestin-only minipills contain derivatives of 17α-alkyl-19-nortestosterone but no estrogen. Although they do inhibit ovulation to some degree, their efficacy also reflects changes in the cervical mucus that inhibit fertilization and endometrial changes that inhibit implantation. They are slightly less effective than the combination estrogen/progestin formulations. Their major adverse effect is breakthrough bleeding.

Progestins also are used for long-acting contraception. A depot formulation of
medroxyprogesterone (DePO-ProVERA) injected subcutaneously or intramuscularly provides effective contraception for 3 months. Its use has been associated with decreased bone mineral density. Subdermal implants of progestin-impregnated rods provide effective contraception over several years. The only implant system currently approved in the U.S. is IMPLANON, which incorporates 3-ketodesogestrel, an active metabolite of desogestrel, into an inert matrix. An intrauterine device that releases levonorgestrel (MIRENA) provides highly effective contraception for up to 5 years. It acts predominantly to inhibit gamete function and survival via local changes in the cervical mucus.

**POSTCOITAL CONTRACEPTION**

Postcoital (or emergency) contraception is indicated for use in cases of mechanical failure of barrier devices or in circumstances of unprotected intercourse. It is not intended as a regular method of contraception. The mechanisms of action of the postcoital contraceptives are not fully understood.

**PLAN-B one-step**, which contains 2 tablets of the progestin levonorgestrel (0.75 mg each), is marketed specifically for postcoital contraception and may be obtained in the U.S. without a prescription by women >18 years of age. Treatment is most effective if the first dose is taken within 72 h of intercourse, followed by a second dose 12 h later; a single dose of 1.5 mg within 72 h of intercourse appears to be equally effective. Other options for postcoital contraception include mifepristone (MIFEPREX), which is not FDA-approved for this indication but is highly effective in oral doses ranging from 10-50 mg when taken within 5 days after unprotected intercourse, and copper intrauterine devices when inserted within 4 days of unprotected intercourse. Mifepristone also has abortifacient activity when used in a different treatment regimen. The selective progesterone receptor modulator ulipristal (ELLA, ELLAONE) was recently approved as an emergency contraceptive, effective up to 120 h after unprotected intercourse; see Chapter 40 for details.

**PREGNANCY TERMINATION**

If contraception is not used or fails, either mifepristone (RU-486, MIFEPREX) or methotrexate (50 mg/m² intramuscularly or orally) can
be used to terminate an unwanted pregnancy in settings outside surgical centers. A prostaglandin then is administered to stimulate uterine contractions and expel the detached conceptus; in the U.S., prostaglandins used include dinoprostone (PGE$_2$; PROSTIN E2) administered vaginally or the PGE$_1$ analog misoprostol (CYTOTEC) given orally or vaginally, both of which are used off label for this purpose. Prostaglandins used in other countries include the PGE$_2$ analog sulprostone (NALADOR) and the PGE$_1$ analog gemeprost (CERVAGEM).

**MIFEPRISTONE.** Mifepristone is a 17α-alkyl-19-nortestosterone derivative that acts as a competitive antagonist at the progesterone receptor. Its actions are associated with focal hemorrhage and breakdown of the stromal extracellular matrix that ultimately leads to the breakdown of the uterine endometrium. In addition, mifepristone increases the sensitivity of the uterus to the uterotonic effects of prostaglandins. Mifepristone is metabolized through a series of reactions initiated by hepatic CYP3A4. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity, and the drug should be used cautiously in women who are anemic or receiving anticoagulants.

As approved by the FDA, mifepristone (600 mg) is taken for pregnancy termination within 49 days after the start of a woman’s last menstrual period. The synthetic PGE$_1$ analog misoprostol (400 μg) is administered orally 48 h later; vaginal administration is at least as effective but is not FDA-approved. Complete abortion using this procedure exceeds 90%; when termination of pregnancy fails or is incomplete, surgical intervention is required. Repeated doses of misoprostol alone (e.g., 800 μg vaginally or sublingually every 3 h or every 12 h for 3 doses) also have been effective in settings where mifepristone is unavailable. Vaginal bleeding follows pregnancy termination and typically lasts from 1-2 weeks but rarely (in 0.1% of patients) is severe enough to require blood transfusion. A high percentage of women also experience abdominal pain and uterine cramps, nausea and vomiting, and diarrhea secondary to the prostaglandin. Because mifepristone carries a risk of serious, and sometimes fatal, infection and bleeding following its use for medical abortion, a black box warning has been added to the product labeling. Women receiving mifepristone
should be informed of these risks and cautioned to seek immediate medical attention if symptoms or signs of these conditions occur. Fulminant septic shock associated with *Clostridium sordellii* infections may result and is attributable to the combined effects of uterine infection and inhibition of glucocorticoid action by mifepristone.

**METHOTREXATE.** Methotrexate is a potent abortifacient, probably as a result of the ability of the placenta to concentrate FH$_2$Glu$_n$ (dihydrofolate polyglutamate) and its analogs (see Chapter 61).

**DRUG THERAPY IN GYNECOLOGY**

**INDUCTION OF SEXUAL MATURATION**

A number of clinical disorders, including Turner syndrome and other forms of gonadal dysgenesis, are associated with impaired production of ovarian steroids in phenotypic females. Such patients typically fail to develop secondary sexual characteristics at the normal time of puberty (sexual infantilism) or fail to have menses (primary amenorrhea). In these cases, steroid hormones are administered to induce development of the secondary sex characteristics; however, treatment is initiated only after the diagnosis is ascertained and underlying disorders that might respond to more specific therapy (e.g., prolactinomas) are excluded (see Chapter 38).

Types of estrogens used and the treatment regimens may vary by country or individual preference. Examples include conjugated estrogens, 0.3-1.25 mg; micronized 17β-estradiol, 0.5-2.0 mg; ethinyl estradiol, 5-20 μg; and transdermal 17β-estradiol, 25-50 μg. To achieve optimal breast development, treatment typically is initiated with a low dose of estrogen (e.g., conjugated estrogens at a starting dosage of 0.3 mg/day or ethinyl estradiol at 5 μg/day) starting in patients between ages 10 and 12 years or immediately if the diagnosis is made after this age. After 3-6 months, the dosage is increased (e.g., 0.9-1.25 mg/day of conjugated estrogens or 20 μg/day of ethinyl estradiol). Once this is achieved, a progestin (e.g., medroxyprogesterone, 10 mg/day, or micronized progesterone, 200-400 μg/day) for 12 days each cycle is added to the regimen to optimize
breast development and permit cyclical menses, thereby avoiding endometrial hyperplasia and its consequent risk of uterine cancer. Once menses are established, many clinicians will switch to a standard low-dose oral contraceptive pill or even may use an extended-cycle formulation.

Short stature, a universal feature of non-mosaic Turner syndrome, usually is treated with human growth hormone, often together with an androgen such as oxandrolone (see Chapter 41). Initiating treatment with human growth hormone and androgen and delaying the onset of estrogen therapy generally produces a better growth response (see Chapter 38).

**MENOPAUSE**

Menopause refers to the permanent cessation of menstrual periods (i.e., for >12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age.

The decline in estradiol levels produces a variety of symptoms and signs, including vasomotor disturbances (hot flashes or flushes), sweating, irritability, sleep disturbances, and atrophy of estrogen-dependent tissue. In addition, postmenopausal women are at increased risk for osteoporosis, bone fractures, and coronary heart disease and experience increased memory loss and other cognitive difficulties.

**ESTROGEN THERAPY.** The observed estrogen deficiency associated with menopause, as well as a number of studies showing positive effects of estrogen replacement therapy on these parameters, led to widespread use of hormone replacement therapy in peri- and postmenopausal women.

The initial publication of data from the Women’s Health Initiative (WHI), a large, randomized, placebo-controlled trial, dramatically altered therapeutic approaches to menopause. As expected, treatment of postmenopausal women with 0.625 mg of conjugated estrogen plus 2.5 mg of medroxyprogesterone (in women with a uterus) or with 0.625 mg of conjugated estrogen alone (in women lacking a uterus) improved bone mineral density and decreased the risk of
fractures and colorectal cancer. In addition, estrogen therapy in both the estrogen plus progestin and the estrogen-alone groups was associated with an increased incidence of deep venous thrombosis and stroke; and the incidence of breast cancer and coronary heart disease also increased in women receiving both estrogen and progestin. In women >65 years of age, hormone therapy did not improve cognitive function or protect against dementia. Based on these findings, it was recommended that hormone replacement therapy not be used to decrease the risk of coronary heart disease, cognitive impairment, or dementia. Subsequent subgroup analyses of the WHI data suggest that cardiovascular risk was not increased when hormone therapy was initiated within 10 years of menopause and that the risks of estrogen therapy may be minimal in women who are perimenopausal or recently menopausal.

Available routes of estrogen administration for hormone replacement therapy include oral, transdermal (patch, gel, and spray), and vaginal (cream, ring, and tablets) (see Table 66–3 of the 12th edition of the parent text). In women who have undergone hysterectomy, estrogen alone is used. For women with an intact uterus, a progestin also is administered to oppose the proliferative effect of the estrogen on the uterine endometrium.

Table 66–3

FDA Use-in-Pregnancy Ratings

| Category A: Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy. |
| Category B: No evidence of risk in humans. Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities despite adverse findings in animals, or, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote, but remains a possibility. |
| Category C: Risk cannot be ruled out. Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy, but the potential benefits may outweigh the potential risk. |
| Category D: Positive evidence of risk. Studies in humans, or investigational or post-marketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective. |
| Category X: Contraindicated in pregnancy. Studies in animals or humans, or investigational or post-marketing reports, have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient. |

Other therapies for vasomotor symptoms include phytoestrogens (e.g., soy
products), herbal extracts (e.g., black cohosh), selective serotonin reuptake inhibitors (e.g., fluoxetine, controlled-release paroxetine, sertraline), clonidine, and gabapentin. However, hormone replacement remains the most effective therapy for vasomotor symptoms in menopausal women. Current recommendations advise using estrogen replacement at the lowest possible effective dose and for the shortest duration to treat moderate to severe vasomotor symptoms and vaginal dryness. For vaginal dryness alone, topical preparations are preferred.

ENDOMETRIOSIS

Endometriosis is an estrogen-dependent disorder that results from endometrial tissue ectopically located outside of the uterine cavity. It predominantly affects women during their reproductive years, with a prevalence of 0.5-5% in fertile women and 25-40% in infertile women. Diagnosis typically is made at laparoscopy, either prompted by unexplained pelvic pain (dysmenorrhea or dyspareunia) or infertility. The infertility is thought to reflect involvement of the fallopian tubes with the underlying process and, possibly, impaired oocyte maturation.

Because the proliferation of ectopic endometrial tissue is responsive to ovarian steroid hormones, many symptomatic approaches to therapy aim to produce a relatively hypoestrogenic state. Combination oral contraceptives have been standard first-line treatment for symptoms of endometriosis, and ample evidence from observational trials supports their benefit. The predominant mechanism of action is believed to be suppression of gonadotropin secretion, with subsequent inhibition of estrogen biosynthesis. Progestins (e.g., medroxyprogesterone, dienogest) also have been used to promote decidualization of the ectopic endometrial tissue. The levonorgestrel intrauterine system, which is approved for contraception, also has been used off label for this indication, as well as for menorrhagia.

Stable GnRH agonists can suppress gonadotropin secretion and thus effect medical castration. Drugs that carry an indication for endometriosis include leuprolide (LUPRON), goserelin (ZOLADEX), and nafarelin (SYNAREL); other
GnRH agonists also may be used off label for this purpose (see Chapter 38). Due to significant decreases in bone density and symptoms of estrogen withdrawal, “add-back” therapy with either a low-dose synthetic estrogen (e.g., conjugated equine estrogens, 0.625-1.25 mg) or a high-dose progestin (e.g., norethindrone, 5 mg) has been used when the duration of therapy has exceeded 6 months. Danazol (DANOCRINE), a synthetic androgen that inhibits gonadotropin production via feedback inhibition of the pituitary-ovarian axis, also is FDA-approved for endometriosis therapy; it rarely is used now because of its significant adverse effects, including hirsutism and elevation of hepatic transaminases. In Europe and elsewhere, the antiprogestin gestrinone has been employed.

HIRSUTISM

Hirsutism, or increased hair growth in the male distribution, affects ~10% of women of reproductive age. It can be a relatively benign, idiopathic process or part of a more severe disorder of androgen excess that includes overt virilization (voice deepening, increased muscle mass, male pattern balding, clitoromegaly) and often results from ovarian or adrenal tumors. Specific etiologies associated with hirsutism include congenital adrenal hyperplasia, polycystic ovary syndrome (PCOS), and Cushing syndrome. After excluding serious pathology such as a steroid-producing malignancy, the treatment largely becomes empirical.

Pharmacotherapy is directed at decreasing androgen production and action. Initial therapy often involves treatment with combination oral contraceptive pills, which suppress gonadotropin secretion and thus the production of ovarian androgens. The estrogen also increases the concentration of sex hormone–binding globulin, thereby diminishing the free concentration of testosterone. The full effect of this suppression may take up to 6-9 months. GnRH agonists downregulate gonadotropin secretion and also may be used to suppress ovarian steroid production.

In patients who fail to respond to ovarian suppression, efforts to block androgen action may be effective. Spironolactone (ALDACTONE), a mineralocorticoid-
receptor antagonist, and flutamide (EULEXIN; see Chapter 41) inhibit the androgen receptor. In Europe and elsewhere, cyproterone (50-100 mg/day) is used as an androgen-receptor blocker, often in conjunction with a combination oral contraceptive. Male offspring of women who become pregnant while taking any of these androgen inhibitors are at risk of impaired virilization secondary to impaired synthesis or action of dihydrotestosterone (Pregnancy Risk Category X, see Table 66–3). The antifungal ketoconazole (NIZORAL), which inhibits CYP steroid hydroxylases (see Chapters 42 and 57), also can block androgen biosynthesis but may cause liver toxicity. Topical eflornithine (VANIQA), an ornithine decarboxylase inhibitor, has been used with some success to decrease the rate of facial hair growth.

Non-pharmacological approaches include bleaching, depilatory treatments (e.g., shaving, treatment with hair-removing chemicals), or methods that remove the entire hair follicle (e.g., plucking, electrolysis, laser ablation).

**INFECTIONS OF THE FEMALE REPRODUCTIVE TRACT**

A variety of pathogens can cause infections of the female reproductive tract that range from vaginitis to pelvic inflammatory disease; Table 66–2 shows current recommendations for pharmacotherapy of selected sexually transmitted gynecological infections as issued by the Centers for Disease Control and Prevention.

The individual drugs used for systemic or topical therapy are described in more detail in Section VII. Infections have been implicated as important factors in preterm labor, as discussed further in “Prevention or Arrest of Preterm Labor.”

**FERTILITY INDUCTION**

Infertility (i.e., the failure to conceive after 1 year of unprotected sex) affects 10-15% of couples in developed nations and is increasing in incidence as more women choose to delay childbearing until later in life. The major impediment to pregnancy in an infertile couple can be attributed primarily to the woman in approximately one-third, to the man in approximately one-third, and to both in approximately one-
third. The likelihood of a successful pharmacological induction of fertility in these couples depends greatly on the reason for the infertility.

Defined abnormalities in the male partner that lead to impaired fertility (e.g., hypogonadism, Y chromosome microdeletions, Klinefelter syndrome) typically are detected by analysis of a semen sample; most often, male infertility is idiopathic. The medical therapy for some of these conditions is discussed in Chapters 38 and 41.

Anovulation accounts for ~50% of female infertility and is a major focus of pharmacological interventions used to achieve conception. Thus, whether a woman is ovulating is a key question. In infertile women who ovulate, analysis of the patency of the fallopian tubes and the structure of the uterus is an important part of the diagnostic evaluation. A number of approaches have been used to stimulate ovulation in anovulatory women. Often, a stepwise approach is taken, initially using simpler and less expensive treatments, followed by more complex and expensive regimens if initial therapy is unsuccessful. In obese patients with PCOS, the inclusion of lifestyle modifications directed at weight loss is warranted based on the association of obesity with anovulation, pregnancy loss, and complicated pregnancies (e.g., gestational diabetes, pre-eclampsia). Definitive evidence that weight loss improves fertility is not currently available.

**CLOMIPHENE.** Clomiphene citrate (Clomid, Serophene) is a potent anti-estrogen that primarily is used for treatment of anovulation in the setting of an intact hypothalamic—pituitary axis and adequate estrogen production (e.g., PCOS). By inhibiting the negative feedback effects of estrogen at hypothalamic and pituitary levels, clomiphene increases follicle-stimulating hormone (FSH) levels—typically by ~50%—and thereby enhances follicular maturation (see Chapter 40). A typical regimen is 50 mg/day orally for 5 consecutive days starting between days 2 and 5 of the cycle. If this regimen fails to induce ovulation, the dose of clomiphene is increased, first to the FDA-approved maximum of 100 mg/day and possibly as high as 150 or 200 mg/day. Although clomiphene is effective in inducing ovulation in perhaps 75% of women, successful pregnancy ensues in only 40-50% of those who ovulate.
Untoward effects of clomiphene include the ovarian hyperstimulation syndrome (OHSS) and increased incidences of multifetal gestations (twins in ~5-10% and more than 2 babies in ~0.3% of pregnancies), ovarian cysts, hot flashes, headaches, and blurred vision. A few studies have suggested that prolonged use (e.g., >12 cycles) may increase the risk of ovarian and endometrial cancer; thus, the recommended maximum number of cycles is 6. Clomiphene should not be administered to pregnant women (FDA Category X).

*Tamoxifen* may be as effective as clomiphene for ovulation induction but is not FDA-approved for this indication.

**GONADOTROPINS.** The preparations of gonadotropins available for clinical use are detailed in Chapter 38. Gonadotropins are indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, and also are used to induce ovulation in women with PCOS who do not respond to clomiphene. Figure 66–1 shows a typical regimen for ovulation induction. Gonadotropin-induced ovulation results in multiple births in up to 10-20% of cases due to the pharmacologically induced development of more than 1 pre-ovulatory follicle and the release of more than 1 ovum.
Figure 66–1 Idealized regimens using exogenous gonadotropins for fertility induction. **A. Step-up regimen for ovulation induction.** After menses, daily injections of gonadotropin (75 IU) are started. Follicle maturation is assessed by serial measurement of plasma estradiol and follicle size, as discussed in the text. If an inadequate response is seen, the dose of gonadotropin is increased to 112 or 150 IU/day. When 1 or 2 follicles have achieved a size of ≥17 mm in diameter, final follicle maturation and ovulation are induced by injection of human chorionic gonadotropin (hCG). Fertilization then is achieved at 36 h after hCG injection by intercourse or intrauterine insemination (IUI). If more than 2 mature follicles are seen, the cycle is terminated and barrier contraception is used to avoid triplets or higher degrees of multifetal gestation. **B. Long protocol for ovarian hyperstimulation using gonadotropin-releasing hormone (GnRH) agonist to inhibit premature ovulation, followed by in vitro fertilization (IVF).** After the GnRH agonist has inhibited endogenous secretion of gonadotropins, therapy with exogenous gonadotropins is initiated. Follicle maturation is
assessed by serial measurements of plasma estradiol and follicle size by
ultrasonography. When 3 or more follicles are ≥17 mm in diameter, then
ovulation is induced by injection of hCG. At 32-36 h after the hCG injection, the
eggs are retrieved and used for IVF. Exogenous progesterone is provided
to promote a receptive endometrium, followed by embryo transfer at 3-5 days after
fertilization. C. Protocol for ovarian hyperstimulation in an IVF protocol using a
GnRH antagonist. The cycle duration is shorter because the GnRH antagonist
does not induce a transient flare of gonadotropin secretion that might disrupt the
timing of the cycle, but many other elements of the cycle are analogous to those
in B. IU, intrauterine.

Gonadotropin induction also is used for ovarian stimulation in conjunction with
in vitro fertilization (IVF; see Figure 66–1). In this setting, larger doses of FSH
(typically 225-300 IU/day) are administered to induce the maturation of multiple
(ideally at least 5 and up to 20) oocytes that can be retrieved for IVF and
intrauterine transfer. To prevent the LH surge and subsequent premature
luteinization of the ovarian follicles, gonadotropins typically are administered in
conjunction with a GnRH agonist.

GnRH antagonists also can be used to inhibit endogenous LH secretion. Because
they do not transiently increase gonadotropin secretion, they can be initiated
later in the cycle in a “short protocol.” Current regimens include daily injection
in a dose of 0.25 mg (ganirelix [ANTAGON] or cetrorelix [CETROTIDE]) starting on
the fifth or sixth day of gonadotropin stimulation or a single dose of 3 mg of
cetrorelix administered on day 8 or 9 of the late follicular phase. Using either the
long or short protocols, hCG (at typical doses of 5000-10,000 IU of urine-
derived product or 250 µg of recombinant hCG) is given to induce final oocyte
development, and the mature eggs are retrieved from the pre-ovulatory follicles
at 32-36 h thereafter. The retrieved ova are fertilized in vitro with sperm (IVF) or
by intracytoplasmic sperm injection; 1 or 2 embryos then are transferred to the
uterus 3-5 days after fertilization.

Repeated injections of hCG, while sustaining the corpus luteum, may increase
the risk of OHSS. Thus, standard IVF regimens typically provide exogenous
progesterone replacement to support the fetus until the placenta acquires the
biosynthetic capacity to take over this function; regimens include progesterone
in oil (50-100 mg/day intramuscularly) or micronized progesterone (180-300 mg
twice daily vaginally). Vaginal preparations containing 100 mg (ENDOMETRIN) or
90 mg (Prochieve, Crinone) of micronized progesterone are approved for administration 2 or 3 times daily as part of IVF and other fertility technologies.

Aside from the attendant complications of multifetal gestation, the major side effect of gonadotropin treatment is OHSS. Symptoms and signs include abdominal pain and/or distention, nausea and vomiting, diarrhea, dyspnea, oliguria, and marked ovarian enlargement on ultrasonography. OHSS can lead to hypovolemia, electrolyte abnormalities, acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction. In ovulation induction, incipient OHSS should be suspected if routine laboratory investigation reveals the presence of more than 4 to 6 follicles >17 mm or a serum estradiol level of >1500 pg/mL; in this setting, hCG should be withheld and barrier contraception used. In an effort to avoid overt hyperstimulation, the FSH can be withheld for a day or 2 (“coasting”) if the plasma level of estradiol is near the top of this range. In either case, ovulation induction with recombinant LH, which has a considerably shorter $t_{1/2}$ than hCG, or with a GnRH agonist may diminish the incidence of OHSS. The potential deleterious effects of gonadotropins are debated. There is no evidence that the gonadotropins themselves or components of the IVF process increase the rate of congenital abnormalities in babies born from stimulated oocytes.

**INSULIN SENSITIZERS.** PCOS affects 4-7% of women of reproductive age and is the most frequent cause of anovulatory infertility. Inasmuch as PCOS patients often exhibit hyperinsulinemia and insulin resistance, insulin sensitizers such as metformin have been evaluated for their effects on ovulation and fertility (see Chapter 43). Although several small trials suggested that metformin increased ovulation in PCOS patients relative to placebo; metformin was less effective than clomiphene in inducing ovulation, promoting conception, or improving live birth rates.

Preliminary results suggested that the use of rosiglitazone (Avandia), pioglitazone (Actos), and other members of the thiazolidinedione family may increase ovulation in PCOS patients; however, there is considerable reluctance to use these drugs in this setting given their association with an increased risk of congestive heart failure and myocardial ischemia.

**AROMATASE INHIBITORS.** Aromatase are under evaluation as potential drugs for infertility. By inhibiting estrogen biosynthesis, these drugs decrease
estrogen negative feedback and thus increase FSH levels and stimulate follicle development. The aromatase inhibitor anastrozole (ARIMIDEX) has been used off label for ovulation induction. Some data suggest that anastrozole is less effective than clomiphene in inducing follicle maturation but more likely to lead to pregnancy.

**DRUG THERAPY IN OBSTETRICS**

**GENERAL PRINCIPLES OF DRUG THERAPY OF PREGNANT WOMEN**

The processes of evaluating potential adverse effects of various drugs as described in Chapter 1, often do not provide sufficient information regarding safety in pregnant women or children. Individuals at the extremes of the age spectrum are particularly vulnerable to the toxic effects of drugs (see Chapter 4). In pregnant women, the placenta provides a barrier for the transfer of certain drugs from the mother to the fetus; however, many compounds can freely cross the placental barrier and access the fetal circulation.

The teratogenic effects of thalidomide on limb formation, alcohol on development of the CNS and cognition, and diethylstilbestrol (DES) on genital development in males and females are stark reminders of the dangers of fetal exposure to drugs.

**PRECAUTIONS AND RECOMMENDATIONS.** Based on the relative paucity of human data on the teratogenic effects of drugs and the limited reliability of animal models, a fundamental tenet in treating pregnant women is to minimize, whenever possible, the exposure of mother and fetus to drugs. Of equal importance, substances of abuse (e.g., cigarettes, alcohol, illegal drugs) should be avoided and, whenever possible, eliminated before conception. In addition, all pregnant women should take a multivitamin containing 400 μg of folic acid daily to diminish the incidence of neural tube defects.

The greatest concern is during the period of organogenesis in the first trimester, when a number of the most vulnerable tissues are formed. Cancer chemotherapy
drugs cannot be given with reasonable safety during the first trimester, but most cytotoxics may be administered without teratogenic effects and with maintenance of pregnancy in the third trimester (see Chapters 61-63). Drugs that are used to promote fertility are a special case, since they, by nature of their use, will be present in the mother at the time of conception.

**USE-IN-PREGNANCY LISTING OF DRUGS.** The FDA assigns different levels of risk to drugs for use in pregnant women, as listed in Table 66–3.

Certain drugs are so toxic to the developing fetus that they must never be administered to a pregnant woman (Category X); in some cases (e.g., thalidomide, retinoids), the potential for fetal harm is so great that multiple forms of effective contraception must be in place before the drug is initiated. For other drugs, the risk of adverse effects on the fetus may range from Category A (drugs that have not been proven to have adverse effects on the fetus despite adequate investigation) to Category D (drugs with risks that sometimes may be justified based on the severity of the underlying condition; see “Pregnancy-Induced Hypertension/Pre-eclampsia” and “Tocolytic Therapy for Established Preterm Labor”). Unfortunately, the FDA listings may be overly simplistic or outdated for a given drug; for example, oral contraceptives are listed as Category X, even though considerable data now indicate that birth defects are not increased in women taking oral contraceptives at the time of conception.

Nursing mothers constitute a second special situation with respect to potential adverse effects of drugs. Some drugs may interfere with milk production and/or secretion (e.g., estrogen-containing oral contraceptives) and thus should be avoided if possible in mothers who wish to breast-feed. Other drugs may be secreted into breast milk and expose the baby to potentially toxic levels during the vulnerable perinatal period.

**PREGNANCY-INDUCED HYPERTENSION/PRE-ECLAMPSIA**

Hypertension affects up to 10% of pregnant women in the U.S.

Hypertension that precedes pregnancy or manifests before 20 weeks of gestation is believed to overlap considerably in pathogenesis with essential hypertension.
These patients appear to be at increased risk for gestational diabetes and need careful monitoring. In contrast, pregnancy-induced hypertension, or pre-eclampsia, generally presents after 20 weeks of gestation as a new-onset hypertension with proteinuria (>300 mg of urinary protein/24 h); pre-eclampsia is thought to involve placenta-derived factors that affect vascular integrity and endothelial function in the mother, thus causing peripheral edema, renal and hepatic dysfunction, and in severe cases, seizures. Chronic hypertension is an established risk factor for pre-eclampsia. The consensus panel recommended initiation of drug therapy in women with a diastolic blood pressure >105 mm Hg or a systolic blood pressure >160 mm Hg. If severe pre-eclampsia ensues, with marked hypertension and evidence of end-organ damage, then termination of the pregnancy by delivery of the baby is the treatment of choice, provided that the fetus is sufficiently mature to survive outside the uterus. If the baby is very preterm, then hospitalization and pharmacotherapy may be employed in an effort to permit further fetal maturation in utero.

Several drugs commonly used for hypertension in non-pregnant patients (e.g., angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists) should not be used in pregnant women due to unequivocal evidence of adverse fetal effects. Many experts will convert the patient to the centrally acting α adrenergic agonist α-methyldopa (ALDOMET; 250 mg twice daily) (FDA Category B), which rarely is used for hypertension in non-pregnant patients. Other drugs with reasonable evidence of safety (Category C) also may be used, including the combination α-selective, β-nonselective adrenergic antagonist labetalol (TRANDATE; 100 mg twice daily) and the Ca²⁺ channel blocker nifedipine (PROCARDIA XL, ADALAT CC; 30 mg once daily).

If severe pre-eclampsia or impending labor requires hospitalization, blood pressure can be controlled acutely with hydralazine (5 or 10 mg intravenously or intramuscularly, with repeated dosing at 20-min intervals depending on blood pressure response) or labetalol (20 mg intravenously, with dose escalation to 40 mg at 10 min if blood pressure control is inadequate). In addition to receiving drugs for blood pressure control, women with severe pre-eclampsia or who have CNS manifestations (e.g., headache, visual disturbance, or altered mental status)
are treated as inpatients with magnesium sulfate, based on its documented efficacy in seizure prevention and lack of adverse effects on the mother or baby. Such treatment also should be considered for postpartum women with CNS manifestations: ~20% of episodes of eclampsia occur in women more than 48 h post-delivery.

**PREVENTION OR ARREST OF PRETERM LABOR**

Preterm birth, defined as delivery before 37 weeks of gestation, occurs in >10% of pregnancies in the U.S., is increasing in frequency, and is associated with significant complications, such as neonatal respiratory distress syndrome, pulmonary hypertension, and intracranial hemorrhage. Risk factors for preterm labor include multifetal gestation, premature rupture of the membranes, intrauterine infection, and placental insufficiency. The more premature the baby, the greater the risk of complications, prompting efforts to prevent or interrupt preterm labor.

The therapeutic objective in preterm labor is to delay delivery so that the mother can be transported to a regional facility specializing in the care of premature babies and supportive agents can be administered, such as glucocorticoids to stimulate fetal lung maturation (see Chapter 42) and antibiotics (e.g., erythromycin, ampicillin) to diminish the frequency of neonatal infection with group B β-hemolytic *Streptococcus*. Due to concerns over deleterious effects of antibiotic therapy, antibiotics must not be administered indiscriminately to all women thought to have preterm labor, but rather be reserved for those with premature rupture of the membranes and evidence of infection.

**PREVENTION OF PRETERM LABOR:** Progesterone Therapy. Progesterone levels diminish considerably in association with labor, whereas administration of progesterone inhibits the secretion of pro-inflammatory cytokines and delays cervical ripening. Although progesterone and its derivatives have long been advocated to diminish the onset of preterm labor, results from clinical trials have been controversial and the role of progesterone prophylaxis during pregnancy
remains to be established.

**TOCOLOYTIC THERAPY FOR ESTABLISHED PRETERM LABOR.** Inhibition of uterine contractions of preterm labor, or *tocolysis*, has been a focus of therapy. Although tocolytic agents delay delivery in ~80% of women, they neither prevent premature births nor improve adverse fetal outcomes such as respiratory distress syndrome. Specific tocolytic agents include β adrenergic receptor agonists, MgSO₄, Ca²⁺ channel blockers, COX inhibitors, oxytocin-receptor antagonists, and NO donors ([Figure 66–2](#)).

![Figure 66–2](https://example.com/figure662.png)

**Figure 66–2 Sites of action of tocolytic drugs in the uterine myometrium.** The elevation of cellular Ca²⁺ promotes contraction via the Ca²⁺/calmodulin-dependent activation of myosin light chain kinase (MLCK). Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of
MLCK. Pharmacological manipulations to reduce myometrial contraction include:

- Inhibiting Ca\(^{2+}\) entry (Ca\(^{2+}\) channel blockers, Mg\(_2\)SO\(_4\))
- Reducing mobilization of intracellular Ca\(^{2+}\) by antagonizing GPCR-mediated activation of the G\(_q\)-PLC-IP\(_3\)-Ca\(^{2+}\) pathway (with antagonists of the FP and OXT receptors) or reducing production of the FP agonist, PGF\(_{2\alpha}\) (with COX inhibitors)
- Enhancing relaxation by elevating cellular cyclic AMP (with \(\beta_2\) adrenergic agonists that activate G\(_s\)-AC) and cyclic GMP (with NO donors that stimulate soluble guanylyl cyclase)

AC, adenylyl cyclase; COX, cyclooxygenase; FP, the PGF\(_{2\alpha}\) receptor; OXT, the oxytocin receptor; PLC, phospholipase C; sGC, soluble guanylyl cyclase.

Based on the role of prostaglandins in uterine contraction, COX inhibitors (e.g., indomethacin) have been used to inhibit preterm labor. Because they also can inhibit platelet function and induce closure in utero of the ductus arteriosus, these inhibitors should not be employed in term pregnancies (or in pregnancies beyond 32 weeks of gestation). Atosiban (TRACTOCILE), a nonapeptide analog of oxytocin, competitively inhibits the interaction of oxytocin with its membrane receptor on uterine cells and thereby decreases the frequency of uterine contractions. Atosiban is widely used in Europe, but is not FDA-approved in the U.S. Despite numerous clinical trials, the superiority of any one therapy has not been established, and none of the drugs has been shown definitively to improve fetal outcome. Ca\(^{2+}\) channel blockers and atosiban (not available in the U.S.) appear to provide the best balance of successfully delayed delivery with lesser risks to the mother and baby.

**INITIATION OF LABOR**

Labor induction is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of delivery or pharmacological induction. Such circumstances include premature rupture of the membranes, isoimmunization, fetal growth restriction, uteroplacental insufficiency (as in diabetes, pre-eclampsia, or eclampsia), and gestation beyond 42 weeks.
**PROSTAGLANDINS AND CERVICAL RIPENING.** Prostaglandins play key roles in parturition (see Chapter 33). Thus, PGE₁, PGE₂, and PGF₂α are used to facilitate labor by promoting ripening and dilation of the cervix. They can be administered either orally or via local administration (either vaginally or intracervically). The ability of certain prostaglandins to stimulate uterine contractions also makes them valuable agents in the therapy of postpartum hemorrhage.

Available preparations include dinoprostone (PGE₂), used to facilitate cervical ripening. Dinoprostone is formulated as a gel for intracervical administration via syringe in a dose of 0.5 mg (Prepidil) or as a vaginal insert (pessary) in a dose of 10 mg (Cervidil); the latter is designed to release active PGE₂ at a rate of 0.3 mg/hr for up to 12 h. Dinoprostone should not be used in women with a history of asthma, glaucoma, or myocardial infarction. The major adverse effect is uterine hyperstimulation.

Misoprostol (Cytotec), a synthetic derivative of PGE₁, is used off label either orally or vaginally to induce cervical ripening; typical doses are 100 μg (orally) or 25 μg (vaginally); an advantage of misoprostol in this setting is its considerably lower cost. Adverse effects include uterine hyperstimulation and, rarely, uterine rupture. Misoprostol should be discontinued for at least 3 h before initiating oxytocin therapy.

**OXYTOCIN.** The structure and physiology of oxytocin are discussed in Chapter 38. The obstetrical uses of oxytocin include the induction of labor, the augmentation of labor that is not progressing, and the prophylaxis and/or treatment of postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm.”

**Labor Induction.** Oxytocin (Pitocin, Syntocinon) is the drug of choice for labor induction. It is administered by intravenous infusion of a diluted solution preferably via an infusion pump. Current protocols start with an oxytocin dose of 6 mIU/min, that is increased as needed, up to 40 mIU/min. Uterine hyperstimulation should be avoided. Because the $t_{1/2}$ of intravenous oxytocin is relatively short (12-15 min), the hyperstimulatory effects of oxytocin will dissipate fairly rapidly after the infusion is discontinued. Oxytocin at higher doses activates the vasopressin V₂ receptor and has antidiuretic effects.
Vasodilating actions of oxytocin also have been noted that may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

**Augmentation of Dysfunctional Labor.** Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions, an infusion rate of 10 mIU/min typically is sufficient. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion.

**PREVENTION/TREATMENT OF POSTPARTUM HEMORRHAGE**

*Oxytocin* (10 IU intramuscularly) is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, oxytocin (20 IU) is diluted in 1 L of intravenous solution and infused at a rate of 10 mL/min until the uterus is contracted. The infusion rate then is reduced to 1-2 mL/min until the mother is ready for transfer to the postpartum unit. *Ergot alkaloids* markedly increase the motor activity of the uterus to prevent or treat postpartum hemorrhage in normotensive women. The preferred ergot alkaloids are ergonovine (*ERGOTRATE*) or methylergonovine (*METHERGINE*). They are administered intramuscularly or intravenously, exhibit rapid onsets of action (2-3 min intramuscularly, <1 min intravenously), and their effects persist for 45 min to 3 h depending on the route of administration. Adverse effects include nausea and vomiting, elevated blood pressure, and decreased pain threshold requiring analgesia. The PGE₁ analog *misoprostol* (600 μg administered orally or sublingually) may be used off label to stimulate uterine contractions and prevent or treat postpartum hemorrhage.
chapter 67
Environmental Toxicology: Carcinogens and Heavy Metals

Myriad authoritative textbooks are available in the area of environmental toxicology. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, briefly discusses carcinogens and chemoprevention, and then focuses on the pharmacotherapy of heavy metal intoxication.

ASSESSMENT AND MANAGEMENT OF ENVIRONMENTAL RISK

When assessing the risks of environmental exposures to xenobiotics, one must consider population exposures to low-dose toxicants over long periods of time. Thus, one must give careful attention to the low end of the dose-response curve, using experiments based on chronic exposures. Unlike drugs, which are given to treat a specific disease and should have benefits that outweigh the risks, environmental toxicants usually are only harmful. In addition, exposures to environmental toxicants usually are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

*Epidemiology* and *toxicology* are 2 approaches used to predict the toxic effects of environmental exposures. Epidemiologists monitor health effects in humans and use statistics to associate those effects with exposure to an environmental stress, such as a toxicant. Toxicologists perform laboratory studies to try to understand the potential toxic mechanisms of a chemical to predict whether it is likely to be toxic to humans. Information from both approaches is integrated into *environmental risk assessment*. Risk assessment is used to develop laws and regulations to limit exposures to environmental toxicants to a level that is considered safe.

EPIDEMIOLOGICAL APPROACHES TO RISK ASSESSMENT
Assessing human exposures over long periods of time and drawing conclusions about the health effects of a single toxicant present great challenges. Epidemiologists usefully rely on biomarkers in assessing risk. There are 3 types of biomarkers:

- **Biomarkers of exposure** usually are measurements of toxicants or their metabolites in blood, urine, or hair. Blood and urine concentrations measure recent exposures, while hair levels measure exposure over a period of months. An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead.

- **Biomarkers of toxicity** are used to measure toxic effects at a subclinical level and include measurement of liver enzymes in the serum, changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function.

- **Biomarkers of susceptibility** are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant. Some biomarkers simultaneously provide information on exposure, toxicity, and susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B₁ provides evidence of both exposure and a toxic effect (in this case, DNA damage). Such biomarkers are valuable because they can support a proposed mechanism of toxicity.

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses. **Ecological studies** correlate frequencies of exposures and health outcomes between different geographical regions. These studies can detect rare outcomes but are prone to confounding variables, including population migration. **Cross-sectional studies** examine the prevalence of exposures and outcomes at a single point in time. Such studies determine an association but do not provide a temporal relationship and are not effective for establishing causality. **Case-control studies** start with a group of individuals affected by a disease, which then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is good for examining rare outcomes because the endpoint is known. However, case-control studies rely on
assessments of past exposures that often are unreliable and can be subject to bias. *Prospective cohort studies* measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are good at establishing causality, but they are extremely expensive, particularly when measuring very rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance. One of the key types of human studies used in drug development is the randomized clinical trial (see *Chapter 1*). Such studies cannot be used to directly measure the effects of environmental toxicants (for obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposure to toxicants and disease.

**TOXICOLOGICAL APPROACHES TO RISK ASSESSMENT**

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effect on humans. The significance of these model systems to human health is not always established. Toxicologists also test chemicals at the high end of the dose-response curve in order to see enough occurrences of an outcome to obtain statistical significance. As a result, there often is uncertainty about the effects of very low doses of chemicals. To determine the applicability of model studies, toxicologists study the mechanisms involved in the toxic effects of chemicals.

To predict the toxic effects of environmental chemicals, toxicologists perform subchronic (3 months of treatment for rodents) and chronic studies (2 years for rodents) in at least 2 different animal models. Subchronic experiments provide a model for occupational exposures, while chronic experiments are used to predict effects from lifetime exposures to chemicals in food or the environment. Doses are chosen with the goal of having 1 concentration that does not have a significant effect, 1 concentration that results in statistically significant toxicity at the low end of the dose-response curve, and 1 or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in *Figure 67–1*. An animal study provides 2 numbers that estimate the risk from a chemical. The *no observed adverse effect level* (NOAEL) is the highest dose used that does not result in a statistically
significant increase in negative health outcomes. The *lowest observed adverse effect level* (LOAEL) is the lowest dose that results in a significant increase in toxicity. The NOAEL is divided by 10 for each source of uncertainty to determine a reference dose (RfD), which is commonly used as a starting point for determining regulations on human exposures to chemicals. The modifiers used to determine the RfD are based on the uncertainties between the experimental and human exposure. The most common modifiers used are for interspecies variability (human to animal) and interindividual variability (human to human), in which case RfD = NOAEL/100. When a NOAEL is unavailable, a LOAEL may be used, in which case another 10-fold uncertainty factor is used. The use of factors of 10 in the denominator for determination of RfD is an application of the “precautionary principle,” which attempts to limit human exposure by assuming a worst-case scenario for each unknown variable. Animal studies typically are designed to obtain statistical significance with a 10% increase in an outcome. As a result, there is considerable uncertainty about what occurs below that level, as demonstrated in Figure 67–1. Toxicologists often assume that there is a threshold dose (T), below which there is no toxicity. However, many carcinogens and other toxicants with specific molecular targets (e.g., lead) do not exhibit a threshold. Ideally, mechanistic studies should be done to predict which dose-response curve is most likely to fit a given chemical.
Figure 67–1 LOAEL and NOAEL. The theoretical dose-response curve from an animal study demonstrates the no observed adverse effect level (NOAEL) and the lowest observed adverse effect level (LOAEL). Below the NOAEL level, there is considerable uncertainty as to the shape of the response curve. It could continue linearly to reach a threshold dose (T) where there would be no harmful effects from the toxicant, or it could have a number of different possible inflection points. Each of these curves would reflect very different effects on human populations. *, statistically significant; BW, body weight.

Toxicologists perform a variety of mechanistic studies to understand how a chemical might cause toxicity. Computer modeling using a compound’s 3-dimensional structure to determine quantitative structure-activity relationships (QSARs) is commonly performed on both drugs and environmental chemicals. QSAR approaches can determine which chemicals are likely to exhibit toxicities or bind to specific molecular targets. Cell-based approaches in prokaryotes and eukaryotes are used to determine whether a compound damages DNA or causes cytotoxicity. DNA damage and the resulting mutagenesis often are determined with the Ames test. The Ames test uses Salmonella typhimurium strains with
specific mutations in the gene needed to synthesize histidine. These strains are treated with chemicals in the presence or absence of a metabolic activating system, usually the supernatant fraction from homogenized rat liver. If a compound is a mutagen in the Ames test, it reverts the mutation in the histidine operon and allows the bacteria to form colonies on plates with limited histidine. Gene chip microarrays assess gene expression in cells or tissues from animals treated with a toxicant and provide a very useful tool to identify the molecular targets and pathways altered by toxicant exposures. The susceptibility of knockout mice to a toxicant can help to determine whether the knocked-out genes are involved in the metabolic activation and detoxification of a given toxicant.

CARCINOGENS AND CHEMOPREVENTION

CARCINOGENESIS

The International Agency for Research on Cancer (IARC) classifies compounds into groups based on risk assessments using human, animal, and mechanism data. Chemicals in group 1 are known human carcinogens; group 2A includes chemicals that probably are carcinogenic in humans; group 2B chemicals possibly are carcinogenic in humans; group 3 chemicals lack data to suggest a role in carcinogenesis; and group 4 are those with data indicating they are unlikely to be carcinogens. Table 67–1 presents information of some Group 1 carcinogens.

Table 67–1

Examples of Important Carcinogens

a
The transformation of a normal cell to a malignancy is a multi-stage process, and exogenous chemicals can act at 1 or more of these stages (Figure 67–2). A classic model of chemical carcinogenesis is tumor initiation followed by tumor promotion. A tumor initiator causes gene mutations that increase the ability of cells to proliferate and avoid apoptosis. A tumor promoter does not directly modify genes but changes signaling pathways and/or the extracellular environment to cause initiated cells to proliferate. Although this model is an oversimplification, it demonstrates the types of changes that must occur to transit a normal cell into tumorigenesis.
Carcinogenesis: initiation and promotion. There are many steps that occur between the exposure to a genotoxic carcinogen and the development of cancer. Processes in red lead to the development of cancer, while those in green reduce the risk. Non-genotoxic carcinogens act by enhancing steps leading to cancer and/or inhibiting protective processes. A chemopreventive agent acts by inhibiting steps leading to cancer or by increasing protective processes.

Chemical carcinogens cause cancer through genotoxic and non-genotoxic mechanisms (Figure 67–2). Genotoxic carcinogens induce tumor formation through damage to DNA. Typically, genotoxic carcinogens undergo metabolism in a target tissue to a reactive intermediate. This reactive intermediate can directly damage DNA via covalent reaction to form a DNA adduct. Alternatively, it can indirectly damage DNA through the formation of reactive oxygen species (ROS), which can oxidize DNA or form lipid peroxidation products that react with DNA. If DNA damage from a genotoxic carcinogen is not repaired prior to DNA replication, a mutation can result. If this mutation is in a key tumor suppressor gene or proto-oncogene, it provides advantages in proliferation or survival. Alternatively, if the mutation is in a DNA repair gene, the mutation increases the probability that other mutations will occur. Genotoxic carcinogens are tumor initiators.

Benzo[a]pyrene, a key carcinogen in tobacco smoke, is an example of a genotoxic carcinogen that forms both direct DNA adducts and ROS. Benzo[a]pyrene is oxidized by CYPs to a 7,8-dihydrodiol, which represents a proximate carcinogen (a more carcinogenic metabolite). This metabolite can either undergo a second oxidation step by a CYP to form a diol epoxide, which
readily reacts with DNA, or it can undergo oxidation by aldo-keto reductases to form a catechol, which will redox cycle to form ROS.

Non-genotoxic carcinogens increase the incidence of cancer without damaging DNA. Many non-genotoxic carcinogens bind to receptors that stimulate proliferation or other tumor-promoting effects, such as tissue invasion or angiogenesis. For example, phorbol esters mimic diacylglycerol and activate PKC isoforms. This in turn stimulates MAP kinase pathways, leading to proliferation, invasiveness, and angiogenesis (see Chapter 3). In most normal cells, prolonged activation of this pathway stimulates apoptosis, but cells with defective apoptotic mechanisms due to preceding mutation(s) are resistant to this effect. Estrogenic carcinogens activate estrogen receptor-α (ERα) and stimulate proliferation and invasiveness of estrogen responsive cells. Chronic inflammation is another mechanism of non-genotoxic carcinogenesis. Inflammatory cytokines stimulate PKC signaling, leading to proliferation, invasiveness, and angiogenesis. Irritants such as asbestos are examples of carcinogens that work through inflammation. Chronic exposure to hepatotoxic chemicals (or chronic liver diseases) also causes non-genotoxic carcinogenesis by stimulating compensatory proliferation to repair the liver damage. This damage and repair process increases the likelihood of DNA damage becoming a mutation, causes chronic inflammation, and selects for cells that proliferate faster or are less sensitive to apoptosis.

Tumor initiation also may occur through non-genotoxic mechanisms. For example, some heavy metals do not directly react with DNA but interfere with proteins involved in DNA synthesis and repair, increasing the likelihood that an error will be made during replication. Non-genotoxic carcinogens also can cause heritable changes to gene expression by altering the methylation state of cytosines in 5’-CpG-3 islands of gene promoters, thus acting as tumor initiators. Methylation can silence tumor suppressor genes, while demethylation of protooncogenes can increase their expression.

**CHEMOPREVENTION**

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed *chemopreventive agents*. Chemoprevention strategies often are based on epidemiological
studies of nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer. A number of compounds for the prevention of cancer are in clinical trials (Table 67–2). There currently are no drugs approved for chemoprevention of environmental carcinogenesis, but there are approved drugs to prevent carcinogenesis due to endogenous estrogen (tamoxifen and raloxifene) and viruses (hepatitis B and human papillomavirus vaccines).

Chemopreventive agents interfere with the processes of initiation and promotion (see Figure 67–2). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates and similar compounds inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive group includes γ-glutamylcysteine synthase light chain (the gene responsible for the rate-determining step in GSH synthesis) and quinone reductase (NQO1). Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts. Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants. For example, flavonoids and other
polyphenols found in a wide variety of plants are potent antioxidants that inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and prevent them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. The COX-2 inhibitor celecoxib has demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early termination of the trial. Studies examining long-term treatment with aspirin for cardiovascular benefits found that aspirin also reduces the incidence of colorectal adenomas. Natural compounds, such as α-tocopherol, also can exert chemoprevention by reducing inflammation.

One successful approach to chemoprevention is modification of nuclear receptor signaling. Promising preliminary data suggested that retinoids might be beneficial for preventing lung and other cancers. The selective ER modulators tamoxifen and raloxifene reduce the incidence of breast cancer in high-risk women and are approved for chemoprevention in these patients.

**AFLATOXIN B₁.** Promising agents are being developed as chemopreventants of hepatocarcinogenesis mediated by aflatoxin B₁. Aflatoxins are produced by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts. *A. flavus* is abundant in regions with hot and wet climates.

**ADME.** Aflatoxin B₁ is readily absorbed from the GI tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism. Aflatoxin B₁ is metabolized by CYPs, including 1A2 and 3A4, to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M₁) or 3 position (aflatoxin Q₁; Figure 67–3). The hydroxylation products are less susceptible to epoxidation and are therefore detoxification products. The 8,9-epoxide is highly reactive toward DNA and is the reactive intermediate
responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via nonenzymatic hydrolysis or conjugation with GSH. Aflatoxin M₁ enters the circulation and is excreted in urine and milk. Hydroxylated aflatoxin metabolites also can undergo several additional phase 1 and phase 2 metabolic pathways prior to excretion in urine or bile.

\[\text{Figure 67–3 Metabolism and actions of aflatoxin B}_{1}\text{. Following ingestion and absorption of food containing } A. \text{ flavus, aflatoxin B}_{1}\text{ undergoes activation by CYPs to its 8,9-epoxide, which can be detoxified by glutathione S-transferases (GSTs) or by spontaneous hydration. Alternatively, it can react with cellular macromolecules such as DNA and protein, leading to toxicity and cancer. Oltipraz, green tea polyphenols (GTPs), and isothiocyanates (ITCs) decrease aflatoxin carcinogenesis by inhibiting the CYPs involved aflatoxin activation and increasing the synthesis of GSH for GSTs involved in detoxification.}\]

**Toxicity.** Aflatoxin B₁ primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is relatively rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

**Carcinogenicity.** Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and supporting animal data, IARC has classified aflatoxin B₁ and several other natural aflatoxins as known human carcinogens
Aflatoxin exposure and hepatitis B virus work synergistically to cause hepatocellular carcinoma. Separately, aflatoxin or hepatitis B exposure increases the risk of hepatocellular carcinoma 3.4- or 7.3-fold, respectively; those exposed to both have a 59-fold increased risk of cancer compared to unexposed individuals. Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position. The N7-guanine adduct mispairs with adenine, leading to G → T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG to AGT mutation in codon 249 of the p53 tumor suppressor gene, resulting in the replacement of an arginine with cysteine.

The interaction between aflatoxin and hepatitis B that is responsible for the increased incidence of hepatocellular carcinoma is not well understood. Hepatitis B influences the metabolism of aflatoxin B₁ by upregulating CYPs, including 3A4, and decreasing glutathione S-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

**Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma.** Inhibiting CYP activity or increasing glutathione conjugation will reduce the intracellular concentration of the 8,9-epoxide and thus prevent DNA adduct formation. One drug that has been tested as a modifier of aflatoxin metabolism is oltipraz. Oltipraz, an anti-schistosomal drug, potently inhibits CYPs and induces genes regulated by the ARE. Oltipraz increases the excretion of aflatoxin N-acetylcysteine, indicating enhanced glutathione conjugation of the epoxide. At 500 mg/wk, oltipraz reduced the levels of aflatoxin M₁, consistent with inhibition of CYP activity.

Green tea polyphenols also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin–albumin adducts and a large increase in the excretion of aflatoxin N-acetylcysteine, consistent with a protective effect.
Another approach used for the chemoprevention of aflatoxin hepatocarcinogenesis is the use of “interceptor molecules.” Chlorophyllin, an over-the-counter mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. In vitro, chlorophyllin inhibits CYP activity and acts as an antioxidant. In a phase 2 trial, administration of 100 mg of chlorophyllin with each meal reduced aflatoxin–N7-guanine adduct levels in the urine by >50%. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine will reduce the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination can also reduce human exposure. A more cost-effective primary prevention approach is to improve food storage to limit the spread of *A. flavus*, which requires a warm and humid environment.

**METALS**

*Arsenic, lead,* and *mercury* are the top 3 substances of concern due to their toxicity and likelihood of human exposure as listed under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as Superfund).

Many of the toxic metals in the environment also are carcinogens (*Table 67–3*). In addition, several essential metals also are toxic under conditions of overdose. Copper and especially iron are associated with toxicities, primarily targeting the liver through generation of ROS.

**Table 67–3**

*Toxic Metals with Frequent Environmental or Occupational Exposure*
Not listed in Table 67–3 is the metal gold, which has its own uses and toxicities. Among heavy metals, perhaps only gold is addictive: gold has been used for centuries for relief of the itching palm, and many cannot get enough of its influence.

**LEAD.** Chronic exposure of populations to even very low levels of lead (Pb) has major deleterious effects that are only now beginning to be understood.

**Exposure.** Until late in the 20th century, the potential for exposure to Pb was high. In the U.S., paint containing Pb for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was eliminated in 1996. Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of Pb exposure. Pb is not degradable and remains throughout the environment in dust, soil, and the paint of older homes. Young children often are exposed to lead by nibbling sweet-tasting paint chips or eating dust and soil in and around older homes. Renovation
or demolition of older buildings may cause substantial Pb exposure. Removal of Pb from gasoline caused Pb levels in air pollution to drop by >90% between 1982 and 2002. Acidic foods and beverages dissolve Pb when stored in containers with Pb in their glaze or lead-soldered cans. Pb exposure also has been traced to other sources such as lead toys, non-Western folk medicines, cosmetics, retained bullets, artists’ paint pigments, ashes and fumes from painted wood, jewelers’ wastes, home battery manufacture, and lead type. The CDC recommends screening of children at 6 months of age and the use of aggressive Pb abatement for children with blood Pb levels >10 μg/dL.

Chemistry and Mode of Action. Divalent lead is the primary environmental form; inorganic tetravalent Pb compounds are not naturally found. Organo-Pb complexes primarily occur with tetravalent Pb and include the gasoline additive tetraethyl lead. Pb toxicity results from molecular mimicry of other divalent metals, principally zinc and calcium. Because of its size and electron affinity, Pb alters protein structure and can inappropriately activate or inhibit protein function.

Absorption, Distribution, and Excretion. Pb exposure occurs through ingestion or inhalation. Children absorb a much higher percentage of ingested Pb (~40% on average) than adults (<20%). Absorption of ingested Pb is drastically increased by fasting. Dietary calcium or iron deficiencies increase Pb absorption, suggesting that Pb is absorbed through divalent metal transporters. The absorption of inhaled Pb generally is much more efficient (~90%). Tetraethyl Pb is readily absorbed through the skin; transdermal absorption is not a route of exposure for inorganic Pb.

About 99% of Pb in the bloodstream binds to hemoglobin. Pb initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, Pb is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of Pb is found in bone. Growing bones will accumulate higher levels of Pb and can form lead lines visible by radiography. Bone Pb is very slowly reabsorbed into the bloodstream. Small quantities of Pb accumulate in the brain. Pb readily crosses the placenta. Pb is excreted primarily in the urine. The concentration of Pb in urine is directly proportional to its concentration in plasma. Pb is excreted in milk and sweat and deposited in hair and nails. The serum $t_{1/2}$ of Pb is 1-2 months, with a steady state achieved in ~6
months. Pb accumulates in bone, where its $t_{1/2}$ is estimated at 20-30 years.

**Health Effects.** The nervous, hematological, cardiovascular, and renal systems are the most sensitive.

**Neurotoxic Effects.** The biggest concerns with low-level Pb exposure are cognitive delays and behavior changes in children. Pb interferes with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Together, these alterations in brain development result in decreased IQ, poor performance on exams, and behavioral problems such as distractibility, impulsivity, short attention span, and inability to follow even simple sequences of instructions. Because different areas of the brain mature at different times, the neurobehavioral changes vary between children, depending on the timing of the Pb exposure. Children with very high Pb levels (>70 μg/dL) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are ~25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

Encephalopathy in adults requires blood Pb levels >100 μg/dL. The symptoms are similar to those observed with children. Pb induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between Pb exposure and decreased performance on cognitive function tests. The neurodevelopmental effects of Pb primarily result from inhibition of Ca$^{2+}$ transporters and channels and altered activities of Ca$^{2+}$ responsive proteins, including PKC and calmodulin. These actions limit the normal activation of neurons caused by Ca$^{2+}$ release and cause inappropriate production and/or release of neurotransmitters. At high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions. This effect is likely responsible for encephalopathy.

**Cardiovascular and Renal Effects.** Elevated blood pressure is a lasting effect of lead exposure. Lead exposure also is associated with an increased risk of death due to cardiovascular and cerebrovascular disease. In the kidney, even low-level Pb exposure (blood levels <10 μg/dL) depresses glomerular filtration. Higher levels (>30 μg/dL)
cause proteinuria and impaired transport, while very high levels (>50 μg/dL) causepermanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. The cardiovascular effects of Pb are thought to involve the production of ROS through an unknown mechanism. Pb also forms inclusion bodies with various proteins, including metallothionein, in the kidney. The formation of these bodies essentially chelates the Pb and appears to be protective.

**Hematological Effects.** Chronic Pb intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to Fe-deficient anemia. The anemia is thought to result from both decreased erythrocyte life span and inhibition of several enzymes involved in heme synthesis, which is observed at very low lead levels (see Figures 67–4 and 67–5). Pb also causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling.

**GI Effects.** Pb affects the smooth muscle of the gut, producing intestinal symptoms that are an early sign of high-level exposure to the metal. The abdominal syndrome often begins with a persistent metallic taste, mild anorexia, muscle discomfort, malaise, headache, and constipation (or occasionally, diarrhea). As intoxication advances, symptoms worsen and include intestinal spasms and pain (lead cholic). Intravenous calcium gluconate can relieve this pain.

**Carcinogenesis.** IARC recently upgraded Pb to “probably carcinogenic in humans” (group 2A). Epidemiological studies have shown associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to Pb develop kidney tumors, and some rats develop gliomas. Pb is not mutagenic but increases clastogenic events. Pb carcinogenesis may result from inhibition of DNA binding zinc-finger proteins, including those...
involved in DNA repair and synthesis. Pb is a good example of a non-genotoxic carcinogen.

**Treatment.** The most important response to Pb poisoning is removal of the source of exposure. Supportive measures should be undertaken to relieve symptoms. Chelation therapy is warranted for children and adults with high blood Pb levels (>45 μg/dL and >70 μg/dL, respectively) and/or acute symptoms of Pb poisoning. Although chelation therapy is effective at lowering blood Pb levels and relieving immediate symptoms, it does not reduce the chronic effects of Pb beyond the benefit of abatement alone.

**MERCURY.** Mercury (Hg) has been used industrially since ancient Greece due to its capacity to amalgamate with other metals. Mercury also was used as a therapeutic drug for several centuries. Its use for the treatment of syphilis inspired Paracelsus’s observation that “the dose makes the poison,” one of the central concepts of toxicology, and also gave rise to the cautionary expression, “A night with Venus, a year with Mercury.” The phrase “mad as a hatter” originated from the exposure of hatters to metallic Hg vapor during production of felt for hats using mercury nitrate.

**Exposure.** Hg vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Hg also enters the atmosphere through human activities such as combustion of fossil fuels. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury. Methyl mercury concentrates in lipids and will bioaccumulate up the food chain so that concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are quite high (Figure 67–6).
Figure 67–6 Mobilization of mercury in the environment. Metallic mercury (Hg⁰) is vaporized from the Earth’s surface both naturally and through human activities such as burning coal. In the atmosphere, Hg⁰ is oxidized to form divalent inorganic mercury (Hg²⁺), which falls to the surface in rain. Aquatic bacteria can methylate Hg²⁺ to form methyl mercury (MeHg⁺). MeHg⁺ in plankton is consumed by fish. Because of its lipophilicity, MeHg⁺ bioaccumulates up the food chain.

The primary source of exposure to metallic Hg in the general population is vaporization of Hg in dental amalgam. There also is limited exposure through broken thermometers and other Hg-containing devices. Human exposure to organic Hg primarily is through the consumption of fish. Workers are exposed to metallic and inorganic mercury, most commonly though exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which Hg is used as a catalyst. Hg is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to Hg from amalgam. Hg can be used to extract gold during mining. Mercuric salts are used as pigments in paints.
Thimerosal is an antimicrobial agent used as a preservative in some vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to methyl mercury. Some have argued that thimerosal might contribute to autism; however, studies have not found an association between thimerosal use in vaccines and negative health outcomes. Nonetheless, with the exception of some influenza (flu) vaccines, thimerosal is no longer used as a preservative in routinely recommended childhood vaccines.

**Chemistry and Mode of Action.** There are 3 general forms of Hg of concern to human health. *Metallic, or elemental, mercury* (Hg\(^0\)) is the liquid metal found in thermometers and dental amalgam; it is quite volatile, and exposure is often to the vapor. *Inorganic mercury* can be either monovalent (mercurous, Hg\(^{1+}\)) or divalent (mercuric, Hg\(^{2+}\)) and forms a variety of salts. *Organic mercury* compounds consist of divalent mercury complexed with 1 or occasionally 2 alkyl groups. The organic mercury compound of most concern is methyl mercury (MeHg\(^+\)), which is formed environmentally from inorganic Hg by aquatic microorganisms. Both Hg\(^{2+}\) and MeHg\(^+\) readily form covalent bonds with sulfur, an interaction that accounts for most of the biological effects of mercury. At very low concentrations, Hg reacts with sulfhydryl residues on proteins and disrupts their functions. There also may be an autoimmune component to Hg toxicity.

**ADME.** Hg\(^0\) vapor is readily absorbed through the lungs (~70-80%), but GI absorption of elemental (liquid) Hg is negligible. Absorbed Hg\(^0\) distributes throughout the body and crosses membranes such as the blood-brain barrier and the placenta via diffusion. Hg\(^0\) is oxidized by catalase in the erythrocytes and other cells to form Hg\(^{2+}\). Some Hg\(^0\) is eliminated in exhaled air. After a few hours, distribution and elimination of Hg\(^0\) resemble the properties of Hg\(^{2+}\). Hg\(^0\) vapor also is oxidized to Hg\(^{2+}\) and retained in the brain.

GI absorption of Hg salts averages ~10-15% but varies with the individual patient and the particular salt. Hg\(^{1+}\) will form Hg\(^0\) or Hg\(^{2+}\) in the presence of sulfhydryl groups. Hg\(^{2+}\) primarily is excreted in the urine and feces; a small amount also can be reduced to Hg\(^0\) and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of Hg also are excreted in sweat and breast milk and deposited in hair and nails. The \(t_{1/2}\) for inorganic Hg is ~1-2 months.
Orally ingested MeHg\(^+\) is almost completely absorbed from the GI tract. MeHg\(^+\) readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys. MeHg\(^+\) can be demethylated to form inorganic Hg\(^{2+}\). The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain. MeHg\(^+\) is excreted in the urine and feces, with the fecal pathway dominating. The \(t_{1/2}\) for MeHg\(^+\) is 2 months. Complexes between MeHg\(^+\) and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across membranes.

**Health Effects**

**Metallic Mercury.** Inhalation of high levels of Hg vapor over a short duration is acutely toxic to the lung. Respiratory symptoms start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of Hg also is toxic to the CNS (Figure 67–7).
Toxicity to the nervous system is the primary concern with chronic exposure to Hg vapor. Symptoms include tremors (particularly of the hands), emotional lability (irritability, shyness, loss of confidence, and nervousness), insomnia, memory loss, muscular atrophy, weakness, paresthesia, and cognitive deficits. These symptoms intensify and become irreversible, with increases in duration and concentration of exposure. Other common symptoms of chronic Hg exposure include tachycardia, labile pulse, severe salivation, gingivitis, and kidney damage.

**Inorganic Salts of Mercury.** Ingestion of Hg\(^{2+}\) salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. Acute exposure to Hg\(^{2+}\) salts (typically in suicide attempts) leads to renal tubular necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney.

**Organic Mercury.** The CNS is the primary target of methyl mercury toxicity. Symptoms of methyl mercury exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and, following severe exposure, paralysis and death. Children exposed in utero can develop severe symptoms, including mental retardation and neuromuscular deficits, even in the absence of symptoms in the mother.

**Treatment.** With exposure to metallic Hg, termination of exposure is critical and respiratory support may be required. Emesis may be used within 30-60 min of exposure to inorganic Hg, provided the patient is awake and alert and there is no corrosive injury. Maintenance of electrolyte balance and fluids is important for patients exposed to inorganic Hg. Chelation therapy is beneficial in patients with acute inorganic or metallic Hg exposure. There are limited treatment options for methyl mercury. Chelation therapy does not provide clinical benefits, and several chelators potentiate the toxic effects of methyl mercury. Nonabsorbed thiol resins may be beneficial by preventing reabsorption of methyl mercury from the GI tract.
Because of the conflicting effects of mercury and ω-3 fatty acids, there is considerable controversy regarding the restriction of fish intake in women of reproductive age and children. The EPA recommends limiting fish intake to 12 oz (2 meals) per week. Many experts feel this recommendation is too conservative, and the FDA is considering revising their recommendation to state that the benefits of fish consumption outweigh the risks. The recommendation that women consume fish that is lower in Hg content (i.e., canned light tuna, salmon, pollock, catfish) and avoid top predators, such as swordfish, shark, and tilefish, is not controversial.

**ARSENIC.** Arsenic (As) is a metalloid that is common in rocks and soil. The use of arsenic in drugs has been mostly phased out, but arsenic trioxide (ATO) is still used as an effective chemotherapy agent for acute promyelocytic leukemia (see Chapter 61).

**Exposure.** The primary source of exposure to As is through drinking water. Levels of As in drinking water average 2 μg/L (ppb) in the U.S. but can be >50 μg/L (5 times the EPA standard) in private well water, particularly in California, Nevada, and Arizona. Drinking water from other parts of the world sometimes is contaminated with much higher levels of As (sometimes several hundred μg/L), and widespread poisonings have resulted (see Figure 67–8 in the 12th edition of the parent text). Arsenic can enter the environment through the use of arsenic-containing pesticides, mining, and burning of coal. Food, particularly seafood, often is contaminated with As. The average daily human intake of As is 10 μg/day, almost exclusively from food and water.

![Figure 67–8 Metabolism of arsenic. AS3MT, arsenite methyltransferase; DMAV, dimethylarsinic acid; GSH, reduced glutathione; GSSG, oxidized glutathione; MMAIII, monomethylarsonous acid; MMAV, monomethylarsonic acid; SAH, S-adenosyl-L-homocysteine; SAM, S-adenosyl-L-methionine.](image-url)
Before 2003, >90% of As used in the U.S. was as a preservative in pressure-treated wood, but the lumber industry has voluntarily replaced As with other preservatives. As-treated wood is thought to be safe unless burned. The major source of occupational exposure to As is in the production and use of organic arsenicals as herbicides and insecticides. Exposure to metallic As, arsine, arsenic trioxide, and gallium arsenide also occurs in high-tech industries, such as the manufacture of computer chips and semiconductors.

Chemistry and Mode of Action. Arsenic exists in its elemental form and trivalent (arsenites/arsenious acid) and pentavalent (arsenates/As acid) states. Arsine is a gaseous hydride of trivalent As that exhibits toxicities that are distinct from other forms. The toxicity of a given arsenical is related to the rate of its clearance from the body and its ability to concentrate in tissues. In general, toxicity increases in the sequence: organic arsenicals < As$^{5+}$ < As$^{3+}$ < arsine gas (AsH$_3$). Like mercury, trivalent arsenic compounds form covalent bonds with sulfhydryl groups. The pyruvate dehydrogenase system is particularly sensitive to inhibition by trivalent arsenicals because the 2 sulfhydryl groups of lipoic acid react with As to form a 6-membered ring. Inorganic arsenate (pentavalent) inhibits the electron transport chain. It is thought that arsenate competitively substitutes for phosphate during the formation of ATP, forming an unstable arsenate ester that is rapidly hydrolyzed.

ADME. Poorly water-soluble forms such as arsenic sulfide, lead arsenate, and arsenic trioxide are not well absorbed. Water-soluble As compounds are readily absorbed from both inhalation and ingestion. GI absorption of As dissolved in drinking water is >90%. At low doses, As is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulfhydryl content, exhibit high concentrations of As. After an acute high dose (i.e., fatal poisoning), As is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals (see Figure 67–8). Trivalent compounds can be oxidized to pentavalent compounds, but there is no evidence for demethylation of methylated
arsenicals. Humans excrete much higher levels of monomethyl-As (MMA) compounds than most other animals. The trivalent methylated arsenicals are more toxic than inorganic arsenite, due to an increased affinity for sulfhydryl groups; formation of MMA$_{III}$ now is considered a bioactivation pathway. Elimination of arsenicals by humans primarily is in the urine, although some is also excreted in feces, sweat, hair, nails, skin, and exhaled air. Compared to most other toxic metals, arsenic is excreted quickly ($t_{1/2}$ 1-3 days). In humans, ingested inorganic As in urine is a mixture of 10-30% inorganic arsenicals, 10-20% monomethylated forms, and 60-80% dimethylated forms.

Health Effects. With the exception of arsine gas, the various forms of inorganic As exhibit similar toxic effects. Inorganic As exhibits a broad range of toxicities and has been associated with effects on every organ system tested. Acute exposure to large doses of As (>70-180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of As’s combined effect on multiple organs.

Cardiovascular System. Acute and chronic As exposure cause myocardial depolarization, cardiac arrhythmias, and ischemic heart disease; these are known side effects of As trioxide for the treatment of leukemia. Chronic exposure to As causes peripheral vascular disease, the most dramatic example of which is “blackfoot disease,” a condition characterized by cyanosis of the extremities, particularly the feet, progressing to gangrene. Arsenic dilates capillaries and increases their permeability, causing edema, an effect likely responsible for peripheral vascular disease following chronic exposure.

Skin. Dermal symptoms often are diagnostic of As exposure. Arsenic induces hyperkeratinization of the skin (including formation of multiple corns or warts), particularly of the palms of the hands and the soles of the feet. It also causes areas of hyperpigmentation interspersed with spots of hypopigmentation. These symptoms can be observed in individuals exposed to drinking water with As concentrations of at least 100 μg/L and are typical in those chronically exposed to much higher levels. Hyperpigmentation can be observed after 6 months of
exposure; hyperkeratinization takes years. Children are more likely to develop these effects than adults.

**GI Tract.** Acute or subacute exposure to high-dose As by ingestion causes GI symptoms ranging from mild cramping, diarrhea, and vomiting to GI hemorrhaging and death. GI symptoms are caused by increased capillary permeability, leading to fluid loss. At higher doses, fluid forms vesicles that can burst, leading to inflammation and necrosis of the submucosa and then rupture of the intestinal wall. GI symptoms are not observed with chronic exposure to lower levels of As.

**Nervous System.** The most common neurological effect of acute or subacute As exposure is peripheral neuropathy involving both sensory and motor neurons. This effect is characterized by the loss of sensation in the hands and feet, often followed by muscle weakness. Neuropathy occurs several days after exposure and can be reversible following cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children. Acute high-dose As exposure causes encephalopathy in rare cases, with symptoms that can include headache, lethargy, mental confusion, hallucination, seizures, and coma.

**Other Non-Cancer Toxicities.** Acute and chronic As exposures induce anemia and leukopenia, likely via direct cytotoxic effects on blood cells and suppression of erythropoiesis. Arsenic also may inhibit heme synthesis and cause fatty infiltrations, central necrosis, and cirrhosis in the liver. Arsenic can cause severe kidney damage. Inhaled As is irritating to the lungs; ingested As may induce bronchitis progressing to bronchopneumonia in some individuals. Chronic exposure to As is associated with an increased risk of diabetes.

**Carcinogenesis.** In regions with very high As levels in drinking water, there are substantially higher rates of skin cancer, bladder cancer, and lung cancer. There also are associations between As exposure and other cancers, including liver, kidney, and prostate tumors. IARC classifies arsenic as “carcinogenic to humans (group 1).” Humans exposed to As in utero and in early childhood have an elevated risk of lung cancer.

Arsenic does not directly damage DNA; rather, As is thought to work through changes in gene expression, DNA methylation, inhibition of
DNA repair, generation of oxidative stress, and/or altered signal transduction pathways. In humans, exposure to As potentiates lung tumorigenesis (5-fold increase) from tobacco smoke. Arsenic co-carcinogenesis may involve inhibition of proteins involved in nucleotide excision repair. Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transcription at very low concentrations and inhibiting it at slightly higher levels.

**Arsine Gas.** Arsine gas is a rare cause of industrial poisonings. Arsine induces rapid and often fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with O₂. A few hours after exposure, patients can develop headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 h. Arsine induces renal toxicities that can progress to kidney failure. Fatality results in ~25% of cases of arsine exposure.

**Treatment.** Following acute exposure to As, stabilize the patient and prevent further absorption of the poison. Close monitoring of fluid levels is important because As can cause fatal hypovolemic shock. Chelation therapy is effective following short-term exposure to As but has very little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove As often is warranted following arsine gas exposure.

**CADMIUM.** Cadmium (Cd) is used in electroplating, galvanization, plastics, paint pigments, and Ni-Cd batteries.

**Exposure.** Exposure to Cd is through food (estimated average daily intake, μg/day) and tobacco (1 cigarette contains 1-2 μg of Cd). Workers in metal-processing industries can be exposed to high levels of Cd, particularly by inhalation.

**Chemistry and Mode of Action.** Cd exists as a Cd²⁺ and does not undergo oxidation-reduction reactions. The mechanism of Cd toxicity is not fully understood. Like lead and other divalent metals, Cd can replace zinc in zinc-finger domains of proteins and disrupt them. Cd induces formation of ROS, resulting in lipid peroxidation and glutathione depletion, upregulates
inflammatory cytokines, and may disrupt the beneficial effects of NO.

**Absorption, Distribution, and Excretion.** Cd is not well absorbed from the GI tract (1.5-5%) but is better absorbed via inhalation (~10%). Cd primarily distributes first to the liver and later the kidney, with those 2 organs accounting for 50% of the absorbed dose. Little Cd crosses the blood-brain barrier or the placenta. Cd primarily is excreted in the urine and exhibits a $t_{1/2}$ of 10-30 years.

**Toxicity.** Acute Cd toxicity primarily is due to local irritation along the absorption route. Inhaled Cd causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested Cd induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody. Cd bound to metallothionein is transported to the kidney, where it can be released. The initial toxic effect of Cd on the kidney is increased excretion of small-molecular-weight proteins, especially $\beta_2$ microglobulin and retinol-binding protein. Cd also causes glomerular injury and decreased filtration. Chronic occupational exposure to Cd is associated with an increased risk of renal failure and death. Cd levels consistent with normal dietary exposure also can cause renal toxicity. Workers with long-term inhalation exposure to Cd exhibit decreased lung function. Symptoms initially include bronchitis and fibrosis of the lung, leading to emphysema. Chronic obstructive pulmonary disease increases mortality in Cd-exposed workers. When accompanied by vitamin D deficiency, Cd exposure increases the risks for fractures and osteoporosis, possibly due to interference with renal $\text{Ca}^{2+}$ and phosphate regulation.

**Carcinogenicity.** Chronic occupational exposure to inhaled Cd increases the risk of developing lung cancer. Cd causes chromosomal aberrations in exposed workers and human cells. It also increases mutations and impairs DNA repair in human cells. Cd substitutes for zinc in DNA repair proteins and polymerases and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks. Cd also may alter cell signaling pathways and disrupts cellular controls of proliferation. Cd acts as a non-genotoxic carcinogen.

**Treatment.** Patients suffering from inhaled Cd may require respiratory
support. Patients suffering from kidney failure due to Cd poisoning may require a transplant. Chelation therapy following Cd poisoning has no clinical benefits and may result in adverse effects.

CHROMIUM. Chromium (Cr) is an industrially important metal used in a number of alloys, particularly stainless steel (at least 11% chromium). Cr can be oxidized to multiple valence states, with the trivalent (Cr\textsuperscript{III}) and hexavalent (Cr\textsuperscript{VI}) forms being the 2 of biological importance. Chromium exists almost exclusively as the trivalent form in nature, and Cr\textsuperscript{III} is an essential metal involved in the regulation of glucose metabolism. Cr\textsuperscript{VI} is thought to be responsible for the toxic effects of Cr.

Exposure. Exposure to Cr in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to Cr during chromate production, stainless steel production and welding, Cr plating, ferrochrome alloy and chrome pigment production, and in tanning industries. Exposure usually is to a mixture of Cr\textsuperscript{III} and Cr\textsuperscript{VI}.

Chemistry and Mode of Action. Cr occurs in its metallic state or in any valence state between divalent and hexavalent. Cr\textsuperscript{III} is the most stable and common form. Cr\textsuperscript{VI} is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of Cr\textsuperscript{III} and Cr\textsuperscript{VI} is thought to be differences in their absorption and distribution. Cr\textsuperscript{VI} resembles sulfate and phosphate and can be taken into the cell by anion transporters where it undergoes a series of reduction steps, ultimately forming Cr\textsuperscript{III}, which causes most of the toxic effects. Cr\textsuperscript{III} readily interacts covalently with DNA. Cr\textsuperscript{VI} also induces oxidative stress and hypersensitivity reactions.

ADME. Smaller particles are better deposited in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50-85% of inhaled Cr\textsuperscript{VI} particles (<5 μm) are absorbed. Absorption of ingested Cr is <10%. Cr\textsuperscript{VI} crosses membranes by facilitated transport; Cr\textsuperscript{III} crosses by diffusion. Cr\textsuperscript{VI} is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; Cr\textsuperscript{VI} also is retained in erythrocytes. Excretion primarily is through urine, with small amounts excreted
in bile and breast milk and deposited in hair and nails. The $t_{1/2}$ of ingested Cr$^{VI}$ is $\sim 40$ h; the $t_{1/2}$ of Cr$^{III}$ is $\sim 10$ h.

**Toxicity.** Acute exposure to very high doses of Cr causes death via damage to multiple organs, particularly the kidney. Chronic low-dose Cr exposure causes toxicity at the site of contact. Thus, workers exposed to inhaled Cr develop symptoms of lung and upper respiratory tract irritation, decreased pulmonary function, and pneumonia. Chronic exposure to Cr via ingestion causes symptoms of GI irritation (e.g., oral ulcer, diarrhea, abdominal pain, indigestion, and vomiting). Cr$^{VI}$ is a dermal irritant and can cause ulceration or burns. Some individuals develop allergic dermatitis following dermal exposure to Cr. Cr-sensitized workers often also develop asthma.

**Carcinogenicity.** Cr$^{VI}$ compounds are known human carcinogens (group 1). There is insufficient evidence for carcinogenesis from metallic and Cr$^{III}$ (group 3). Workers exposed to Cr$^{VI}$ via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to Cr$^{VI}$ in drinking water increases the risk of developing stomach cancer. There are multiple potential mechanisms for Cr$^{VI}$ carcinogenicity. Reduction of Cr$^{VI}$ to Cr$^{III}$ within the cell occurs with concomitant oxidation of cellular molecules. Cr$^{III}$ forms a large number of covalent DNA adducts, primarily at the phosphate backbone. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following Cr$^{VI}$ exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Cr also forms toxic cross-links between DNA and protein. Chronic inflammation due to Cr-induced irritation also may promote tumor formation.

**Treatment.** There are no standard protocols for treatment of acute Cr poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, glutathione, or N-acetylcysteine to reduce Cr$^{VI}$ to Cr$^{III}$ after exposure but before absorption to limit bioavailability. These compounds and EDTA also increase urinary excretion of Cr after high-dose, particularly if given soon enough. Exchange transfusion to remove Cr from plasma and erythrocytes may be beneficial.
TREATMENT OF METAL EXPOSURE

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as 5- or 6-membered rings. The ideal chelator would have the following properties: high solubility in water, resistance to biotransformation, ability to reach sites of metal storage, ability to form stable and nontoxic complexes with toxic metals, and ready excretion of the metal-chelator complex. A low affinity for the essential metals Ca and Zn also is desirable, because toxic metals often act through competition with these metals for protein binding. The structures of the most commonly used chelators are shown in Figure 67–9.
In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is recommended only for acute poisonings.

**ETHYLENEDIAMINETETRAACETIC ACID (EDTA).** EDTA and its various salts are effective chelators of divalent and trivalent metals. Calcium disodium EDTA (CaNa$_2$EDTA) is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than Ca$^{2+}$. CaNa$_2$EDTA is effective for the treatment of acute lead poisoning, particularly in combination with dimercaprol, but is not an effective chelator of Hg or As in vivo.

**Chemistry and Mechanism of Action.** Accessible metal ions with a higher affinity for CaNa$_2$EDTA than Ca$^{2+}$ will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells. CaNa$_2$EDTA mobilizes several endogenous metallic cations, including those of Zn, Mn, and Fe. Additional supplementation with Zn following chelation therapy may be beneficial. The most common therapeutic use of CaNa$_2$EDTA is for acute lead intoxication. CaNa$_2$EDTA does not provide clinical benefits for the treatment of chronic lead poisoning.

CaNa$_2$EDTA is available as edetate calcium disodium (calcium disodium versenate). Intramuscular administration of CaNa$_2$EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa$_2$EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis. To minimize nephrotoxicity, adequate urine production should be established prior to and during treatment with CaNa$_2$EDTA. However,
in patients with lead encephalopathy and increased intracranial pressure, excess fluids must be avoided, and intramuscular administration of CaNa$_2$EDTA is recommended.

**ADME.** Less than 5% of CaNa$_2$EDTA is absorbed from the GI tract. After intravenous administration, CaNa$_2$EDTA has a $t_{1/2}$ of 20-60 min. In blood, CaNa$_2$EDTA is found only in the plasma; it is excreted in the urine by glomerular filtration. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; very little gains access to the spinal fluid (5% of the plasma concentration).

**Toxicity.** Rapid intravenous administration of Na$_2$EDTA causes hypocalcemic tetany. Slow infusion (<15 mg/min) elicits no symptoms of hypocalcemia in a normal individual because of the availability of extracirculatory stores of Ca$^{2+}$. CaNa$_2$EDTA can be administered intravenously with no untoward effects because the change in the concentration of Ca$^{2+}$ in the plasma and total body is negligible. The principal toxic effect of CaNa$_2$EDTA is on the kidney, most likely due to chelation of essential metals, particularly Zn, in proximal tubular cells. The early renal effects usually are reversible with cessation of treatment. Other side effects associated with CaNa$_2$EDTA include malaise, fatigue, excessive thirst followed by chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. CaNa$_2$EDTA is teratogenic in laboratory animals; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks. Other undesirable effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions similar to those of vitamin B$_6$ deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

**DIMERCAPROL.** Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas; hence its alternative name, British anti-Lewisite (BAL). Arsenicals form a stable and relatively nontoxic chelate ring with dimercaprol. Dimercaprol interacts with other heavy metals as well.
Chemistry and Mechanism of Action. The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. The sulfur–metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL–metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted. Dimercaprol is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol limits toxicity from As, Au, and Hg, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with CaNa$_2$EDTA to treat Pb poisoning.

ADME and Therapeutic Use. Dimercaprol is given by deep intramuscular injection as a 100 mg/mL solution in peanut oil and should not be used in patients who are allergic to peanut products. Peak concentrations in blood are attained in 30-60 min. The $t_{1/2}$ is short, and metabolic degradation and excretion essentially are complete within 4 h. Dimercaprol and its chelates are excreted in both urine and bile. Dimercaprol is contraindicated following chronic exposures to heavy metals because it does not prevent neurotoxic effects., and should not be used in patients with hepatic insufficiency, except when this condition is a result of As poisoning.

Toxicity. Side effects occur in ~50% of subjects receiving 5 mg/kg intramuscularly. Dimercaprol causes an immediate rise in systolic and diastolic arterial pressures accompanied by tachycardia; these return to normal within 2 h. Dimercaprol also can cause anxiety, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the appearance of painful sterile abscesses at the injection site. The dimercaprol–metal complex breaks down easily in an acidic medium; production of alkaline urine protects the kidney during therapy. Children react similarly to adults, although ~30% also may experience a fever that disappears on drug withdrawal.
Succimer (2,3-dimercaptosuccinic acid [DMSA], Chemet) is an orally effective chelator that is chemically similar to dimercaprol but contains 2 carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug.

ADME. After absorption, succimer is biotransformed to a mixed disulfide with cysteine. Succimer lowers blood Pb levels and attenuates toxicity of Pb. The succimer–Pb chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation. *Succimer has several desirable features over other chelators.* It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as Zn, Cu, or Fe. Thus, succimer exhibits a better toxicity profile relative to other chelators. Succimer also is effective as a chelator of As, Cd, Hg, and other toxic metals.

Therapeutic Use. Succimer is approved for treatment of children with blood Pb levels >45 μg/dL. It also is used off label for the treatment of adults with Pb poisoning and As and Hg intoxication.

Toxicity. Succimer is much less toxic than dimercaprol. Commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. Transient elevations in hepatic transaminases have been observed with succimer treatment. In a few patients, rashes necessitate discontinuation of therapy.

SODIUM 2, 3-DIMERCAPTOPROPAINE SULFONATE (DMPS). DMPS is another dimercapto compound used for the chelation of heavy metals. DMPS is not approved by the FDA but is approved for use in Germany. DMPS is available from compounding pharmacies and is used by some doctors in the U.S.

Chemistry and Mode of Action. DMPS is a clinically effective chelator of Pb, As, and especially Hg. It is orally available and is rapidly excreted, primarily by the kidneys. It is negatively charged and exhibits distribution properties similar to those of succimer. DMPS is less toxic than dimercaprol but mobilizes Zn and Cu and thus is more toxic than succimer. There is evidence suggesting that DMPS might be effective for treatment of chronic heavy metal poisonings.
**PENICILLAMINE; TRIENTINE.** Penicillamine (Cuprimine, Depen) is an effective chelator of Cu, Hg, Zn, and Pb and promotes the excretion of these metals in the urine.

Penicillamine’s chelating properties led to its use in patients with Wilson disease (excess body burden of Cu due to diminished excretion) and heavy-metal intoxications. Penicillamine is a more toxic and less potent and selective chelator of heavy metals than other chelation drugs; thus, it is not a first-line treatment for acute intoxication with Pb, Hg, or As. Because it is inexpensive and orally bioavailable, it often is given at low doses following treatment with CaNa₂EDTA and/or dimercaprol to ensure that the concentration of metal in the blood stays low following the patient’s release from the hospital.

**ADME.** Penicillamine is well absorbed (40-70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak plasma concentrations are obtained between 1 and 3 h. Penicillamine is relatively stable in vivo compared to its unmethylated parent compound cysteine. Hepatic biotransformation primarily is responsible for degradation of penicillamine, and very little drug is excreted unchanged. Metabolites are found in both urine and feces. N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of Hg, presumably because it is more resistant to metabolism.

**Therapeutic Use.** Penicillamine is available for oral administration. For chelation therapy, the usual adult dose is 1-1.5 g/day in 4 divided doses, given on an empty stomach to avoid interference by metals in food. Penicillamine is used in Wilson disease, cystinuria, and rheumatoid arthritis (rarely). For the treatment of Wilson disease, 1-2 g/day usually is administered in 4 doses. The urinary excretion of Cu should be monitored to determine whether the dosage of penicillamine is adequate.

**Toxicity.** Penicillamine induces cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, dermatomyositis, adverse effects on collagen, dryness, and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in up to one-third of patients taking penicillamine. Hematological reactions include leukopenia, aplastic anemia, and agranulocytosis, which may be fatal. Renal toxicity is manifested as reversible proteinuria and hematuria, but it may progress to
nephrotic syndrome with membranous glomerulopathy. Rare fatalities have been reported from Goodpasture syndrome. Although uncommon, severe dyspnea has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis has been induced by long-term therapy. Penicillamine is a teratogen in animals, but for pregnant women with Wilson disease, the benefits outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt. Contraindications to therapy include pregnancy, renal insufficiency, or a previous history of penicillamine-induced agranulocytosis or aplastic anemia.

**TRIENTINE.** Penicillamine is the drug of choice for treatment of Wilson disease. Trientine (triethylene tetramine dihydrochloride, SYPRINE) is an acceptable alternative for patients who cannot tolerate penicillamine (see “Toxicity,” above). Trientine drug is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in 2 to 4 divided portions on an empty stomach. Trientine may cause iron deficiency; this can be overcome with short courses of Fe therapy, but iron and trientine should not be ingested within 2 h of each other.

**DEFEROXAMINE; DEFERASIROX; DEFERIPRONE.**
Deferoxamine (deferoxamine mesylate, DESFERAL) has high affinity for ferric iron ($K_a = 1031$) and a very low affinity for calcium ($K_a = 102$). It removes Fe from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.

**ADME and Therapeutic Use.** Deferoxamine is poorly absorbed after oral administration, and parenteral administration is required. For severe Fe toxicity (serum Fe levels >500 μg/dL), the intravenous route is preferred. The drug is administered at 10-15 mg/kg/h by constant infusion. Rapid boluses usually are associated with hypotension. Deferoxamine may be given intramuscularly in moderately toxic cases (serum Fe 350-500 μg/dL) at a dose of 50 mg/kg with a maximum dose of 1 g. Hypotension also can occur with this route. For chronic Fe intoxication (e.g., thalassemia), an intramuscular dose of 0.5-1.0 g/day is recommended. Continuous subcutaneous administration (1-2 g/day) is almost as effective as intravenous administration. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Deferoxamine
also has been used for the chelation of aluminum in dialysis patients. Deferoxamine is metabolized by plasma enzymes and excreted in the urine.

**Toxicity.** Deferoxamine causes a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy; both visual and auditory changes have been described. A “pulmonary syndrome” has been associated with high-dose (10-25 mg/kg/h) deferoxamine therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications include renal insufficiency and anuria; during pregnancy, deferoxamine should be used only if clearly indicated.

**DEFERASIROX.** Deferasirox (Exjade) is FDA-approved for treatment of chronic Fe overload in patients receiving therapeutic blood transfusions. It is administered orally.

**DEFERIPRONE.** Deferiprone (Ferriprox) is an oral Fe chelator FDA-approved for treatment of Fe overload in patients with thalassemia receiving therapeutic blood transfusions.
Appendix I
Principles of Prescription Order Writing and Patient Compliance

LATIN NOT SPOKEN HERE

In writing prescriptions, use English (in the U.S.) or the dominant language of the patient. Latin is no longer the international language of medicine, but a number of commonly used abbreviations derive from obsolete Latin usage and persist in prescription writing. Avoid using them.

Some Latin seems firmly embedded in pharmacy practice. “Rx” is said to be an abbreviation for the Latin word *recipere*, meaning “take” or “take thus,” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. The abbreviation “Sig” for the Latin *Signatura*, is used on the prescription to mark the directions for administration of the medication.

WHO CAN PRESCRIBE MEDICINES?

In many states in the U.S., healthcare practitioners other than M.D. and D.O. physicians can write prescriptions. Licensed physician’s assistants (P.A.), nurse practitioners, pharmacists, and clinical psychologists can prescribe medications under various circumstances.

CURRENT PRACTICE

The prescription consists of the *superscription*, the *inscription*, the *subscription*, the *signa*, and the *name and signature of the prescriber*, all contained on a single form (Figure AI–1).
Figure AI–1 *The prescription.* The prescription must be accurately and legibly prepared to identify the patient, the medication to be dispensed, and the mode of drug administration. Avoid abbreviations and Latin; they lead to dispensing errors. Include the therapeutic purpose in the subscription (e.g., “for control of blood pressure”) to prevent errors in dispensing. For example, the use of Losartan for the treatment of hypertension may require 100 mg/day (1.4 mg/kg/day), whereas for treatment of congestive heart failure, the dose of this AngII receptor antagonist generally should not exceed 50 mg/day. Including the therapeutic purpose of the prescription also can assist patients in organizing and understanding their medications. Including the patient’s weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.

The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (Take). The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed, or the name and strength of each ingredient to be compounded.
The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence such as: “dispense 30 tablets.” The *sig* or “Sig” is the instruction for the patient as to how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., prescriptions should always be written in English. Many physicians continue to use Latin abbreviations; e.g., “1 cap tid pc,” will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions only mystifies the prescription and is discouraged. The pharmacist should always write the label in English (or, as appropriate, in the language of the patient). The use of such abbreviations or symbols is a confounding practice; many serious dispensing errors can be traced to the use of abbreviations.

Avoid the instruction “take as directed.” Such directions assume an understanding on the part of the patient that may not be realized, and are inadequate for the pharmacist, who must determine the intent of the physician before dispensing the medication. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions should begin with “take” or “give”; for externally applied products, the word “apply”; for suppositories, “insert”; and for eye, ear, or nose drops, “place” is preferable to “instill.”

**Include Patient Information and Dosage Calculations.** The patient’s name and address are needed on the prescription order to ensure that the correct medication goes to the proper patient and also for identification and recordkeeping. For medications whose dosage involves a calculation, a patient’s pertinent factors, such as weight, age, or body surface area, also should be listed on the prescription; both the calculated dose and the dosage formula used, such as “240 mg every 8 hours (40 mg/kg/day),” should be included to allow another healthcare professional to double-check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling such prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or antiseizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist.
Proper Prescribing Practices Can Help to Prevent Adverse Drug Events. The Institute of Medicine (IOM) estimates that the annual number of medical errors in the U.S. resulting in death is between 44,000 and 98,000. Adverse drug events occur in ~3% of hospitalizations. Good practices (Table AI–1) can minimize these adverse drug events.

Table AI–1

**Prescribing Practices to Avoid Adverse Drug Events**

- Write all orders legibly using metric measurements of weight and volume.
- Include patient age and weight on the prescription, when appropriate, so dosage can be checked.
- Use Arabic (decimal) numerals rather than Roman numerals (e.g., does “IL-II” mean “IL-11” or “IL-2”?) in some instances, it is preferable for numerals to be spelled out.
- Use leading zeros (0.125 milligrams, not .125 milligrams), never use trailing zeros (5 milligrams, not 5.0 milligrams).
- Avoid abbreviating drug names; abbreviations may lead to misinterpretation.
- Avoid abbreviating directions for drug administration; write out directions clearly in English.
- Be aware of possibilities for confusion in drug names. Some drug names sound alike when spoken and may look alike when spelled out. The U.S. Pharmacopeial Convention Medication Errors Reporting Program maintains a current list of 750 drug names that can be confused (www.usp.org). Alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- Provide the patient’s diagnosis on the prescription order to prevent dispensing errors based on sound-alike or look-alike drug names. For example, an order for administration of magnesium sulfate must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose and/or the patient’s diagnosis can prevent this error.
- Write clearly. Both physician and pharmacist share in the responsibility for preventing adverse drug events by writing prescriptions clearly (When in doubt, write it out!) and questioning intent whenever an order is ambiguous (When in doubt, check it out!). Pharmacists must clarify their concerns with prescribers, not patients.
- Think.
- Think again.

**PROPER USE OF PRESCRIPTION PAD**

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions under the U.S. Controlled Substances Act (CSA) of 1970. Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI–1). When using institutional blanks that do not bear the physician’s
information, the physician always should print his or her name and phone number on the face of the prescription to facilitate communication with other healthcare professionals if questions arise. U.S. law requires that prescriptions for controlled substances include the name, address, and Drug Enforcement Administration (DEA) registration number of the physician.

The date of the prescription is an important part of the patient’s medical record, and it can assist the pharmacist in recognizing potential problems. For example, when an opioid is prescribed for pain due to an injury, and the prescription is presented to a pharmacist 2 weeks after issuance, the drug may no longer be indicated. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled. The CSA requires that all orders for controlled substances (Table AI–1) be dated as of, and signed on, the day issued and prohibits filling or refilling orders for substances in schedules III and IV >6 months after their date of issuance. When writing the original prescription, the physician should designate the number of refills allowed. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician. A statement such as “refill prn” (refill as needed) is not appropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are desired, “zero” (not “0”) should be written in the refill space to prevent alteration of the prescriber’s intent. Refills for controlled substances are discussed later, in “Refills” under “Controlled Substances.”

Concern about the rising cost of healthcare has favored the dispensing of so-called generic drugs. A drug is called by its generic name (in the U.S., this is the U.S. Adopted Name or USAN) or the manufacturer’s proprietary name, called the trademark, trade name, or brand name. In most U.S. states, pharmacists have the authority to dispense generic drugs rather than brand-name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription (“do not substitute”), although this generally is unnecessary because the U.S. Food and Drug Administration (FDA) requires that generic medications meet the same bioequivalence standards as their brand-name counterparts. In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted on the prescription. Occasions when substituting generic medications is discouraged are
limited to products with specialized release systems and narrow therapeutic indices, or when substantial patient confusion and potential noncompliance may be associated with substitution.

**CHOICE AND AMOUNT OF DRUG PRODUCT DISPENSED**

Inappropriate choice of drugs by physicians is a problem in prescribing. Physicians must rely on unbiased sources when seeking drug information that will influence their prescribing habits; use of the original medical literature will ensure instruction of the prescriber’s best judgment. The amount of a drug to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed, because this not only is expensive for the patient but may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family if used inappropriately. *Better to require several refills of a prescription than to prescribe and dispense more than necessary at one time.*

**THE PRESCRIPTION AS A COMMODITY**

Prescribers must be aware that patients may visit their doctor to “get” a prescription. Physicians must educate their patients about the importance of viewing medicines as to be used only when really needed and that remaining on a particular medicine when their condition is stable may be preferable to seeking the newest medications available. The Federal Food and Drug Administration Modernization Act of 1997 permits the use of print and television advertising of prescription drugs. The law requires that all drug advertisements contain (among other things) summary information relating to side effects, contraindications, and effectiveness. The benefits of these types of direct-to-consumer (DTC) advertising are controversial. Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health
insurers, government, and consumers. In the face of a growing demand for particular brand-name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide them with evidence-based drug information.

**CONTROLLED SUBSTANCES**

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the federal CSA. The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into 5 schedules (Table AI–2); individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the jurisdiction in which they are licensed, and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances. Criminal prosecution and penalties for misuse generally depend on the schedule of a substance and the amount of drug in question.

<table>
<thead>
<tr>
<th>Table AI–2</th>
</tr>
</thead>
</table>

**Controlled Substance Schedules**
State agencies may impose additional regulations, such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. Some U.S. states, such as California, have placed marijuana, classified by the FDA as a schedule I substance, in a special category by decriminalizing its possession and sale for medical use. Under California’s medical marijuana laws, patients and caregivers are exempt from prosecution by the state of California, contrary federal law notwithstanding. This legal difference of opinion between state and federal regulation is the source of considerable controversy. Generally, the most stringent law takes precedence, whether it is federal, state, or local.
PRESCRIPTION ORDERS FOR CONTROLLED SUBSTANCES. To be valid, a prescription for a controlled substance must be issued for a legitimate medical purpose by an individual practitioner acting in the usual course of his or her professional practice. An order that does not meet these criteria, is not considered a legitimate prescription within the meaning of the law, and thus does not protect either the physician who issued it or the pharmacist who dispensed it. Most states prohibit physicians from prescribing controlled substances for themselves; it is prudent to comply with this guideline even if it is not mandated by law.

EXECUTION OF THE ORDER. Prescriptions for controlled substances should be dated and signed on the day of their issuance and must bear the full name and address of the patient and the printed name, address, and DEA number of the practitioner and should be signed the way one would sign a legal document. Preprinted orders are not allowed in most states, and pre-signed blanks are prohibited by federal law. When oral orders are not permitted (schedule II), the prescription must be written with ink or typewritten. The order may be prepared by a member of the physician’s staff, but the prescriber is responsible for the signature and any errors that the order may contain.

ORAL ORDERS. Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician in the same manner as a prescription for a noncontrolled substance, although it is in the physician’s best interest to keep his or her DEA number as private as possible (see “Preventing Diversion”). Schedule II prescriptions may be telephoned to a pharmacy only in emergency situations, i.e.:

- Immediate administration is necessary.
- No appropriate alternative treatment is available.
- It is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 h. If mailed, the prescription must be postmarked within 72 h. The pharmacist must notify the DEA if this prescription is not received.
REFILLS. No prescription order for a schedule II drug may be refilled under any circumstance. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed 5 refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

PREVENTING DIVERSION. Prescription blanks often are stolen and used to sustain abuse of controlled substances. To prevent this type of diversion, prescription pads should be protected in the same manner as one would protect a personal checkbook. A prescription blank should never be pre-signed for a staff member to fill in at a later time. Also, a minimum number of pads should be stocked, and they should be kept in a locked, secure location. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies. Ideally, the physician’s full DEA number should not be pre-printed on the prescription pad, because most prescriptions will not be for controlled substances and will not require the registration number, and anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write “pharmacist call to verify” or “call for registration number.” This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must fill the prescription during the prescriber’s office hours. Pharmacists can ascertain the authenticity of a physician’s DEA number using an algorithm.

Another method employed by the drug seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuance of a patient’s addiction is not a legitimate medical purpose.

DRUG STANDARDS AND CLASSIFICATION
The U.S. Pharmacopeial Convention, Inc. is a nongovernmental organization that disseminates authoritative standards and information
on medicines and other healthcare technologies. This organization is home to the U.S. Pharmacopeia (USP), which, together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and the governments of other countries and are recognized worldwide. Drug monographs are published in the USP/National Formulary (USP-NF), the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP-NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity, such as insulin.

The USP also is home to the *USP Dictionary of U.S. Adopted Names (USAN) and International Drug Names*. This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include 1 or more of the following: U.S. Adopted Names, official drug names for the *National Formulary* (NF), previously used official names, International Nonproprietary Names, British Approved Names, Japanese Accepted Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information such as Chemical Abstract Service (CAS), registry number (RN), molecular formula, molecular weight, pharmacological and/or therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic website that can be accessed for useful drug naming, classification, and standards information ([www.usp.org](http://www.usp.org)).

In the U.S., drug products also are coded under the National Drug Code (NDC). In the U.S., the NDC serves as a universal product identifier for drugs used in humans. The current edition of the National Drug Code Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, known as the NDC number, identifies the labeler/vendor, product, and package size. The labeler/vendor code is assigned by the FDA. The second segment, the product code, identifies a
specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer. In addition to classification of drugs by therapeutic category, drugs also are grouped by control schedule. Drug schedules in the U.S. are listed in Table AI–2 and are discussed above under “Controlled Substances.”

The FDA also categorizes drugs that may be used in pregnant women. These categories are similar to those used in other countries and provide guidance based on available science. The categories range from A to X, in increasing order of concern:

**Pregnancy Category A:** Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Because of the obvious nature of the risk associated with the use of medications during gestation, the FDA requires a body of high-quality data on a drug before it can be considered for Pregnancy Category A.

**Pregnancy Category B:** Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women, OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.

**Pregnancy Category C:** Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

**Pregnancy Category D:** There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

**Pregnancy Category X:** Studies in animals or humans have demonstrated fetal abnormalities, and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.
Physicians should realize that the pregnancy categories by themselves provide little guidance for the physician treating pregnant women. For example, angiotensin-converting enzyme (ACE) inhibitors such as captopril cause developmental toxicity (Category X) only after the first trimester. Physicians’ primary responsibility remains treating the pregnant patient. However, the risks of withholding treatment to the mother because of possible risks to the fetus have to be considered as well.

Drugs also are grouped by their potential for misuse under British and U.N. legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C.

COMPLIANCE

Compliance is the extent to which the patient follows a regimen prescribed by a healthcare professional. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—compliance, adherence, therapeutic alliance, or concordance—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The patient’s quality-of-life beliefs may differ from the clinician’s therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Hundreds of variables that may influence compliance behavior have been identified. A few of the most frequently cited are discussed here, along with some suggestions for improving compliance, although none provides 100% compliance (Table AI–3).

Table AI–3

Suggestions for Improving Patient Compliance
Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled; therapeutic failures can result. Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy. The reported incidence of patient noncompliance usually is in the range of 30-60%; the rate for long-term regimens is c50%.

**THE PATIENT–PROVIDER RELATIONSHIP**

Patient satisfaction with the physician has a significant impact on compliance behavior. Patients are more likely to follow instructions and recommendations when their expectations for the patient–provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence; thus, cultivating good interpersonal and communication skills is essential.

When deciding on a course of therapy, it can be useful to discuss a patient’s habits and daily routine as well as the therapeutic options with the patient. This information may suggest cues for remembrance. A lack of information about a patient’s lifestyle can lead to situations such as prescribing a medication to be taken with meals 3 times daily for a patient who only eats twice a day or a
medication to be taken each morning for a patient who works a night shift and sleeps during the day. Rarely is there only 1 treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance.

PATIENTS AND THEIR BELIEFS

Patients are more likely to be compliant when they perceive that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, and that the benefits outweigh the costs, and when they believe in their own efficacy to execute the therapy. The actual severity of and susceptibility to an illness is not necessarily an issue; rather, the patient’s perception of severity affects compliance. Patients’ beliefs can lead them to deliberately alter their therapy, whether for convenience, for personal experiments, because of a desire to remove themselves from the sick role, as a means to exercise a feeling of control over their situation, or for other reasons. This reinforces the need for excellent communication and a good patient–provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome.

Pharmacists have a legal and professional responsibility to offer medication counseling and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient’s therapy can help identify compliance and other problems, educate the patient, and notify the physician as appropriate. Indeed, data from the Asheville Project indicate that a pharmacist-based medication management program provides significant advantages with respect to compliance, health outcomes, and cost.

Elderly patients often face a number of barriers to compliance related to their age: increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and the use of a greater number of concurrent medicines (both prescription and over-the-counter) whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects. There are drugs known to be inappropriate to prescribe
to elderly patients and some that may adversely affect compliance. Despite these obstacles, evidence does not show that elderly patients in general are significantly less compliant than any other age group. Physicians must be careful in choosing medications for the elderly. Pharmacists must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted.

**THE THERAPY**

Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for noncompliance, as will the patient whose disease is chronic. The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients but are not necessarily predictive, especially if patient beliefs or other positive factors tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another. The cost of medicine can be a heavy burden for patients with limited economic resources, and healthcare providers should be sensitive to this fact. Mobile phones and tablets running drug formulary/therapeutic applications can provide the costs of medications, as can physicians who are familiar with the patient’s insurance plan. Mobile phone systems that provide reminders and collect patient response information are being introduced and may become more popular as patients and providers become increasingly tech savvy.

**ELECTRONIC PRESCRIBING**

The era of e-prescribing has begun. Computerized prescription ordering eliminates some of the subjective features of prescribing. Thus, if the proper information is entered correctly in the electronic system, medication errors due to illegible handwriting, incorrect dose, incorrect medication for medical condition, and drug interactions can be reduced, because each prescription can
be linked to high-quality drug databases that check that the information on the prescription is appropriate for the patient (e.g., age, weight, gender, condition, laboratory values, disease being treated, concurrent medications) and that known warnings and potential problems are brought to the attention of the physician, pharmacist, and patient. Such systems must not be used as a substitute for personal attention to the individual patient by healthcare workers but, rather, as an adjunct measure that ensures safe, high-quality, efficient care.
